To our knowledge, the above question remains an open problem for the Ising model in dimension $d = 3$. The problem has, however, been solved for the simpler case of a SOS interface model. In this case, a nice and rather brief proof of the following result has been given by Chalker (1982): one has $m^{w+} = m^{w-}$, and hence complete wetting, if

$$2\beta(J-K) < -\ln(1 - e^{-8\beta J})$$

It is very plausible that a similar statement is valid for the semi-infinite Ising model and, also that Chalker's method could play a role for extending the proof to this case, provided an additional assumption is made. Namely, that $\beta$ is sufficiently large, and hence $J - K$ small enough, in order to insure the convergence of the cluster expansions and to be able to use them.

## Equilibrium Crystals

The shape of an equilibrium crystal is obtained, according to thermodynamics, by minimizing the surface free energy between the crystal and the medium, for a fixed volume of the crystal phase. Given the orientation-dependent surface tension $\tau(\boldsymbol{n})$, the solution to this variational problem, known under the name of Wulff construction, is the following set:

$$\mathcal{W} = \{\boldsymbol{x} \in \boldsymbol{R}^3 : \boldsymbol{x} \cdot \boldsymbol{n} \leq \tau(\boldsymbol{n}) \text{ for all } \boldsymbol{n}\} \qquad [19]$$

Notice that the problem is scale invariant, so that if we solve it for a given volume of the crystal, we get the solution for other volumes by an appropriate scaling. We notice also that the symmetry $\tau(\boldsymbol{n}) = \tau(-\boldsymbol{n})$ is not required for the validity of formula [19]. In the present case, $\tau(\boldsymbol{n})$ is obviously a symmetric function, but nonsymmetric situations are also physically interesting and appear, for instance, in the case of a drop on a wall discussed in the last section.

The surface tension in the Ising model between the positive and negative phases has been defined in eqn [7]. In the two-dimensional case, this function $\tau(\boldsymbol{n})$ has (as shown by Abraham) an exact expression in terms of some Onsager's function. It follows (as explained in Miracle-Sole (1999)) that the Wulff shape $\mathcal{W}$, in the plane $(x_1, x_2)$, is given by

$$\cosh \beta x_1 + \cosh \beta x_2 \leq \cosh^2 2\beta J / \sinh 2\beta J$$

This shape reduces to the empty set for $\beta \leq \beta_c$, since the critical $\beta_c$ satisfies $\sinh 2J\beta_c = 1$. For $\beta > \beta_c$, it is a strictly convex set with smooth boundary.

In the three-dimensional case, only certain interface models can be exactly solved (see the section "Gibbs states and interfaces"). Consider the Ising model at zero temperature. The ground configurations have only one defect, the microscopic interface $\lambda$, imposed by the boundary condition $(\pm, \boldsymbol{n})$. Then, from eqn [9], we may write

$$\tau(\boldsymbol{n}) = \lim_{L_1, L_2 \to \infty} \frac{n_3}{L_1 L_2} (E_\Lambda(\boldsymbol{n}) - \beta^{-1} N_\Lambda(\boldsymbol{n})) \qquad [20]$$

where $E_\Lambda = 2J|\lambda|$ is the energy (all $\lambda$ have the same minimal area) and $N_\Lambda$ the number of ground states. Every such $\lambda$ has the property of being cut only once by all straight lines orthogonal to the diagonal plane $i_1 + i_2 + i_3 = 0$, provided that $n_k > 0$, for $k = 1, 2, 3$. Each $\lambda$ can then be described by an integer function defined on a triangular plane lattice, the projection of the cubic lattice $\mathcal{L}$ on the diagonal plane. The model defined by this set of admissible microscopic interfaces is precisely the TISOS model. A similar definition can be given for the BCSOS model that describes the ground configurations on the body-centered cubic lattice.

From a macroscopic point of view, the roughness or the rigidity of an interface should be apparent when considering the shape of the equilibrium crystal associated with the system. A typical equilibrium crystal at low temperatures has smooth plane facets linked by rounded edges and corners. The area of a particular facet decreases as the temperature is raised and the facet finally disappears at a temperature characteristic of its orientation. It can be argued that the disappearance of the facet corresponds to the roughening transition of the interface whose orientation is the same as that of the considered facet.

The exactly solvable interface models mentioned above, for which the function $\tau(\boldsymbol{n})$ has been computed, are interesting examples of this behavior, and provide a valuable information on several aspects of the roughening transition. This subject has been reviewed by Abraham (1986), van Beijeren and Nolden (1987), and Kotecky (1989).

For example, we show in **Figure 3** the shape predicted by the TISOS model (one-eighth of the shape because of the condition $n_k > 0$). In this model, the interfaces orthogonal to the three coordinate axes are rigid at low temperatures.

For the three-dimensional Ising model at positive temperatures, the description of the microscopic interface, for any orientation $\boldsymbol{n}$, appears as a very difficult problem. It has been possible, however, to analyze the interfaces which are very near to the particular orientations $\boldsymbol{n}_0$, discussed in the

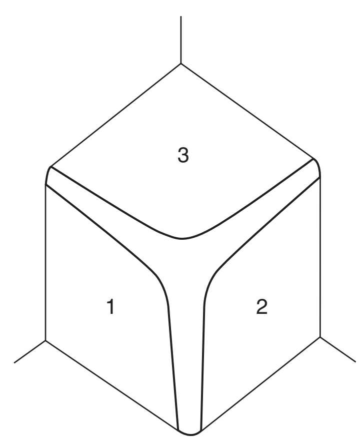

**Figure 3** Cubic equilibrium crystal shown in a projection parallel to the (1,1,1) direction. The three regions (1, 2, and 3) indicate the facets and the remaining area represents a curved part of the crystal surface.

section "Gibbs states and interfaces." This analysis allows us to determine the shape of the facets in a rigorous way.

We first observe that the appearance of a facet in the equilibrium crystal shape is related, according to the Wulff construction, to the existence of a discontinuity in the derivative of the surface tension with respect to the orientation. More precisely, assume that the surface tension satisfies the convexity condition of Theorem 1, and let this function $\tau(\boldsymbol{n}) = \tau(\theta, \phi)$ be expressed in terms of the spherical coordinates of $\boldsymbol{n}$, the vector $\boldsymbol{n}_0$ being taken as the $x_3$-axis. A facet orthogonal to $\boldsymbol{n}_0$ appears in the Wulff shape if and only if the derivative $\partial\tau(\theta, \phi)/\partial\theta$ is discontinuous at the point $\theta = 0$, for all $\phi$. The facet $\mathcal{F} \subset \partial\mathcal{W}$ consists of the points $\boldsymbol{x} \in \boldsymbol{R}^3$ belonging to the plane $x_3 = \tau(\boldsymbol{n}_0)$ and such that, for all $\phi$ between 0 and $2\pi$,

$$x_1 \cos\phi + x_2 \sin\phi \leq \partial\tau(\theta, \phi)/\partial\theta|_{\theta=0^+} \qquad [21]$$

The step free energy is expected to play an important role in the facet formation. It is defined as the free energy associated with the introduction of a step of height 1 on the interface, and can be regarded as an order parameter for the roughening transition. Let $\Lambda$ be a parallelepiped as in the section "Pure phases and surface tension," and introduce the (step, $\boldsymbol{m}$) boundary conditions (see Figure 2), associated to the unit vectors $\boldsymbol{m} = (\cos\phi, \sin\phi) \in \boldsymbol{R}^2$, by

$$\bar{\sigma}(i) = \begin{cases} 1 & \text{if } i > 0 \text{ or if } i_3 = 0 \text{ and} \\ & \quad i_1 m_1 + i_2 m_2 \geq 0 \\ -1 & \text{otherwise} \end{cases} \qquad [22]$$

Then, the step free energy per unit length for a step orthogonal to $\boldsymbol{m}$ (with $m_2 > 0$) on the horizontal interface, is

$$\tau^{\text{step}}(\phi) = \lim_{L_1\to\infty} \lim_{L_2\to\infty} \lim_{L_3\to\infty} -\frac{\cos\phi}{\beta L_1} \ln \frac{Z^{\text{step},\boldsymbol{m}}(\Lambda)}{Z^{\pm,\boldsymbol{n}_0}(\Lambda)} \qquad [23]$$

A first result concerning this point was obtained by Bricmont and co-workers, by proving a correlation inequality which establish $\tau^{\text{step}}(0)$ as a lower bound to the one-sided derivative $\partial\tau(\theta, 0)/\partial\theta$ at $\theta = 0^+$ (the inequality extends also to $\phi \neq 0$). Thus, when $\tau^{\text{step}} > 0$, a facet is expected.

Using the perturbation theory of the horizontal interface, it is possible to also study the microscopic interfaces associated with the (step, $\boldsymbol{m}$) boundary conditions. When considering these configurations, the step may be viewed as an additional defect on the rigid interface described in the section "Pure phases and surface tension." It is, in fact, a long wall going from one side to the other side of the box $\Lambda$. The step structure at low temperatures can then be analyzed with the help of a new cluster expansion. As a consequence of this analysis, we have the following theorem.

**Theorem 5** *If the temperature is low enough, that is, if $\beta J \geq c_3$, where $c_3$ is a given constant, then the step free energy, $\tau^{\text{step}}(\phi)$, exists, is strictly positive, and extends by positive homogeneity to a strictly convex function. Moreover, $\beta\tau^{\text{step}}(\phi)$ is an analytic function of $\zeta = e^{-2J\beta}$, for which an explicit convergent series expansion can be found.*

Using the above results on the step structure, similar methods allow us to evaluate the increment in surface tension of an interface tilted by a very small angle $\theta$ with respect to the rigid horizontal interface. This increment can be expressed in terms of the step free energy, and one obtains the following relation.

**Theorem 6** *For $\beta J \geq c_3$, we have*

$$\partial\tau(\theta, \phi)/\partial\theta|_{\theta=0^+} = \tau^{\text{step}}(\phi) \qquad [24]$$

This relation, together with eqn [21], implies that one obtains the shape of the facet by means of the two-dimensional Wulff construction applied to the step free energy. The reader will find a detailed discussion on these points, as well as the proofs of Theorems 5 and 6, in Miracle-Sole (1995).

From the properties of $\tau^{\text{step}}$ stated in Theorem 5, it follows that the Wulff equilibrium crystal presents well-defined boundary lines, smooth and without straight segments, between a rounded part of the crystal surface and the facets parallel to the three main lattice planes.

It is expected, but not proved, that at a higher temperature, but before reaching the critical temperature, the facets associated with the Ising model undergo a roughening transition. It is then natural to believe that the equality [24] is true for any $\beta$ larger than $\beta_R$, allowing us to determine the facet shape from eqns [21] and [24], and that for $\beta \leq \beta_R$, both sides in this equality vanish, and thus, the disappearance of the facet is involved. However, the condition that the temperature is low enough is needed in the proofs of Theorems 5 and 6.

# Stochastic Differential Equations

**F Russo**, Université Paris 13, Villetaneuse, France

## Introduction

Stochastic differential equations (SDEs) appear today as a modeling tool in several sciences as telecommunications, economics, finance, biology, and quantum field theory.

An SDE is essentially a classical differential equation which is perturbed by a random noise. When nothing else is specified, SDE means in fact ordinary SDE; in that case it corresponds to the perturbation of an ordinary differential equation. Stochastic partial differential equations (SPDEs) are obtained as random perturbation of partial differential equations (PDEs).

One of the most important difference between deterministic and stochastic ordinary differential equations is described by the so-called Peano type phenomenon. A classical differential equation with continuous and linear growth coefficients admits global existence but not uniqueness as classical calculus text books illustrate studying equations of the type

$$\frac{\mathrm{d}X}{\mathrm{d}t}(t) = \sqrt{X(t)}, \quad X(0) = 0$$

However, if one perturbs the right member of the equality with an additive Gaussian white noise $(\xi_t)$ (even with very small intensity), then the problem becomes well stated. A similar phenomenon happens with linear PDEs of evolution type perturbed with a spacetime white noise.

SDEs constitute a vast subject and account for an incredible amount of relevant contributions. We try to orientate the reader about the main axes trying to indicate references to the different subfields. We will prefer to refer to monographs when available, instead of articles.

## Motivation and Preliminaries

In the whole article $T$ will be a strictly positive real number. Let us consider continuous functions $b:\mathbb{R}_+ \times \mathbb{R}^d \to \mathbb{R}^d$, $a:\mathbb{R}_+ \times \mathbb{R}^{d\times m} \to \mathbb{R}^d$ and $x_0 \in \mathbb{R}^d$. We consider a differential problem of the following type:

$$\begin{aligned} \frac{\mathrm{d}X_t}{\mathrm{d}t} &= b(t, X_t) \\ X_0 &= x_0 \end{aligned} \qquad [1]$$

Let $(\Omega, \mathcal{F}, \mathbb{P})$ be a complete probability space. Suppose that previous equation is perturbed by a random noise $(\xi_t)_{t\geq 0}$. Because of modeling reasons it could be reasonable to suppose $(\xi_t)_{t\geq 0}$ satisfying the following properties.

1. It is a family of independent random variables (r.v.'s)
2. $(\xi_t)_{t\geq 0}$ is "stationary", that is, for any positive integer $n$, positive reals $h, t_0, t_1, \ldots, t_n$, the law of $(\xi_{t_0+h}, \ldots, \xi_{t_n+h})$ does not depend on $h$.

More precisely we perturb eqn [1] as follows:

$$\frac{dX_t}{dt} = b(t, X_t) + a(t, X_t)\xi_t \qquad X_0 = x_0 \tag{2}$$

We suppose for a moment that $d = m = 1$. In reality no reasonable real-valued process $(\xi_t)_{t\geq 0}$ fulfilling previous assumptions exists. In particular, if process $(\xi_t)$ exists (resp. $(\xi_t)$ exists and each $\xi_t$ is a square-integrable r.v.), then the process cannot have continuous paths (resp. it cannot be measurable with respect to $\Omega \times \mathbb{R}_+$). However, suppose that such a process exists; we set $B_t = \int_0^t \xi_s ds$. In that case, properties (1) and (2) can be translated into the following on $(B_t)$.

(P1) It has independent increments, which means that for any $t_0, \dots, t_n, h \geq 0, B_{t_1+h} - B_{t_0+h}, \dots, B_{t_n+h} - B_{t_{n-1}+h}$ are independent r.v.'s.
(P2) It has stationary increments, which means that for any $t_0, \dots, t_n, h \geq 0$, the law of $(B_{t_1+h} - B_{t_0+h}, \dots, B_{t_n+h} - B_{t_{n-1}+h})$ does not depend on $h$.

On the other hand, it is natural to require that

(C1) $B_0 = 0$ a.s.,
(C2) it is a continuous process, that is, it has continuous paths a.s.

Equation [2] should be rewritten in some integral form

$$X_t = X_0 + \int_0^t b(s, X_s)ds + \int_0^t a(s, X_s)dB_s \tag{3}$$

Clearly the paths of process $(B_t)$ cannot be differentiable, so one has to give meaning to integral $\int_0^t a(s, X_s)dB_s$. This will be intended in the "Itô" sense, see considerations below.

An important result of probability theory says that a stochastic process $(B_t)$ fulfilling properties P1, P2 and C1, C2 is essentially a "Brownian motion". More precisely, there are real constants $b, \sigma$ such that $B_t = bt + \sigma W_t$, where $(W_t)$ is a classical Brownian motion defined below.

**Definition 1**

(i) A (continuous) stochastic process $(W_t)$ is called classical "Brownian motion" if $W_0 = 0$ a.s., it has independent increments and the law of $W_t - W_s$ is a Gaussian $N(0, t - s)$ *r.v.*
(ii) A $m$-dimensional Brownian motion is a vector $(W^1, \dots, W^m)$ of independent classical Brownian motions.

Let $(\mathcal{F}_t)_{t\geq 0}$ be a filtration fulfilling the usual conditions, see (Karatzas and Shreve (1991, section 1.1). There one can find basic concepts of the theory of stochastic processes as the concept of adapted, progressively measurable process. An adapted process is also said to be nonanticipating towards the filtration $(\mathcal{F}_t)$ which represents the state of the information at each time $t$. A process $(X_t)$ is said to be adapted if for any $t, X_t$ is $\mathcal{F}_t$-measurable. The notion of progressively measurable process is a slight refinement of the notion of adapted process.

**Definition 2**

(i) A (continuous) $(\mathcal{F}_t)$ adapted process $(W_t)$ is called (classical) $(\mathcal{F}_t)$-Brownian motion if $W_0 = 0$, if for any $s < t$ $W_t - W_s$ is an $N(0, t - s)$ distributed r.v. which is independent of $\mathcal{F}_s$.
(ii) An $(\mathcal{F}_t)$-$m$-dimensional Brownian motion is a vector $(W^1, \dots, W^m)$ of $(\mathcal{F}_t)$-classical independent Brownian motions.

From now on, we will consider a probability space $(\Omega, \mathcal{F}, \mathbb{P})$ equipped with a filtration $(\mathcal{F}_t)_{t\geq 0}$ fulfilling the usual conditions. From now on all the considered filtrations will have that property.

Let $W = (W_t)_{t\geq 0}$ be an $(\mathcal{F}_t)_{t\geq 0}$-$m$-dimensional classical Brownian motion. In Karatzas and Shreve (1991, chapter 3) and Revuz and Yor (1999, chapter 4), one introduces the notion of stochastic Itô integral announced before. Let $Y = (Y^1, \dots, Y^m)$ be a progressively measurable $m$-dimensional process such that $\int_0^T \|Y_s\|^2 ds < \infty$, then the Itô integral $\int_0^T Y_s dW_s$ is well defined. In particular the indefinite integral $\int_0^{\cdot} Y_s dW_s$ is an $(\mathcal{F}_t)$-progressively measurable continuous process. If $Y$ is an $\mathbb{R}^{d\times m}$ matrix-valued process, the integral $\int_0^t Y_s dW_s$ is componentwise defined and it will be a vector in $\mathbb{R}^d$. The analogous of differential calculus in the framework of stochastic processes is Itô calculus, see again Karatzas and Shreve (1991, chapter 3) and Revuz and Yor (1999, chapter 4). Important tools are the concept of quadratic variation $[X]$ of a stochastic process when it exists. For instance, the quadratic variation $[W]_t$ of a classical Brownian motion equals $t$. If $M_t = \int_0^t Y_s dW_s$, then $[M]_t = \int_0^t \|Y_s\|^2 ds$. One celebrated theorem of P Lévy states the following: if $(M_t)$ defines a continuous $(\mathcal{F}_t)$-local martingale such that $[M_t] \equiv t$, then $M$ is an $(\mathcal{F}_t)$-classical Brownian motion. That theorem is called the "Lévy characterization theorem of Brownian motion." Itô formula constitutes the natural generalization of fundamental theorem of differential calculus to the stochastic calculus. Another significant tool is Girsanov theorem; it states essentially the following: suppose that the following so-called "Novikov condition" is verified:

$$\mathbb{E}\left(\exp\left(\frac{1}{2}\int_0^T \|Y_t\|^2\right)dt\right) < \infty$$

Then the process $\tilde{W}_t = W_t + \int_0^t Y_s \mathrm{d}s, t \in [0,T]$ is again an $m$-dimensional $(\mathcal{F}_t)$-classical Brownian motion under a new probability measure $Q$ on $(\Omega, \mathcal{F}_T)$ defined by

$$\mathrm{d}Q = \mathrm{d}P \exp\left(\int_0^t Y_s \mathrm{d}W_s - \frac{1}{2}\|Y_s\|^2 \mathrm{d}s\right)$$

Let $\xi$ be an $\mathcal{F}_0$-measurable r.v., for instance, $\xi \equiv x \in \mathbb{R}^d$. We are interested in the SDE

$$\begin{aligned} \mathrm{d}X_t &= a(t, X_t)\,\mathrm{d}W_t + b(t, X_t)\,\mathrm{d}t \\ X_0 &= \xi \end{aligned} \quad [4]$$

**Definition 3** A progressively measurable process $(X_t)_{t\in[0,T]}$ is said to be solution of [4] if a.s.

$$X_t = Z + \int_0^t a(t, X_t)\,\mathrm{d}W_t + \int_0^t b(t, X_t)\,\mathrm{d}t \quad \forall t \in [0,T] \quad [5]$$

provided that the right-hand side member makes sense. In particular, such a solution is continuous. The function a (resp. b) is called the diffusion (drift) coefficient of the SDE. $a$ and $b$ may sometimes be allowed to be random; however, this dependence has to be progressively measurable. Clearly, we can define the notion of solution $(X_t)_{t\geq 0}$ on the whole positive real axis.

We remark that those equations are called Itô SDEs. A solution of previous equation is named diffusion process.

## The Lipschitz Case

The most natural framework for studying the existence and uniqueness for SDEs appears when the coefficients are Lipschitz.

A function $\gamma : [0,T] \times \mathbb{R}^m \longrightarrow \mathbb{R}^d$ is said to have "polynomial growth" (with respect to $x$ uniformly in $t$), if for some $n$ there is a constant $C > 0$ with

$$\sup_{t\in[0,T]} \|\gamma(t,x)\| \leq C(1 + \|x\|^n) \quad [6]$$

The same function is said to have "linear growth" if [6] holds with $n = 1$. A function $\gamma : \mathbb{R}_+ \times \mathbb{R}^m \to \mathbb{R}^d$ is said to be "locally Lipschitz" (with respect to $x$ uniformly in $t$), if for every $t \in [0,T], K > 0$, $\gamma_{|[0,T]\times[-K,K]}$ is Lipschitz (with respect to $x$ uniformly with respect to $t$).

Let $a : \mathbb{R}_+ \times \mathbb{R}^{d\times m} \longrightarrow \mathbb{R}^d, b : \mathbb{R}_+ \times \mathbb{R}^d \longrightarrow \mathbb{R}^d$, be Borel functions, $\xi$ an $\mathbb{R}^d$-valued r.v. $\mathcal{F}_0$-measurable and $(W_t)_{t\geq 0}$ be a $m$-dimensional $(\mathcal{F}_t)$-Brownian motion.

Classical fixed-point theorems allow to establish the following classical result.

**Theorem 1** *We suppose a and b locally Lipschitz with linear growth. Let $\xi$ be a square-integrable r.v. that is $\mathcal{F}_0$-measurable. Then [4] has a unique solution X. Moreover,*

$$\mathbb{E}\left(\sup_{t\leq T} |X_t|^2\right) < \infty$$

**Remark 1**

(i) Equation [4] can be settled similarly by putting initial condition $x$ at some time $s$. In that case the problem is again well stated. If $\xi \equiv x$ is a deterministic point of $\mathbb{R}^d$, then we will often denote by $X^{s,x}$ the solution of that problem.

(ii) If the coefficients are only locally Lipschitz, the equation may be solved until a stopping time. If $d = 1$, it is possible to state necessary and sufficient conditions for nonexplosion (Feller test).

(iii) The theorem above admits several generalizations. For instance, the Brownian motion can be replaced by general semimartingales, (possibly with jumps as Lévy processes).

An important role of diffusion processes is the fact that they provide probabilistic representation to PDEs of parabolic (and even elliptic) type. We will only mention here the parabolic framework.

We denote $A(t,x) = a(t,x)a(t,x)^*$, where $*$ means transposition for matrices. $(t,x) \to A(t,x) = (A_{ij}(t,x))$ is a $d \times d$ matrix-valued function. Let us consider also continuous functions $k : [0,T] \times \mathbb{R}^d \to \mathbb{R}^d, g : [0,T] \times \mathbb{R}^d \to \mathbb{R}^d$ with polynomial growth or non-negative.

Given a solution of [4], we can associate its generator $(L_t, t \in [0,T])$ setting

$$L_t f(x) = \frac{1}{2}\sum_{i,j=1}^d A_{ij}(t,x)\partial_{ij}^2 f(x) + b(t,x) \cdot \nabla f(x)$$

Feynman–Kac theorem is stated below and it provides probabilistic representation of an associated parabolic linear PDEs.

**Theorem 2** *Suppose there is a function $v : [0,T[ \times \mathbb{R}^d \to \mathbb{R}^d$ continuous with polynomial growth of class $C^{1,2}([0,T] \times \mathbb{R}^d)$ satisfying the following Cauchy problem:*

$$\begin{aligned} (\partial_t v + L_t)v - kv &= g \\ v(T,x) &= f(x) \end{aligned} \quad [7]$$

*Then*

$$v(s,x) = E\bigg(f(X_T)\exp\left(-\int_s^T k(\theta, X_\theta)\,\mathrm{d}\theta\right) - \int_s^T g(t, X_t)\exp\left\{-\int_s^t k(\theta, X_\theta)\,\mathrm{d}\theta\right\}\mathrm{d}t\bigg)$$

*for* $(s,x) \in [0,T] \times \mathbb{R}^d$, *where* $X = X^{s,x}$. *In particular, such a solution is unique.*

**Remark 2**

(i) In order to obtain "classical solutions" of the above Cauchy problem, one needs some conditions. It is the case, for instance, when the following ellipticity condition holds on $A$:

$$\exists c > 0,\ \forall (t,x) \in [0,T] \times \mathbb{R}^n,\ \forall (\xi_1, \ldots, \xi_n) \in \mathbb{R}^n$$

$$\sum_{i,j}^{d} A_{ij}(t,x)\xi_i\xi_j \geq c \sum_{i=1}^{d} |\xi_i|^2 \qquad [8]$$

In the degenerate case, it is possible to deal with viscosity solutions, in the sense of P L Lions. This theorem establishes an important link between deterministic PDEs and SDEs.

(ii) A natural generalization of Feynman–Kac theorem comes from the system of forward–backward SDEs in the sense of Pardoux and Peng.

(iii) Other types of probabilistic representation do appear in stochastic control theory through the so-called verification theorems, see for instance, Fleming and Soner (1993) and Yong and Zhou (1999). In that case, the (nonlinear) Hamilton–Jacobi–Bellmann deterministic equation is represented by a controlled SDE.

(iv) Another bridge between nonlinear PDEs and diffusions can be provided in the framework of interacting particle systems with chaos propagation, see Graham *et al.* (1996) for a survey on those problems. Among the most significant nonlinear PDEs investigated probabilistically, we quote the case of porous media equations. For instance, for a positive integer $m$, a solution to

$$\partial_t u = \tfrac{1}{2}\partial^2_{xx}(u^{2m+1}) \qquad [9]$$

can be represented by a (nonlinear) diffusion of the type, see Benachour *et al.* (1996),

$$\begin{aligned} \mathrm{d}X_t &= u^m(s, X_s)\,\mathrm{d}W_t \\ u(t,\cdot) &= \text{law density of } X_t \end{aligned} \qquad [10]$$

## Different Notions of Solutions

Let $a$ and $b$ as at the beginning of the previous section. Let $(\Omega, \mathcal{F}, \mathbb{P})$ be a probability space, a filtration $(\mathcal{F}_t)_{t\geq 0}$ fulfilling the usual conditions, an $(\mathcal{F}_t)_{t\geq 0}$-classical Brownian motion $(W_t)_{t\geq 0}$. Let $\xi$ be an $\mathcal{F}_0$-measurable r.v. In the section "Motivation and preliminaries," we defined the notion of solution of the following equation:

$$\begin{aligned} \mathrm{d}X_t &= b(t, X_t)\,\mathrm{d}t + a(t, X_t)\,\mathrm{d}W_t \\ X_0 &= \xi \end{aligned} \qquad [11]$$

This equation will be denoted by $E(a,b)$ (without initial condition). However, as we will see, the general concept of solution of an SDE is more sophisticated and subtle than in the deterministic case. We distinguish several variants of existence and uniqueness.

**Definition 4** (Strong existence). We will say that equation $E(a,b)$ admits strong existence if the following holds. Given any probability space $(\Omega, \mathcal{F}, \mathbb{P})$, a filtration $(\mathcal{F}_t)_{t\geq 0}$, an $(\mathcal{F}_t)_{t\geq 0}$-Brownian motion $(W_t)_{t\geq 0}$, an $\mathcal{F}_0$-measurable and square-integrable r.v. $\xi$, there is a process $(X_t)_{t\geq 0}$ solution to $E(a,b)$ with $X_0 = \xi$ a.s.

**Definition 5** (Pathwise uniqueness). We will say that equation $E(a,b)$ admits pathwise uniqueness if the following property is fulfilled. Let $(\Omega, \mathcal{F}, \mathbb{P})$ be a probability space, a filtration $(\mathcal{F}_t)_{t\geq 0}$, an $(\mathcal{F}_t)_{t\geq 0}$ Brownian motion $(W_t)_{t\geq 0}$. If two processes $X, \tilde{X}$ are two solutions such that $X_0 = \tilde{X}_0$ a.s., then $X$ and $\tilde{X}$ coincide.

**Definition 6** (Existence in law or weak existence). Let $\nu$ be a probability law on $\mathbb{R}^d$. We will say that $E(a,b;\nu)$ admits weak existence if there is a probability space $(\Omega, \mathcal{F}, \mathbb{P})$, a filtration $(\mathcal{F}_t)_{t\geq 0}$, an $(\mathcal{F}_t)_{t\geq 0}$-Brownian motion $(W_t)_{t\geq 0}$, and a process $(X_t)_{t\geq 0}$ solution of $E(a,b)$ with $\nu$ being the law of $X_0$.

We say that $E(a,b)$ admits weak existence if $E(a,b;\nu)$ admits weak existence for every $\nu$.

**Definition 7** (Uniqueness in law). Let $\nu$ be a probability law on $\mathbb{R}^d$. We say that $E(a,b;\nu)$ has a unique solution in law if the following holds. We consider an arbitrary probability space $(\Omega, \mathcal{F}, \mathbb{P})$ and a filtration $(\mathcal{F}_t)_{t\geq 0}$ on it; we consider also another probability space $(\tilde{\Omega}, \tilde{\mathcal{F}}, \tilde{\mathbb{P}})$ equipped with another filtration $(\tilde{\mathcal{F}}_t)_{t\geq 0}$; we consider an $(\mathcal{F}_t)_{t\geq 0}$-Brownian motion $(W_t)_{t\geq 0}$, and an $(\tilde{\mathcal{F}}_t)_{t\geq 0}$-Brownian motion $(\tilde{W}_t)_{t\geq 0}$; we suppose having a process $(X_t)_{t\geq 0}$ (resp. a process $(\tilde{X}_t)_{t\geq 0}$) solution of $E(a,b)$ on the first (resp. on the second) probability space such that both the law of $X_0$ and $\tilde{X}_0$ are identical to $\nu$. Then $X$ and $\tilde{X}$ must have the same law as r.v. with values in $E = C(\mathbb{R}_+)$ (or $C[0,T]$).

We say that $E(a,b)$ has a unique solution in law if $E(a,b;\nu)$ has a unique solution in law for every $\nu$.

There are important theorems which establish bridges among the preceding notions. One of the most celebrated is the following.

**Proposition 1** (Yamada–Watanabe). *Consider the equation* $E(a,b)$.

(i) *Pathwise uniqueness implies uniqueness in law.*

(ii) *Weak existence and pathwise uniqueness imply strong existence.*

*A version can be stated for $E(a,b;\nu)$ where $\nu$ is a fixed probability law.*

**Remark 3**

(i) If $a$ and $b$ are locally Lipschitz with linear growth, Theorem [1] implies that $E(a,b)$ admits strong existence and pathwise uniqueness.
(ii) If $a$ and $b$ are only locally Lipschitz, then pathwise uniqueness is fulfilled.

### Existence and Uniqueness in Law

A way to create weak solutions of $E(1,b)$ when $(t,x)\to b(t,x)$ is Borel with linear growth is the Girsanov theorem. Suppose $d=1$ for simplicity. Let us consider an $(\mathcal{F}_t)$-classical Brownian motion $(X_t)$. We set

$$W_t = X_t - \int_0^t b(s, X_s)\mathrm{d}s$$

Under some suitable probability $Q,(W_t)$ is an $(\mathcal{F}_t)$-classical Brownian motion. Therefore, $(X_t)$ provides a solution to $E(1,b;\delta_0)$.

We continue with an example where $E(a,b)$ does not admit pathwise uniqueness, even though it admits uniqueness in law.

**Example 1** We consider the stochastic equation

$$X_t = \int_0^t \mathrm{sign}(X_s)\mathrm{d}W_s \qquad [12]$$

with

$$\mathrm{sign}(x) = \begin{cases} 1 & \text{if } x \geq 0 \\ -1 & \text{if } x < 0 \end{cases}$$

It corresponds to $E(a,b;\delta_0)$ with $b=0$ and $a(x)=\mathrm{sign}(x)$.

If $(W_t)_{t\geq 0}$ is an $(\mathcal{F}_t)$-classical Brownian motion, then $(X_t)_{t\geq 0}$ is $(\mathcal{F}_t)_{t\geq 0}$-continuous local martingale vanishing at zero such that $[X]_t \equiv t$. According to Lévy characterization theorem stated earlier, $X$ is an $(\mathcal{F}_t)_{t\geq 0}$-classical Brownian motion. This shows in particular that $E(a,b;\delta_0)$ admits uniqueness in law. In the sequel, we will show that $E(a,b;\delta_0)$ also admits weak existence.

Let now $(\Omega,\mathcal{F},\mathbb{P})$ be a probability space, an $(\mathcal{F}_t)_{t\geq 0}$-classical Brownian motion with respect to a filtration and $(X_t)_{t\geq 0}$ such that [12] is verified. Then $\tilde{X}_t = -X_t$ can also be shown to be a solution. Therefore, $E(a,b;\delta_0)$ does not admit pathwise uniqueness.

We continue stating a result true in the multi-dimensional case.

**Proposition 3** (Stroock–Varadhan). *Let $\nu$ be a probability on $\mathbb{R}^d$ such that*

$$\int_{\mathbb{R}} \|x\|^{2m}\nu(\mathrm{d}x) < +\infty \qquad [13]$$

*for a certain $m>1$. We suppose that $a,b$ are continuous with linear growth. Then $E(a,b;\nu)$ admits weak existence.*

From now on, a function $\gamma:[0,T]\times\mathbb{R}^m\to\mathbb{R}^d$ will be said Hölder-continuous if it is Hölder-continuous in the space variable $x\in\mathbb{R}^m$ uniformly with respect to the time variable $t\in[0,T]$.

Stroock and Varadhan (1979) also provide the following result, which is an easy consequence of their theorem 7.2.1.

**Proposition 4** *We suppose $a,b$ both Hölder-continuous, bounded such that condition; [8] is fulfilled. Then SDE $E(a,b;\nu)$ admits weak uniqueness.*

**Remark 4**

(i) The Hölder condition and [8] in Proposition 4 may be relaxed and replaced with the solvability of a Cauchy problem of a parabolic PDE with suitable terminal value.
(ii) In the case $d=1$, if $a,b$ are bounded and just Borel with [8] for $x$ on each compact, then $E(a,b;\nu)$ admits weak existence and uniqueness in law. See Stroock and Varadhan (1979, exercises 7.3.2 and 7.3.3).
(iii) If $d=2$, the same holds as at previous point provided that moreover $a$ does not depend on time.

We proceed with some more specifically unidimensional material stating some results from K J Engelbert and W Schmidt, who furnished necessary and sufficient conditions for weak existence and uniqueness in law of SDEs.

For a Borel function $\sigma:\mathbb{R}\to\mathbb{R}$, we first define

$$Z(\sigma) = \{x\in\mathbb{R} | \sigma(x)=0\}$$

then we define the set $I(\sigma)$ as the set of real numbers $x$ such that

$$\int_{x-\varepsilon}^{x+\varepsilon} \frac{\mathrm{d}y}{\sigma^2(y)} = \infty, \quad \forall\varepsilon>0$$

**Proposition 5** (*Engelbert–Schmidt criterion*). *Suppose that $a:\mathbb{R}\to\mathbb{R}$, that is, does not depend on time and we consider the equation without drift $E(a,0)$.*

(i) *$E(a,0)$ admits weak existence (without explosion) if and only if*

$$I(a) \subset Z(a) \qquad [14]$$

(ii) $E(a, 0)$ *admits weak existence and uniqueness in law if and only if*

$$I(a) = Z(a) \quad [15]$$

**Remark 5**

(i) If $a$ is continuous then, [14] is always verified. Indeed, if $a(x) \neq 0$, there is $\varepsilon > 0$ such that

$$|a(y)| > 0, \quad \forall y \in [x - \varepsilon, x + \varepsilon]$$

Therefore, $x$ cannot belong to $I(a)$.

(ii) Equation [14] is verified also for some discontinuous functions as, for instance, $a(x) = \mathrm{sign}(x)$. This confirms what was affirmed previously, that is, the weak existence (and uniqueness in law) for $E(a, 0)$.

(iii) If $a(x) = 1_{\{0\}}(x)$, [14] is not verified.

(iv) If $a(x) = |x|^\alpha, \alpha \geq 1/2$, then

$$Z(a) = I(a) = \{0\}$$

So there is at most one solution in law for $E(a, 0)$.

(v) The proof is technical and makes use of Lévy characterisation theorem of Brownian motion.

### Results on Pathwise Uniqueness

**Proposition 6** (Yamada–Watanabe). *Let $a, b : \mathbb{R}_+ \times \mathbb{R} \to \mathbb{R}$ and consider again $E(a, b)$. Suppose $b$ globally Lipschitz and $h : \mathbb{R}_+ \to \mathbb{R}_+$ strictly increasing continuous such that*

(i) $h(0) = 0$;

(ii) $\int_0^\varepsilon (1/h^2)(y)\mathrm{d}y = \infty, \quad \forall \varepsilon > 0$; and

(iii) $|a(t, x) - a(t, y)| \leq h(x - y)$.

*Then pathwise uniqueness is verified.*

**Remark 6**

(i) In Proposition 6, one typical choice is $h(u) = u^\alpha, \alpha > 1/2$.

(ii) Pathwise uniqueness for $E(a, b)$ holds therefore if $b$ is globally Lipschitz and $a$ is Hölder-continuous with parameter equal to 1/2.

**Corollary 1** *Suppose that the assumptions of Proposition 6 are verified and $a, b$ continuous with linear growth. Then $E(a, b; \nu)$ admits strong existence and pathwise uniqueness, whenever $\nu$ verifies condition [13].*

**Proof** It follows from Propositions 6 and 3 together with Proposition 1 (ii). □

**Remark 7** Suppose $d = 1$. Pathwise uniqueness for $E(a, b)$ also holds under the following assumptions.

(i) $a$, $b$ are bounded, $a$ is time independent and $a \geq \text{const.} > 0$, $h$ as in Proposition 6. This result has an analogous form in the case of spacetime white noise driven SPDEs of parabolic type, as proved by Bally, Gyongy, and Pardoux in 1994.

(ii) a independent on time, $b$ bounded and $a \geq \text{const.} > 0$; moreover, $|a(x) - a(y)|^2 \leq |f(y) - f(x)|$ and $f$ is increasing and bounded.

For illustration we provide some significant examples.

**Example 2**

$$X_t = \int_0^t |X_s|^\alpha \, \mathrm{d}W_s, \quad t \geq 0 \quad [16]$$

We set $a(x) = |x|^\alpha, 0 < \alpha < 1$. This is equation $E(a, 0)$ with $a(x) = |x|^\alpha$. According to Engelbert–Schmidt notations, we have $Z(a) = \{0\}$. Moreover

(i) If $\alpha \geq 1/2$, then $I(a) = \{0\}$.

(ii) If $\alpha < 1/2$ then $I(a) = \emptyset$.

Therefore, according to Proposition 5, $E(a, 0)$ admits weak existence. On the other hand, if $\alpha \geq 1/2$,

$$|x^\alpha - y^\alpha| \leq h(|x - y|) \quad [17]$$

where $h(z) = z^\alpha$. According to Proposition 6, [16] admits pathwise uniqueness and by Corollary [1], also strong existence. The unique solution is $X \equiv 0$.

If $\alpha < 1/2, X \equiv 0$ is always a solution. This is not the only one; even uniqueness in law is not true.

**Example 3** Let $a(x) = \sqrt{|x|}, b$ Lipschitz. Then $E(a, b)$ admits strong existence and pathwise uniqueness. In fact, $a$ is Hölder-continuous with parameter 1/2 and the second item of Remark 6 applies; so pathwise uniqueness holds. Strong existence is a consequence of Propositions 3 and 1 (ii).

An interesting particular case is provided by the following equation. Let $x_0, \sigma, \delta \geq 0, k \in \mathbb{R}$. The following equation admits strong existence and pathwise uniqueness.

$$Z_t = x_0 + \sigma \int_0^t \sqrt{|Z_s|} \, \mathrm{d}W_s + \int_0^t (\delta - kX_s) \, \mathrm{d}s \qquad t \in [0, T] \quad [18]$$

Equation [18] is widely used in mathematical finance and it constitutes the model of Cox–Ingersoll–Ross: the solution of the mentioned equation represents the short interest rate.

Consider now the particular case where $k = 0$, $\sigma = 2$. According to some comparison theorem for SDEs, the solution $Z$ is always non-negative and

therefore the absolute value may be omitted. The equation becomes

$$Z_t = x_0 + 2\int_0^t \sqrt{Z_s}\,\mathrm{d}W_s + \delta t \qquad [19]$$

**Definition 8** The unique solution $Z$ to

$$Z_t = x_0 + 2\int_0^t \sqrt{Z_s}\mathrm{d}W_s + \delta t \qquad [20]$$

is called "square $\delta$-dimensional Bessel process" starting at $x_0$; it is denoted by $\mathrm{BESQ}^\delta(x_0)$; for fine properties of this process, see Revuz and Yor (1999, ch. IX.3).

Since $Z \geq 0$, we call $\delta$-dimensional Bessel process starting from $x_0$ the process $X = \sqrt{Z}$. It is denoted by $\mathrm{BES}^\delta(x_0)$.

**Remark 8** Let $d \geq 1$. Let $W = (W^1, \ldots, W^d)$ be a classical $d$-dimensional Brownian motion. We set $X_t = \| W_t \|$. $(X_t)_{t\geq 0}$ is a $d$-dimensional Bessel process.

**Remark 9** If $\delta > 1$, it is possible to see that

$$X_t = W_t + \frac{\delta - 1}{2}\int_0^t \frac{\mathrm{d}s}{X_s}$$

### The Case with Distributional Drift

Pioneering work about diffusions with generalized drift was presented by N I Portenko, but in the framework of semimartingale processes. Recently, some work was done characterizing solutions in the class of the so-called Dirichlet processes, with some motivations in random irregular environment.

A useful transformation in the theory of SDE is the so-called "Zvonkin transformation." Let $(W_t)$ be an $(\mathcal{F}_t)$-classical Brownian motion. Let $a$ (resp. $b$) : $\mathbb{R} \to \mathbb{R}$ (resp. $C^1$) be locally bounded. We suppose moreover $a > 0$. We fix $x_0 \in \mathbb{R}$. Let $(X_t)_{t\geq 0}$ be a solution of

$$X_t = x_0 + \int_0^t b(X_s)\,\mathrm{d}s + \int_0^t a(X_s)\,\mathrm{d}W_s \qquad [21]$$

We set

$$\Sigma(x) = \int_0^x \frac{2b}{a^2}(y)\,\mathrm{d}y$$

and we define $h : \mathbb{R} \to \mathbb{R}$ such that

$$h(0) = 0, \qquad h' = \mathrm{e}^{-\Sigma}$$

$h$ is strictly increasing. We set $\tilde{a}(x) = (ah')(h^{-1}(x))$, where $h^{-1}$ is the inverse of $h$. We set $Y_t = h(X_t)$. Without entering into details, the classical Itô formula allows to show that $(Y_t)$ defines a solution of

$$\mathrm{d}Y_t = \tilde{a}(Y_t)\,\mathrm{d}W_t \qquad Y_0 = h(x_0) \qquad [22]$$

Now, eqn [22] fulfills the requirements of the Engelbert–Schmidt criterion so that it admits weak existence and uniqueness in law. Consequently, unless explosion, one can easily establish the same well-posedness for [21].

Zvonkin transformation also allows to prove strong existence and pathwise uniqueness results for [21]; for instance, when

- $a$ has linear growth, and
- $$y \to \int_0^y \frac{b(s)}{a^2(s)}\mathrm{d}s$$

  is a bounded function.

In fact, problem [22] satisfies pathwise uniqueness and strong existence since the coefficients are Lipschitz with linear growth. Therefore, one can deduce the same for [21].

Veretennikov generalized Zvonkin transformation to the $d$-dimensional case in some cases which include the case $a = 1$ and $b$ bounded Borel.

Zvonkin's procedure suggests also to consider a formal equation of the type

$$\mathrm{d}X_t = \mathrm{d}W_t + \gamma'(X_t)\,\mathrm{d}t \qquad [23]$$

where $\gamma$ is only a continuous function and so $b = \gamma'$ is a Schwartz distribution; $\gamma$ could be, for instance, the realization of an independent Brownian motion of $W$. Therefore, eqn [23] is motivated by the study of irregular random media. When $\sigma = 1, b = \gamma'$, SDE [22], $h' = \mathrm{e}^{-2\gamma}$ still makes sense.

Using the Engelbert–Schmidt criterion, one can see that problem [22] still admits weak existence and uniqueness in the sense of distribution laws. If $Y$ is a solution of [22], $X = h^{-1}(Y)$ provides a natural candidate solution for [21]. R F Bass, Z-Q Chen and F Flandoli, F Russo, and J Wolf investigated generalized SDEs as [23]: in particular, they made previous reasoning rigorous, respectively, in the case of strong and weak solutions, see Flandoli *et al.* (2003).

## Connected Topics

We aim here at giving some basic references about topics which are closely connected to SDEs.

### Stochastic Partial Differential Equations (SPDEs)

If a SDE is a random perturbation of an ordinary differential equation, an SPDE is a random

perturbation of a PDE. Several studies were performed in the parabolic (evolution equation) and hyperbolic case (wave equation). Most of the work was done in the case of a fixed underlying probability spaces. We only quote two basic monographies which should be consulted at first before getting into the subject: the one of Walsh (1986) and the one of Da Prato and Zabczyk (1992).

However, it was possible to establish some results about weak existence and uniqueness in law for SPDEs. One possible tool was a generalization of Girsanov theorem to the case of Gaussian spacetime white noise. Weak existence for the stochastic quantization equation was proved with the help of infinite-dimensional Dirichlet forms by S Albeverio and M Röckner.

We also indicate a beautiful recent monography by Da Prato (2004) which pays particular attention to Kolmogorov equations with infinitely many variables.

### Numerical Approximations

Relevant work was done in numerical approximation of solutions to SDEs and related approximations of solutions to linear parabolic equations via Feynman–Kac probabilistic representation, see Theorem 2). It seems that the stochastic simulations (of improved Monte Carlo type and related topics) for solving deterministic problems are efficient when the space dimension is greater than 4.

### Malliavin Calculus

Malliavin calculus is a wide topic (*see* Malliavin Calculus). Relevant applications of it concern stochastic (ordinary and partial) differential equations. We only quote a monography of Nualart (1995) on those applications. Two main objects were studied.

- Given a solution of an SDE, $(X_t)$, sufficient conditions so that $X_t, t > 0$, has a (smooth) density $p(t, \cdot)$. Small-time asymptotics of this density, when $t \to 0$, and small-drift perturbation were performed, refining Freidlin–Ventsell large-deviation estimates.
- Coming back to SDE [11], one can conceive to consider coefficients $a$, $b$ nonadapted with respect to the underlying filtration $(\mathcal{F}_t)$. On the other hand, the initial condition $\xi$ may be anticipating, that is, not $\mathcal{F}_0$-measurable. In that case, the Itô integral $\int_0^t a(s, X_s) \mathrm{d}W_s$ is not defined. A replacement tool is the so-called "Skorohod integral."

### Rough Paths Approach

A very successful and significant research field is the rough path theory. In the case of dimension $d = 1$, Doss–Sussmann method allows to transform the solution of an SDE into the solution of an ordinary (random) differential equation. In particular, that solution can be seen as depending (pathwise) continuously from the driving Brownian motion $(W_t)$ with respect to the usual topology of $C([0, T])$. Unless exceptions, this continuity does not hold in case of general dimension $d > 1$. Rough paths theory, introduced by T Lyons, allows to recover somehow this lack of continuity and establishes a true pathwise stochastic integration.

### SDEs Driven by Non-semimartingales

At the moment, there is a very intense activity towards SDEs driven by processes which are not semimartingales. In this perspective, we list SDEs driven by fractional Brownian motion with the help of rough paths theory, using fractional and Young type integrals and involving finite cubic variation processes. Among the contributors in that area we quote L Coutin, R Coviello, M Errami, M Gubinelli, Z Qian, F Russo, P Vallois, and M Zähle.

# Stochastic Hydrodynamics

**B Ferrario**, Università di Pavia, Pavia, Italy

## Introduction

Mathematical models in hydrodynamics are introduced to describe the motion of fluids. The basic equations for Newtonian incompressible fluids are the Euler and the Navier–Stokes equations, for inviscid and viscous fluids, respectively. For a given set of body forces acting on the fluid, these nonlinear partial differential equations (PDEs) model the evolution in time of the velocity and pressure at each point of the fluid, given the initial velocity and suitable boundary conditions (*see* Partial Differential Equations: Some Examples). The equations of hydrodynamics offer challenging mathematical problems, like proving the existence and uniqueness of solutions, determining their regularity, their asymptotic behavior for large time, and their stability. To gain some insight into the behavior of fluids, stochastic analysis is introduced into hydrodynamics. In fact, there are various attempts to describe turbulent regime (*see* Turbulence Theories). But, analyzing individual solutions that determine the flow at any time, for a given initial condition, is a desperate task, since the dynamics in a turbulent regime is chaotic and highly unstable. This is a particular chaotic motion with some characteristic statistical properties (see Monin and Yaglom (1987)). The aim of a statistical description of turbulent flow is to single out some relevant collective properties of the flow that, hopefully, make it possible to grasp the salient features of the dynamics. In this sense, stochastic hydrodynamics is germane to the kinetic gas theory. In the next section we shall review a typical topic of stochastic hydrodynamics, the evolution of probability measures. Results on stationary probability measures will be given in the subsequent sections.

Another characteristic of turbulent flows is the lack of space regularity of the velocity field. We shall introduce in the section "The stochastic Navier–Stokes equations" a stochastic model of turbulence, which exhibits lack of regularity of the solutions.

The Euler equations are a singular limit of the Navier–Stokes equations, since they are first order, instead of second-order PDEs. It is little surprise if they involve different mathematical techniques. A full section will be devoted to a discussion of Euler equations and another to the Navier–Stokes equations. Statistics of an inviscid flow, when approximated by vortex motion, will be described in the final section.

## Statistical Solutions

Let $u(t, x)$ be the fluid velocity at time $t$ and point $x \in D \subseteq \mathbb{R}^d$; since the initial velocity is always affected by experimental errors, it is reasonable to assign a measure $\nu$ determining the probability that the initial velocity belongs to a Borel set $\Gamma$ of the space $\mathbb{H}$ of all admissible velocity fields $u = u(x)$.

A spatial statistical solution is a family of probability measures $\mu(t, \cdot), t \geq 0$, each supported

on the set $\mathbb{H}$ such that, given any Borel set $\Gamma$ in $\mathbb{H}$, we have

$$\text{Prob}\{u(t,x) \in \Gamma\} = \mu(t,\Gamma), \quad \forall t > 0 \qquad [1]$$

with the initial condition $\mu(0,\Gamma) = \nu(\Gamma)$. The construction and analysis of statistical solutions $\mu(t,\cdot)$ is one of the crucial mathematical problems in stochastic hydrodynamics (see, e.g., Vishik and Fursikov (1988)).

Hopf gave the first mathematical formulation of the problem of describing turbulent flows by statistical solutions. The first result on the existence of statistical solutions is by Foias in 1973. Hopf (1952) presented an equation in variational derivatives satisfied by the characteristic functional $\chi(t,\phi)$ of the family of measures $\mu(t,\cdot)$ associated with the Navier–Stokes equations. The characteristic functional $\chi(t,\phi)$ is the Fourier transform of the measure $\mu(t,\cdot)$:

$$\chi(t,\phi) = \int_{\mathbb{H}} e^{i\langle\phi,u\rangle}\mu(t,du) \qquad [2]$$

defined for any smooth test function $\phi$.

We now derive the evolution equation for $\chi(t,\phi)$, by assuming that the dynamics takes place in the phase space $\mathbb{H}$ and follows the nonlinear equation

$$\frac{du}{dt} = F(u) \qquad [3]$$

If $u^{\nu}(t)$ is the solution started from $\nu$ at time $t=0$, then its probability distribution is represented by the time-evolved measure $\mu(t,\cdot)$. Therefore, we have that

$$\int_{\mathbb{H}} e^{i\langle\phi,u\rangle}\mu(t,du) = \int_{\mathbb{H}} e^{i\langle\phi,u^{\nu}(t)\rangle}\mu(0,d\nu) \qquad [4]$$

Differentiating in time, we obtain

$$\begin{aligned}\frac{d}{dt}\chi(t,\phi) &= \int_{\mathbb{H}} e^{i\langle\phi,u^{\nu}(t)\rangle} i\langle\phi,F(u^{\nu}(t))\rangle\mu(0,d\nu)\\ &= i\int_{\mathbb{H}} e^{i\langle\phi,\nu\rangle}\langle\phi,F(\nu)\rangle\mu(t,d\nu)\end{aligned} \qquad [5]$$

The last integral is uniquely determined by $\chi$, since the measure $\mu(t,\cdot)$ is uniquely determined by $\chi(t,\phi)$. We denote by $\Phi\chi(t,\phi)$ the last integral in [5]. The evolution equation thus obtained for the characteristic functional $\chi$ is

$$\frac{d}{dt}\chi(t,\phi) = i\Phi\chi(t,\phi), \quad \forall\phi \qquad [6]$$

This is called the Hopf equation associated with the dynamical system [3].

Another way to analyze the evolution of measures is through the moments; instead of the measure $\mu(t,\cdot)$ describing the spatial statistical solution, we deal with the moments of $\mu(t,\cdot)$ of any order. For a nonlinear dynamics [3], the moments equations are an infinite chain of coupled equations, the so-called Friedman–Keller equations.

A prominent role among statistical solutions is played by stationary solutions. They contain all the statistical information in the case of equilibrium in time. We have that the characteristic functional of an invariant measure is constant in time. Therefore,

$$\frac{d}{dt}\chi(t,\phi) = 0$$

Bearing in mind equation [5], this is equivalent to say that the signed measure $\langle\phi,F(\nu)\rangle\mu(t,d\nu)$ vanishes, for any test function $\phi$ and time $t$. Setting $t=0$, we obtain that an invariant measure $\nu$ in the space $\mathbb{H}$ satisfies the Liouville equation

$$\int_{\mathbb{H}} \langle\phi(\nu),F(\nu)\rangle\, d\nu(\nu) = 0 \qquad [7]$$

for appropriate test functions $\phi$. This equation is also called the relation of infinitesimal invariance and the measure $\nu$ is said to be infinitesimally invariant.

The stationary measures are natural candidates to describe the statistical asymptotic behavior of the system when $t\to\infty$. Notice that, in a chaotic system two motions that are arbitrarily close to one another at $t=0$ can evolve in completely different ways. So, to describe satisfactorily the dynamics we take average over a big number of experiments. This is the so-called ensemble average. These averages are assumed to be with respect to an invariant measure $\mu$. The invariant measures must exist and either they are unique or at most one has physical meaning and enters in the functional integral defining the ensemble average. According to the ergodic principle (an assumption not yet proved in hydrodynamics), ensemble averages replace long-time averages: for every initial velocity field $\nu$, except for a set of initial values negligible in some sense, the time average of an observable $\psi$ tends, as time goes to infinity, to the ensemble average

$$\lim_{T\to\infty}\frac{1}{T}\int_0^T \psi(u^{\nu}(t))\, dt = \int_{\mathbb{H}} \psi\, d\mu \qquad [8]$$

However, it is extremely difficult to prove the existence of stationary probability measures for the Navier–Stokes equations solving directly equation [7]. The situation is formally the same as in equilibrium statistical mechanics, where the Liouville equation is in fact solved, leading to the Boltzmann–Gibbs distribution. However, the results in statistical hydrodynamics are far from being satisfactory.

Recent studies to prove the existence of invariant measures for the Navier–Stokes equations are based on stochastic models (see the section "The stochastic Navier–Stokes equations"). On the other hand, for the Euler equations it is possible to construct formally invariant measures, by means of invariant quantities of the classical motion (see the next section).

Finally, we point out that there are techniques using invariant measures to show some results for the time evolution (e.g., the motion exists for almost all initial values with respect to an invariant measure).

## The Euler Equations

We start recalling some basic facts on Euler equations (*see* Incompressible Euler Equations: Mathematical Theory).

The motion of an inviscid, incompressible, and homogeneous fluid is described by the Euler equations, which in Eulerian coordinates read as

$$\begin{aligned} &\frac{\partial u}{\partial t} + (u \cdot \nabla)u + \nabla p = f \\ &\nabla \cdot u = 0 \qquad\qquad \text{in } D \\ &u \cdot n = 0 \quad \text{on } \partial D \end{aligned} \qquad [9]$$

where, at time $t \geq 0$ and position $x \in D, u = u(t,x)$ is the vector velocity, $p = p(t,x)$ the hydrodynamic pressure. The units have been chosen so that the mass density $\rho = 1$. $\nabla$ denotes the nabla vector operator so

$$u \cdot \nabla = \sum_{j=1}^{d} u_j \frac{\partial}{\partial x_j}$$

$$\nabla \cdot u = \sum_{j=1}^{d} \frac{\partial u_j}{\partial x_j}$$

$$\nabla p = \left(\frac{\partial p}{\partial x_1}, \ldots, \frac{\partial p}{\partial x_d}\right)$$

Finally, $f$ denotes the external force. If the spatial domain $D$ has a boundary $\partial D$, then the velocity is assumed to be tangent to the boundary ($n$ denotes the exterior normal vector to the boundary). Some initial condition $u_0$ at time $t = 0$ is assigned.

When $f = 0$, there are invariant quantities for system [9]. In the literature, there are many works suggesting a Gaussian stationary statistics (see, e.g., the paper by Kraichnan (1980)). We consider invariants that are quadratic in the velocity so as to construct (formally) invariant measures of Gibbs type: the *energy*

$$\mathcal{E}(u) := \frac{1}{2}\int_D |u|^2 \, \mathrm{d}x$$

and, only in the two-dimensional case ($d = 2$), the *enstrophy*

$$\mathcal{S}(u) := \frac{1}{2}\int_D |\text{curl } u|^2 \, \mathrm{d}x$$

(with $\text{curl}\, u = \nabla^{\perp} \cdot u \equiv \partial u_2/\partial x_1 - \partial u_1/\partial x_2$ for $d = 2$).

It is natural to look for velocity fields in the following function spaces: the space $H^0$ of finite kinetic energy and the space $H^1$ of finite enstrophy. Clearly, the admissible fields should also obey the boundary conditions and divergence-free condition. If $P$ is the projection operator onto the space of divergence-free vectors, and $B$ is the bilinear form $B(u,v) := P[(u \cdot \nabla)v]$, the Euler equations can be given the structure of an evolution,

$$\frac{\mathrm{d}u}{\mathrm{d}t} = -B(u,u) \qquad [10]$$

obtained by applying the projection operator $P$ to the first equation in [9]. The pressure disappears and can be regarded as a Lagrange multiplier associated with the divergence-free constraint ($\nabla \cdot u = 0$); it can be fully recovered once the velocity field is known. The dynamics is considered in the phase space of divergence-free velocity vectors $\mathbb{H}$ (a large space containing $H^0$ and $H^1$), which is an infinite-dimensional functional space. More precisely, identifying $H^0$ with its dual $(H^0)'$, we introduce the Gelfand's triplet

$$H^1 \subset H^0 \subset (H^1)' = H^{-1}$$

The space $H^\alpha$, with $\alpha = 1, 2, \ldots,$ are the usual Sobolev spaces but with the additional divergence-free and boundary conditions. For $\alpha > 0$ noninteger, the spaces $H^\alpha$ are defined by interpolation, whereas those with $\alpha < 0$ by duality. As usual, regularity in space is related to the spaces $H^\alpha$ with higher exponent $\alpha$. We have that $\mathbb{H} = \cup_{\alpha \in \mathbb{R}} H^\alpha$.

Invariance of $\mathcal{E}$ and $\mathcal{S}$ can be proved resorting to eqn [9] and assuming that $u$ is a smooth vector field. For instance,

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t}\mathcal{E}(u(t)) &= \frac{\mathrm{d}}{\mathrm{d}t}\frac{1}{2}\int_D |u|^2 \, \mathrm{d}x = \int_D u \cdot \frac{\partial u}{\partial t} \, \mathrm{d}x \\ &= -\int_D u \cdot [(u \cdot \nabla)u] \, \mathrm{d}x - \int_D u \cdot \nabla p \, \mathrm{d}x \end{aligned}$$

By integrating by parts and bearing in mind the divergence-free condition and the boundary condition, we conclude that

$$\frac{\mathrm{d}}{\mathrm{d}t}\mathcal{E}(u) = 0$$

In the same way, the invariance of $\mathcal{S}$ can be proved.

As a consequence, the following Gibbs measures which are defined on the space $\mathbb{H}$

$$\mu_{\mathcal{E}}(\mathrm{d}u) = \frac{1}{Z_{\mathcal{E}}}\,\mathrm{e}^{-\mathcal{E}(u)}\,\mathrm{d}u \qquad \mu_{\mathcal{S}}(\mathrm{d}u) = \frac{1}{Z_{\mathcal{S}}}\,\mathrm{e}^{-\mathcal{S}(u)}\,\mathrm{d}u \qquad [11]$$

are heuristically invariant in time. In [11], $Z_{\cdot}$ are the partition functions, that is, they are normalization constants needed to guarantee that $\mu_{\mathcal{E}}$ and $\mu_{\mathcal{S}}$ are genuine probability measures (e.g., $Z_{\mathcal{E}} = \int_{\mathbb{H}} \mathrm{e}^{-\mathcal{E}(u)}\mathrm{d}u$).

Actually, these measures $\mu$ solve the Liouville equation

$$\int_{\mathbb{H}} \langle \phi(u), B(u,u)\rangle \mathrm{d}\mu(u) = 0 \qquad [12]$$

for any test function $\phi$, cylindrical, infinitely differentiable, bounded, and with bounded derivatives.

On the other hand, the (global and not only infinitesimal) invariance means that if there exists a global flow in time which is well defined in a phase space of full measure $\mu$, then the measure $\mu$ is invariant under this dynamics. The measures $\mu_{\mathcal{E}}$ and $\mu_{\mathcal{S}}$ are centered Gaussian measures whose support is in a space larger than $H^0$, as can be proved by standard methods in the theory of Gaussian measures on infinite-dimensional spaces. By the very definition, $\mu_{\mathcal{E}}$ is a cylindrical measure in $H^0$ and $\mu_{\mathcal{S}}$ is cylindrical in $H^1$. Then the support of $\mu_{\mathcal{E}}$ is any Hilbert space $\tilde{\mathbb{H}}$ such that $H^0 \subset \tilde{\mathbb{H}}$ is a Hilbert–Schmidt embedding, and the support of $\mu_{\mathcal{S}}$ is any space $\tilde{\mathbb{H}}$ such that $H^1 \subset \tilde{\mathbb{H}}$ is a Hilbert–Schmidt embedding. When the spatial dimension $d$ is 2, $\mathrm{supp}(\mu_{\mathcal{E}}) = \cap_{\alpha<-1} H^{\alpha}$ and $\mathrm{supp}(\mu_{\mathcal{S}}) = \cap_{\alpha<0} H^{\alpha}$. When $d$ is 3, $\mathrm{supp}(\mu_{\mathcal{E}}) = \cap_{\alpha<-3/2} H^{\alpha}$.

Moreover, $\mu_{\mathcal{E}}(H^0) = \mu_{\mathcal{S}}(H^0) = 0$, that is, the space of finite energy $H^0$ is negligible with respect to these measures. Let us show this property for the "enstrophy measure" $\mu_{\mathcal{S}}$ when $d = 2$. Let $\{e_j\}_{j=1}^{\infty}$ be a complete orthonormal system in $H^0$. Hence, for $u = \sum_j u_j e_j$, we have $\|u\|^2_{H^0} = \sum_j |u_j|^2$ and $\|u\|^2_{H^1} = \sum_j \lambda_j |u_j|^2$ (with $0 < \lambda_1 \leq \lambda_2 \leq \cdots$ and $\lambda_j \sim j$ as $j \to \infty$). Keeping in mind its definition, the measure $\mu_{\mathcal{S}}$ can be considered as a measure on the space of the sequences $\{u_j\}_j$ and written as an infinite product of one-dimensional centered Gaussian measures

$$\mu_{\mathcal{S}}(\mathrm{d}u) = \otimes_j \frac{1}{\sqrt{2\pi\lambda_j^{-1}}}\,\mathrm{e}^{-(\lambda_j/2)|u_j|^2}\,\mathrm{d}u_j \qquad [13]$$

The energy is

$$\mathcal{E}(u) = \frac{1}{2}\sum_j |u_j|^2$$

and the renormalized energy is

$$:\mathcal{E}:(u) = \frac{1}{2}\sum_j \left( |u_j|^2 - \int |u_j|^2 \mu_{\mathcal{S}}(\mathrm{d}u) \right)$$

Since, as can be easily shown $\int (:\mathcal{E}:(u))^2 \mu_{\mathcal{S}}(\mathrm{d}u) < \infty$, $:\mathcal{E}:(u)$ is finite for $\mu_{\mathcal{S}}$-almost every $u$. On the contrary, since $\sum_j \int |u_j|^2 \mu_{\mathcal{S}}(\mathrm{d}u) = \sum_j \lambda_j^{-1} = +\infty$, $\mathcal{E}(u)$ is infinite for $\mu_{\mathcal{S}}$-almost every $u$.

We also note in passing that, for any $\gamma > 0$ and $\beta > -\gamma$

$$\int_{\mathbb{H}} \mathrm{e}^{-\beta:\mathcal{E}:(u)} \frac{\mathrm{e}^{-\gamma\mathcal{S}(u)}}{Z}\,\mathrm{d}u < \infty$$

so that

$$\mu_{\mathcal{S}}^{(\beta),(\gamma)}(\mathrm{d}u) = \frac{\mathrm{e}^{-\beta:\mathcal{E}(u):-\gamma\mathcal{S}(u)}}{\int \mathrm{e}^{-\beta:\mathcal{E}(u):-\gamma\mathcal{S}(u)}\,\mathrm{d}u}\,\mathrm{d}u \qquad [14]$$

is a probability measure, which is infinitesimally invariant for the Euler flow.

Since the space of finite-energy velocity is negligible with respect to these measures, it is necessary to replace the classical solutions having finite energy with generalized solutions. This is not an easy task in the three-dimensional case, whereas some results have been proved for the two-dimensional problem, where the following existence result holds. Let us analyze the quadratic term $B(u,u) = -P[(u\cdot\nabla)u].(u\cdot\nabla)u$ can be rewritten as $\nabla(u\otimes u)$, taking in account the divergence-free condition. Trivially, we have that $\nabla(u\otimes u) = \nabla(u\otimes u - :u\otimes u:)$, where $:u\otimes u: = \int u\otimes u;\ \mu_{\mathcal{S}}(\mathrm{d}u)$. We consider the quadratic expression $(u\otimes u - :u\otimes u:)$. This is integrable with respect to the measure $\mu_{\mathcal{S}}$ in the sense that

$$\int \|u\otimes u - :u\otimes u:\|^2_{H^{-\varepsilon}}\,\mu_{\mathcal{S}}(\mathrm{d}u) < \infty \qquad [15]$$

for any $\varepsilon > 0$. We remark that this property is similar to the integrability of the renormalized energy, which is a quadratic expression as well. This implies that the $H^{-1-\varepsilon}$-norm of $\nabla(u\otimes u)$ is integrable with respect to the measure $\mu_{\mathcal{S}}$. Therefore, $B(u,u)$ is defined for $\mu_{\mathcal{S}}$-a.e. $u$.

Now, let us replace eqn [10] with a system of infinite equations for all the components $u_j$ with respect to the orthonormal basis $\{e_j\}_j$, obtained by taking the scalar product with $e_j$ of both sides of eqn [10]:

$$\frac{\mathrm{d}u_j}{\mathrm{d}t} = B_j(u,u), \quad j = 1,2,\ldots \qquad [16]$$

Each component $B_j(u,u)$ is defined for $\mu_S$-a.e. $u$. These estimates lead to define a weak solution (see Albeverio and Cruzeiro (1990)):

**Theorem 1** *Let $d=2$. There exists a flow $U(t,\omega)$ defined on a probability space $(\Omega,\mathcal{F},P)$ with values in $H^{-\varepsilon-1}$ for any $\varepsilon>0$, $U(\cdot,\omega)\in C(\mathbb{R},H^{-\varepsilon-1})$ P-a.e. $\omega$, such that for each component $U_j$ we have*

$$\begin{aligned} &U_j(t,\omega)\\ &\quad = U_j(0,\omega)+\int_0^t B_j(U(s,\omega),U(s,\omega))\,\mathrm{d}s,\\ &\qquad P-a.e.\omega, \qquad \forall t\in\mathbb{R} \end{aligned}$$

*Moreover, the measure $\mu_S$ is invariant under this flow.*

We point out that uniqueness is an open problem also for $d=2$. But already in the classical analysis of the Euler equations in a bounded domain, uniqueness for initial velocity of finite energy is not known. Working with the measure $\mu_{\mathcal{E}}$ is even worse, especially when $d=3$, because its support is a larger space within which more irregular velocity vectors live. The more irregular the spaces where the flow lives, the more difficult is to handle the nonlinear term $B(u,u)$.

On the other hand, for $d=1$, the mathematical analysis is much easier. For instance, it can be proved (see Robert (2003)) that the one-dimensional inviscid Burgers equation on the line

$$\frac{\partial u}{\partial t}+\frac{\partial}{\partial x}\left(\frac{1}{2}u^2\right)=0 \qquad [17]$$

has intrinsic invariant statistical solution, given by a class of Lévy's processes with negative jumps.

## The Stochastic Navier–Stokes Equations

The Navier–Stokes equations describe advection with velocity $u$ and diffusion with kinematic viscosity $\nu>0$ (*see* Viscous Incompressible Fluids: Mathematical Theory)

$$\left.\begin{aligned} &\frac{\partial u}{\partial t}-\nu\Delta u+(u\cdot\nabla)u+\nabla p=f\\ &\nabla\cdot u=0\\ &u=0 \quad \text{on}\,\partial D \end{aligned}\right. \quad \text{in}\, D \qquad [18]$$

where $\Delta$ is the Laplace operator. Nonslip boundary conditions are assumed. Although the Euler equations [9] are formally obtained from [18] by setting $\nu=0$, the presence of the second-order operator $-\nu\Delta$ makes the analysis needed to prove the existence, uniqueness, and regularity of solutions easier than for the Euler equations. However, at variance with the Euler equations, the Navier–Stokes equations do not possess invariants, since the viscosity dissipates energy. Hence, it is difficult to find explicit expressions of invariant measures for the deterministic Navier–Stokes equations, except the trivial invariant measures concentrated on a stationary solution. However, as soon as a stochastic force is introduced in these equations, it is possible to have nontrivial invariant measures. It is impossible to review here the wide literature concerning the stochastic Navier–Stokes equations and we confine ourselves to make some remarks. Most results are concerned with proving the existence and/or uniqueness of an invariant measure $\mu$, without giving an explicit representation, apart some attempts like Gallavotti (2002), where a formal representation of stationary distributions is given in terms of functional integrals. Some properties of the not explicit invariant measures are given like, for instance, estimates of moments, exponential convergence of the statistical solution for large time.

Stochastic forces can enter in the Navier–Stokes equations in different ways. We can consider randomness in the forcing term, so that the force $f$ in [18] has a deterministic component which represents its mean varying slowly and a stochastic one, which accounts small fluctuations around the mean and varying very rapidly. Alternatively, since the molecules are not rigidly connected to one another in the fluid, they are subjected to fluctuations. A complete description of fluctuations relating the microscopic and macroscopic motion is not achieved at present. However, we shall introduce some models for which rigorous mathematical results can be proved.

The first part of this section concerns the Navier–Stokes equations with noise $n$:

$$\begin{aligned} &\frac{\partial u}{\partial t}-\nu\Delta u+(u\cdot\nabla)u+\nabla p=n\\ &\nabla\cdot u=0 \end{aligned} \qquad [19]$$

for which invariant measures exist, one of which can be ergodic provided that the noise is suitably chosen. In the second part, a Navier–Stokes-type stochastic system is described, which has irregular solutions, as expected in turbulence.

Let us introduce the stochastic Navier–Stokes equations with time white noise. The first equation in [19] is an Itô equation:

$$\partial_t u+[-\nu\Delta u+(u\cdot\nabla)u+\nabla p]=\partial_t w \qquad [20]$$

Here $w=w_{(1)},\ldots,w_{(d)}$ is a Brownian motion, that is, its time derivative $n=\partial w/\partial t$ is a Gaussian

stochastic field with zero mean and correlation function given by

$$\mathbb{E}[n_{(j)}(t,x)n_{(k)}(t',x')] = \delta_{jk}q(x-x')\delta(t-t') \qquad [21]$$

for $j,k=1,\ldots,d$.

We shall use the differential form for the Itô equation [20] always understood in the integral form

$$u(t)-u(0)+\int_0^t[-\nu\Delta u(s)+(u(s)\cdot\nabla)u(s) + \nabla p(s)]\mathrm{d}s = w(t) \qquad [22]$$

Modeling perturbations by a white noise process represents the first step to understand how a random perturbation acts in the mathematical equations, rather than a good physical or numerical model. The first results are in a paper by Bensoussan and Temam (1973).

Obviously, the regularity of the solutions depends on the spatial covariance $q$ of the noise.

Let us consider the following cases.

- $q=\delta$: the noise is white also in space.

An invariant measure is known explicitly. Indeed, assume periodic boundary conditions on the square ($d=2$) or the cube ($d=3$) $D$, which makes the spatial domain a torus. In this case, the Euler and Navier–Stokes equations are set in the same functional spaces. The generator of the stochastic Navier–Stokes equations [20] corresponds to the sum of the generator of the Euler equations [9] and of the stochastic Stokes equations

$$\begin{aligned}\partial_t u &= [\nu\Delta u - \nabla p] + \partial_t w \\ \nabla\cdot u &= 0\end{aligned} \qquad [23]$$

Since the first equation in [23] is linear in the unknown velocity $u$, the Stokes system has a unique invariant measure which is a centered Gaussian measure. In particular, when the noise is a space-time white noise and $d=2$, this is the invariant measure [14] of the enstrophy:

$$\mu_S^{(0),(2\nu)}(\mathrm{d}u) = \frac{1}{Z}\mathrm{e}^{-2\nu S(u)}\mathrm{d}u$$

On a bidimensional torus, it is proved that this measure is not only infinitesimally invariant, but also globally invariant for a unique flow [20] defined for $\mu_S^{(0),(2\nu)}$-a.e. initial velocity. We recall that initial velocities of finite energy are negligible with respect to the measure $\mu_S^{(0),(2\nu)}$.

- $q$ more regular than above, that is, the noise is colored in space.

As soon as the forcing term is more regular in space, the Navier–Stokes system has a solution of finite energy. These are solutions close to those of the deterministic equation. Techniques similar to those used to prove the existence and/or uniqueness of solutions for the deterministic equations work also in the stochastic case with an additive noise (or even a multiplicative noise) to get weak or strong solutions. Global existence in the space $H^0$ is proved for $d=2,3$ and uniqueness only for $d=2$, as is the case for the deterministic Navier–Stokes equations.

The interesting feature is that by adding a noise which acts on all the components with respect to a Hilbert basis (or at least on many components), the stochastic Navier–Stokes system has a unique invariant measure, which is ergodic. This is proved for the spatial dimension $d=2$. By means of the Krylov–Bogoliubov's method, existence of at least an invariant measure is proved by compactness of a family of averaged measures; the limit measures are stationary measures. But, when many modes are perturbed by a noise, there is a mixing effect on the dynamics, avoiding existence of many stationary measures. For the spatial dimension $d=2$, the best result in this context is in Hairer and Mattingly (2004), where the noise acts on very few modes. For the spatial dimension $d=3$, the result in Da Prato and Debussche (2003) shows the existence of an invariant measure; even if there is no uniqueness of the solutions (as in the deterministic case), by a selection principle, they construct a transition semigroup, which has a unique invariant measure, ergodic and strongly mixing.

Mathematical proofs are given for very different noises. (The reader is urged to consult, among the others, the papers by E, Mattingly and Sinai; Flandoli and Maslowski; Mikulevicius and Rozovskii; Vishik and Fursikov. The latter authors study also statistical solutions in two and three dimensions. For a kick noise $n=\sum_k\delta(t-k)q_k(x)$ in equations [19], there are results for $d=2$ by Bricmont, Kupiainen and Lefevere; Kuksin and Shirikyan.)

We conclude that, as far as invariant measures and their ergodicity are concerned, the stochastic Navier–Stokes equations have richer results than the deterministic Navier–Stokes equations. It is appealing to investigate the limit as the intensity of the noise goes to zero, so as to recover the deterministic equation. Now, think of equation [19] with a noise $\varepsilon n$, for $n$ fixed and $\varepsilon\to 0$. Due to the sensitive dependence on initial conditions, even a small noise may have important effects on the dynamics. A conjecture by Kolmogorov is that the unique invariant measure $\mu_\varepsilon$ tends, when $\varepsilon\to 0$, to a specific measure, the so-called Kolmogorov measure, which

would enter into the ergodic principle. This is a difficult problem, not yet solved.

We also mention the analysis of the inviscid limit. Kuksin (2004) showed that the solution $u_\nu$ of the two-dimensional stochastic Navier–Stokes equations

$$\frac{\partial u}{\partial t} - \nu\Delta u + (u \cdot \nabla)u + \nabla p = \sqrt{\nu}n, \quad 0 < \nu \leq 1 \quad [24]$$

on the torus converges in distribution to a stationary solution of the Euler equations. Here $n$ is a random force white in time and smooth in space. More precisely, for each subsequence $u_{\nu_j}$,

$$\lim_{\nu_j \to 0} \lim_{T \to \infty} u_{\nu_j}(T + t) = U(t) \quad [25]$$

and almost every trajectory of the nontrivial limit process $U$ solves the Euler equations [9] without the forcing term. Moreover, the process $U$ keeps memory of some features of the noise force $n$, since the mean values of the enstrophy and of the energy of $U$ depend on the noise $n$.

We now present the second part on stochastic models for viscous fluids. In his 1884 paper, Reynolds introduced the decomposition of turbulent flow into mean and fluctuating flows. The equations obtained are difficult to study. We shall show now a tractable model for a one-dimensional problem ($d = 1$) with a suitable model of fluctuations. Decompose the velocity field into the sum of a mean flow $\overline{u}$ and a fluctuation $\delta$

$$u = \overline{u} + \delta$$

The fluctuation is assumed to be highly irregular; it is reasonable to model it by a stochastic process. If we choose

$$\delta = b\frac{\mathrm{d}w}{\mathrm{d}t}$$

where $b$ is a given velocity field and $\mathrm{d}w/\mathrm{d}t$ is white noise, then the motion of the fluid is governed by a stochastic equation of Itô type. Indeed, the Navier–Stokes equations are balance equations of linear momentum:

$$\frac{Du}{Dt} = \nu\Delta u - \nabla p \quad [26]$$

where $Du/Dt$ is the material time derivative along the trajectory of a particle which is at time $t$ in position $x(t)$ moving with velocity $u$ (so $u(x(t)) = (\mathrm{d}x/\mathrm{d}t)(t)$):

$$\frac{Du}{Dt} = \frac{\mathrm{d}}{\mathrm{d}t}u(t, x(t)) = \frac{\partial u}{\partial t} + (u \cdot \nabla)u \quad [27]$$

According to the mathematical model for the fluctuation, we have

$$\mathrm{d}x(t) = \overline{u}(t, x(t))\mathrm{d}t + b(x(t))\mathrm{d}w(t) \quad [28]$$

Therefore, $D\overline{u}$ is computed by means of Itô's formula

$$D\overline{u}(t, x(t)) = \frac{\partial \overline{u}}{\partial t}\mathrm{d}t + \sum_{k=1}^{d} \frac{\partial \overline{u}}{\partial x_k}\mathrm{d}x_k(t) + \frac{1}{2}\sum_{k,s=1}^{d} \frac{\partial^2 \overline{u}}{\partial x_k \partial x_s} b_k b_s \mathrm{d}t \quad [29]$$

This leads to the stochastic Navier–Stokes-type equations (we neglect the overline symbol)

$$\begin{aligned} &\mathrm{d}_t u + [-\nu\Delta u + (u \cdot \nabla)u + \nabla p + \tfrac{1}{2}Qu]\,\mathrm{d}t \\ &\quad = -(b \cdot \nabla)u\,\mathrm{d}w(t) \quad [30] \\ &\nabla \cdot u = 0 \end{aligned}$$

where $Q$ is the second-order differential operator given by the last term in [29].

Rigorous mathematical results for the above equations have been proved for the one-dimensional case, that is, the Burgers equations on the line. Given an initial velocity of finite energy $u_0 \in H^0$, there exists a unique solution $u \in C([0, T]; H^0) \cap L^2(0, T; H^1)$ (P-a.s.). But it can be shown that for a more regular initial velocity there is no higher regularity of the solution of eqn [30], if $b \neq 0$. This means that these stochastic Burgers equations cannot have too regular nontrivial solutions, as expected in turbulent motion.

## Statistics of Vortices and Bidimensional Turbulence

Onsager (1949) proposed to investigate bidimensional turbulent flows, extending in a rigorous way to hydrodynamics the statistical mechanics approach of Boltzmann. If we are interested in flows of finite energy, the results of the section "The Euler equations" provide no answer to the problem. Another way to proceed is by approximating the Euler equations in a suitable way. Actually, in a two-dimensional turbulent flow, there appears a large-scale organization leading to coherent structures. These are hydrodynamical vortices, whose dynamics is governed by the Euler equations. Onsager suggested to approximate the continuous Euler equations by a great (but finite) number of point vortices. This leads to a finite-dimensional Hamiltonian system, to which the methods of statistical mechanics can be successfully applied. Of course, the crucial point is to pass to the limit, to

recover the continuous system. But there are many different ways to approximate a continuous vorticity by a cloud of point vortices and different approximations may lead to very different statistical equilibrium states.

We present here the approach presented in Lions (1997). To get an idea of a completely different approximation, see, for example, Robert (2003).

Let $D$ be a bounded open smooth simply connected subset of $\mathbb{R}^2$. Then there exists a function $\psi$ (the stream function) such that $u = \nabla^{\perp}\psi$ and $\psi|_{\partial D} = 0$. Given the velocity $u$, we recover the stream function by means of the vorticity $\omega = \operatorname{curl} u = -\Delta\psi$, so $\psi(x) = \int_D g(x,y)\omega(y)\,dy$ (here $g$ is the Green's function of the Laplacian $-\Delta$ and $x$, $y$ are points in $D$). The Euler equations can be written as

$$\frac{\partial\omega}{\partial t} + u \cdot \nabla\omega = 0 \qquad \omega = \operatorname{curl} u \quad [31]$$

Consider now a solution given by vorticity concentrated in a finite number $N$ of points:

$$\omega = \sum_{i=1}^{N} \lambda_i \delta_{x_i(t)} \quad [32]$$

Here the vortex intensities $\lambda_i$ are real values and $x_i(t)$ are distinct points in $D$ for $i = 1, \ldots, N$.

According to the Euler equations, these points evolve as follows (see also Marchioro and Pulvirenti (1994)):

$$\frac{d}{dt}x_j(t) = \nabla^{\perp}_{x_j} \sum_{l=1, l\neq j}^{N} \lambda_l\, g(x_j(t), x_l(t)) + \lambda_j \nabla^{\perp}_{x_j} \tilde{g}(x_j), \quad j = 1, \ldots, N \quad [33]$$

where $\tilde{g}$ is related to the Green's function $g$. This is a Hamiltonian system in $D^N$. Hereafter, we shall suppose that the vortex intensities are the same ($\lambda_i = \lambda\, \forall i$), so that the Hamiltonian is

$$\mathcal{H}(x_1, \ldots, x_N) = \frac{1}{2} \sum_{l,j=1, l\neq j}^{N} g(x_j, x_l) + \sum_{j=1}^{N} \tilde{g}(x_j) \quad [34]$$

By means of $\mathcal{H}$, we define the canonical Gibbs measure

$$\mu^N(dx_1\, dx_2 \cdots dx_N) = \frac{1}{Z(N)}\, e^{-\tilde{\beta}\lambda\mathcal{H}(x_1,\ldots,x_N)} dx_1\, dx_2 \cdots dx_N \quad [35]$$

where $Z(N)$ is the partition function. If $Z(N) < \infty$, then $\mu^N$ is a well-defined probability measure on $D^N$ and, by construction, it is an invariant measure for system [33]. We can prove that $Z(N)$ is finite for $\tilde{\beta}\lambda \in (-8\pi/N, 4\pi)$, so that it is natural to choose as a scaling $\tilde{\beta}\lambda N = \beta$. Hence,

$$\mu^N(dx_1\, dx_2 \cdots dx_N) = \frac{1}{Z(N)}\, e^{-(\beta/N)\mathcal{H}}\, dx_1\, dx_2 \cdots dx_N \quad [36]$$

is considered for $-8\pi < \beta \leq 0$, or $\beta > 0$ with $N > \beta/4\pi$.

Bearing in mind the Onsager approach to approximate the turbulent Euler motion by means of point vortices, we are interested in the limit as $N$ goes to $+\infty$, for $\beta$ fixed in $(-8\pi, +\infty)$. It turns out that, when the number of point vortices becomes very large, their statistical behavior corresponds to a very large number of independent particles moving in a mean force field that they create.

More precisely, consider $\lambda = 1/N, \tilde{\beta} = \beta$. The empirical measure

$$\frac{1}{N}\sum_{i=1}^{N} \delta_{x_i(t)}$$

describing the vorticity, weakly converges to a probability density $\rho$ and each correlation function

$$\rho_j^N(x_1, \cdots, x_j) = \int_D dx_{j+1} \cdots \int_D dx_N \frac{1}{Z(N)}\, e^{-(\beta/N)\mathcal{H}} \quad \text{for } j = 1, \ldots, N-1 \quad [37]$$

weakly converges to $\otimes_{i=1}^{j}\rho = \prod_{i=1}^{j} \rho(x_i)$.

The equation satisfied by $\rho$, also called the mean-field equation, is

$$\rho(x) = \frac{e^{-\beta U(x)}}{\int_D e^{-\beta U(y)}\, dy}, \quad \text{with } U(x) = \int_D g(x,y)\rho(y)\, dy \quad [38]$$

The relation between $U$ and $\rho$ can also be written as $-\Delta U = \rho$ in $D$, $U = 0$ on $\partial D$. We point out that $u = \nabla^{\perp} U$ is a stationary solution of the Euler equations. Indeed, $\omega = -\Delta U = \rho$ and $\rho$ is a function of $U$, let us say $\rho = F(U)$. This gives that $\nabla\omega = \nabla U F'(U)$ and thus the term $u \cdot \nabla\omega$ in the Euler equation [31] vanishes.

It can be proved that there exists a solution of the mean-field equation when $\beta \geq 0$ or when $\beta < 0$ and $D$ is simply connected. Uniqueness is known in some cases, for instance, when $D$ is a bounded open smooth simply connected domain and the velocity is assumed tangent to the boundary.

There are numerical evidences of this approximation approach (see references in Lions (1997) referring to the periodic case). They show that for

large time and large Reynolds number (viscosity $\nu$ close to 0), the vorticity of the solution of the Navier–Stokes equations appears in a simple and organized structure. This stays intact until the viscous dissipation damps it. The important observation is that the organized structure is described quite precisely by the solution of the mean-field equation for some specific $\beta$.

Actually, to say that a fluid is inviscid is an approximation (which may be justified in many contexts), since every fluid displays some kind of viscosity. But turbulence is a phenomenon occurring at very small viscosity. In this sense, the above result provides a description of stationary regime in an ideal fluid, which is a good approximation of some numerical simulations of real fluids. Besides this good agreement with numerical simulations, there is no proof on how to deduce the mean-field equation from the Euler equations (e.g., which parameter $\beta$ has to be chosen in eqn [38]?).

**Remark** The extension of this analysis to three-dimensional flows involves vortex filaments, instead of point vortices. There are attempts to describe interacting vortex filaments as proposed by Chorin. Idealizations of behavior of vortices are introduced to have a tractable mathematical model. The reader is referred to Lions (1997) for a description of nearly parallel vortex filaments and to Flandoli and Bessaih (2003) for more realistic filaments which fold.

# Stochastic Loewner Evolutions

**G F Lawler**, Cornell University, Ithaca, NY, USA

## Introduction

The stochastic Loewner evolution or Schramm–Loewner evolution (SLE) is a family of random curves that appear as scaling limits of curves or cluster boundaries of discrete statistical mechanical models in two dimensions at criticality. The stochastic Loewner evolution was introduced by Oded Schramm as a candidate for the limit of loop-erased random walk and the boundary of percolation clusters, and it is now believed that SLE curves appear in most planar critical systems whose scaling limit satisfies conformal invariance. The curves are defined by solving a Loewner differential equation with a random input.

## Definition

There are three major one-parameter families of SLE curves – chordal, radial, and whole-plane – which correspond to curves connecting two boundary points in a domain, a boundary point and an interior point in a domain, and two points in $\mathbb{C}$, respectively. The parameter is usually denoted $\kappa > 0$. The starting point for defining SLE is to write down the assumptions that one expects from a scaling limit, assuming that the limit is conformally invariant.

In the chordal case, we assume that there is a family of probability measures $\{\mu_D(z,w)\}$, indexed by simply connected proper domains $D \subset \mathbb{C}$ and distinct boundary points $z, w \in \partial D$, supported on continuous curves $\gamma:[0,t_\gamma] \to \bar{D}$ with $\gamma(0)=z$, $\gamma(t_\gamma)=w$, which satisfies the following:

- *Conformal invariance*. If $f: D \to D'$ is a conformal transformation, then the image of $\mu_D(z,w)$ under $f$ is the same as $\mu_{D'}(f(z), f(w))$, up to a time change.
- *Conformal Markov property for* $\mu_D(z,w)$. Suppose $\gamma[0,t]$ is known, and let $g_t$ be a conformal transformation of the slit domain $D \backslash \gamma[0,t]$ onto $D$ with $g_t(\gamma(t)) = z, g_t(w) = w$ (see Figure 1). Then the conditional distribution on $g_t \circ \gamma[t, t_\gamma]$, given $\gamma[0,t]$, is the same, up to a change of parametrization, as the original distribution. (Implicit in this is the assumption that $\gamma(t)$ is on the boundary of $D \backslash \gamma(0,t]$, which will be true, e.g., if $\gamma$ is non-self-intersecting and $\gamma(0,t_\gamma) \subset D$.)

Using the Riemann mapping theorem, one can see that such a family $\{\mu_D(z,w)\}$ is determined (up to reparametrization) by $\mu_{\mathbb{H}}(0,\infty)$, where $\mathbb{H} = \{x + iy : y > 0\}$ denotes the upper half-plane. Suppose $\gamma:[0,\infty) \to \mathbb{C}$ is a simple (i.e., no self-intersections) curve with $\gamma(0)=0$, $\gamma(0,\infty) \subset \mathbb{H}$, and $\sup_t \mathrm{Im}[\gamma(t)] = \infty$. Let $H_t = \mathbb{H} \backslash \gamma[0,t]$. There is a unique conformal transformation $g_t: H_t \to \mathbb{H}$ whose expansion at infinity is

$$g_t(z) = z + \frac{b(t)}{z} + O(|z|^{-2}), \quad z \to \infty$$

(see Figure 2). The coefficient $b(t)$, which is sometimes called the half-plane capacity of $\gamma[0,t]$ and denoted hcap$[\gamma[0,t]]$, is continuous, strictly increasing, and tending to $\infty$. In fact,

$$b(t) = \lim_{y \to \infty} y E[\mathrm{Im}[X_\tau] \mid X_0 = \mathrm{i}y]$$

where $X_s$ denotes a complex Brownian motion and $\tau = \tau_{\gamma[0,t]}$ is the first time $s$ such that $X_s \in \mathbb{R} \cup \gamma[0,t]$. By reparametrizing $\gamma, b(t) = 2t$. With this parametrization, the maps $g_t$ satisfy the Loewner differential equation

$$\dot{g}_t(z) = \frac{2}{g_t(z) - U_t}, \quad g_0(z) = z$$

where $U:[0,\infty) \to \mathbb{R}$ is a continuous function with $U_0 = 0$. In fact, $U_t = g_t(\gamma(t))$. Schramm observed that the measure $\mu_{\mathbb{H}}(0,\infty)$, at least if it were supported on simple curves and the curves were parametrized using half-plane capacity, would produce a random $U_t$. If the assumptions above on $\{\mu_D(z,w)\}$ are translated into assumptions on the "driving function" $U_t$, one shows readily that $U_t$ must be a driftless Brownian motion, that is, $U_t = \sqrt{\kappa} B_t$, for a standard one-dimensional Brownian motion $B_t$.

Chordal SLE$_\kappa$ (in $\mathbb{H}$ connecting 0 and $\infty$) is defined to be the random collection of conformal maps $g_t$ obtained by solving the initial-value problem

$$\dot{g}_t(z) = \frac{2}{g_t(z) - \sqrt{\kappa} B_t}, \quad g_0(z) = z \qquad [1]$$

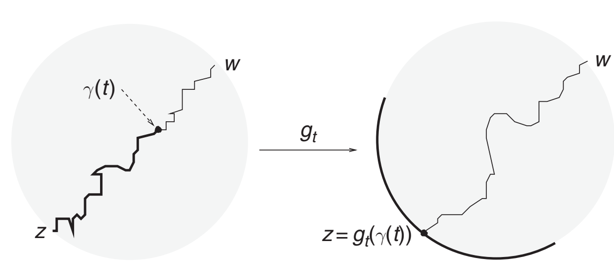

**Figure 1** The map $g_t$ from $D \backslash \gamma[0,t]$ onto $D$.

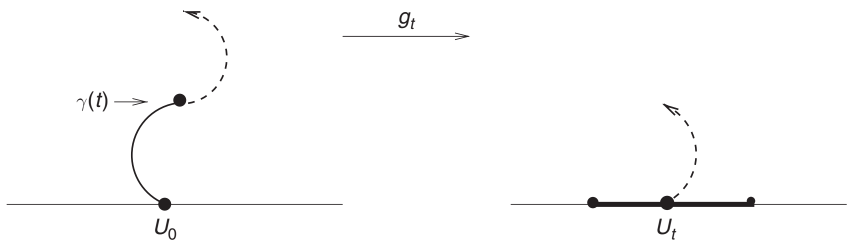

**Figure 2** The map $g_t$ from $\mathbb{H}\backslash\gamma[0,t]$ onto $\mathbb{H}$.

where $B_t$ is a standard one-dimensional Brownian motion. Equation [1] is often given in terms of the inverse $f_t = g_t^{-1}$:

$$\dot{f}_t(z) = -f_t'(z)\frac{2}{z - \sqrt{\kappa}\,B_t}$$

This equation describes a random evolution of conformal maps $f_t$ from $\mathbb{H}$ into subdomains of $\mathbb{H}$. For each $z \in \bar{\mathbb{H}}$, the solution of [1] is defined up to a time $T_z \in [0, \infty]$ with $T_z > 0$ for $z \neq 0$. For fixed $t, g_t$ is the unique conformal transformation of $H_t := \{z \in \mathbb{H} : T_z > t\}$ onto $\mathbb{H}$ with expansion

$$g_t(z) = z + \frac{2t}{z} + \cdots, \quad z \to \infty$$

The chordal $\mathrm{SLE}_\kappa$ path is the random curve $\gamma : [0, \infty) \to \mathbb{H}$ such that for each $t, H_t$ is the unbounded component of $\mathbb{H}\backslash\gamma[0, t]$. It is not immediate from the definition that such a curve $\gamma$ exists, but its existence has been proved. If $G_t = g_{t/\kappa}$, then we can write eqn [1] as

$$\dot{G}_t(z) = \frac{a}{G_t(z) + W_t} \qquad [2]$$

where $a = 2/\kappa$ and $W_t := -\sqrt{\kappa}B_{t/\kappa}$ is a standard Brownian motion. Then $Z_t^z := G_t(z) + W_t$ satisfies the Bessel stochastic differential equation

$$\mathrm{d}Z_t^z = \frac{a}{Z_t^z}\,\mathrm{d}t + \mathrm{d}W_t, \quad Z_0^z = z \qquad [3]$$

This equation is valid up to time $\kappa T_z$, which is the first time that $Z_t^z = 0$.

Although chordal $\mathrm{SLE}_\kappa$ is defined with a particular parametrization, one generally thinks of it as a measure on curves modulo reparametrization. The scaling properties of Brownian motion imply that this measure is invariant under dilations of $\mathbb{H}$. If $D$ is a simply connected domain and $z$, $w$ are distinct boundary points of $D$, chordal $\mathrm{SLE}_\kappa$ in $D$ connecting $z$ and $w$ is defined to be the conformal image of $\mathrm{SLE}_\kappa$ in $\mathbb{H}$ from 0 to $\infty$ under a conformal transformation of $\mathbb{H}$ onto $D$ taking 0 to $z$ and $\infty$ to $w$. There is a one-parameter family of such transformations, but the scale invariance of $\mathrm{SLE}_\kappa$ in $\mathbb{H}$ shows that the image measure is independent of the choice of transformation.

The geometric and fractal properties of the curve $\gamma$ vary greatly as the parameter $\kappa$ changes:

- if $\kappa \leq 4$, $\gamma$ is a simple curve;
- if $4 < \kappa < 8$, $\gamma$ has self-intersections, but is not space filling; and
- if $\kappa \geq 8$, $\gamma$ is a space filling curve.

To see this, one notes that the conformal Markov property implies that there can be double points with positive probability if and only if $T_x < \infty$ occurs with positive probability for $x > 0$. In addition, the curve is space filling if and only if $T_z < \infty$ for all $z$ and $T_w \neq T_z$ for $w \neq z$. The problem is then reduced to a problem about the Bessel equation [3] for which the following holds:

- if $a \geq 1/2$ and $z \neq 0$, the probability that $T_z < \infty$ is zero. If $a < 1/2$, this probability equals 1.
- if $1/4 < a < 1/2$, and $w, z$ are distinct points in $\mathbb{H}$, then there is a positive probability that $T_w = T_z$.
- if $0 < a \leq 1/4$, then with probability 1, $T_w \neq T_z$ for all $w \neq z$.

This kind of argument is typical when studying SLE – geometric properties of the curve are established by analyzing a stochastic differential equation. The Hausdorff dimension of the path $\gamma$ is given by

$$\dim[\gamma[0, \infty)] = \min\left\{1 + \frac{\kappa}{8}, 2\right\}$$

The radial Loewner equation describes the evolution of a curve from the boundary of the unit disk $\mathbb{D} = \{z : |z| < 1\}$ to the origin. Suppose $\gamma : [0, \infty) \to \bar{\mathbb{D}}$ is a simple curve with $\gamma(0) = 1$, $\gamma(0, \infty) \subset \mathbb{D}\backslash\{0\}$, and $\gamma(t) \to 0$ as $t \to \infty$. Let $g_t$ be the unique conformal transformation of $\mathbb{D}\backslash\gamma[0, t]$ onto $\mathbb{D}$ such that $g_t(0) = 0, g_t'(0) > 0$. One can check that $g_t'(0)$ is continuous and strictly increasing in $t$, and hence we can parametrize $\gamma$ in such a way that $g_t'(0) = \mathrm{e}^t$. Using this reparametrization, there is a continuous

$U_t : [0, \infty) \to \mathbb{R}$ with $U_0 = 0$ such that $g_t$ satisfies the radial Loewner equation

$$\dot{g}_t(z) = g_t(z)\frac{e^{iU_t} + g_t(z)}{e^{iU_t} - g_t(z)}, \quad g_0(z) = z$$

If $z \neq 0$, then we can define $h_t(z) = -i \log g_t(z)$ locally near $z$, and this equation becomes

$$\dot{h}_t(z) = \cot\left(\frac{h_t(z) - U_t}{2}\right)$$

Radial $SLE_\kappa$ (connecting 1 and 0 in $\mathbb{D}$) is obtained by setting $U_t = \sqrt{\kappa}B_t$. If $D$ is a simply connected domain, $z \in D, w \in \partial D$, then radial $SLE_\kappa$ in $D$ connecting $w$ and $z$ is obtained by conformal transformation using the unique transformation $f$ of $\mathbb{D}$ onto $D$ with $f(0) = z, f(1) = w$. Again, we think of this as being defined modulo time change. If $a = 2/\kappa$ and $v_t = h_{at/2}$, then

$$\dot{v}_t(z) = \frac{a}{2}\cot\left(\frac{v_t(z) + W_t}{2}\right) \qquad [4]$$

where $W_t := -\sqrt{\kappa}B_{t/\kappa}$ is a standard Brownian motion. If $L_t^z = v_t(z) + W_t$, then we get

$$dL_t^z = \frac{a}{2}\cot\left(\frac{L_t^z}{2}\right)dt + dW_t$$

Radial and chordal SLE are closely related. In fact, if $\gamma$ is a chordal SLE path in $\mathbb{H}$ from 0 to $\infty$, $\tilde{\gamma}$ is a radial SLE path in $\mathbb{D}$ from 1 to 0, and $\eta = -i \log \tilde{\gamma}$, then for small $t$ the distribution of $\eta$ is absolutely continuous to the distribution of a (random time change of) $\gamma$. Showing this involves understanding the behavior of the Loewner equation under conformal transformations. Suppose $\gamma, \tilde{\gamma}$ have been parametrized as in [2] and [4] with $a = 2/\kappa$. Let $g_t^*$ be the conformal transformation of $\mathbb{H} \setminus \eta[0, t]$ onto $\mathbb{H}$ such that

$$g_t^*(z) = z + \frac{a^*(t)}{z} + \cdots, \quad z \to \infty$$

and let $U_t^*$ be the Loewner driving function such that

$$\dot{g}_t^*(z) = \frac{\dot{a}^*(t)}{g_t^*(z) - U_t^*}$$

Here $a^*(t) = \mathrm{hcap}[\eta[0, t]]$. If we consider a time change $\sigma$ such that $a^*(\sigma(t)) = at$ and let $U_t = \tilde{U}_{\sigma(t)}$ be the time-changed driving function, Itô's formula can be used to show that

$$dU_t = \tfrac{1}{2}(1 - 3a)F_t\,dt + d\tilde{W}_t \qquad [5]$$

where the $F_t$ in the drift term depends on $\gamma[0, t]$ and is independent of $a$, and $\tilde{W}$ is a standard Brownian motion. Girsanov's theorem implies that Brownian motions with the same variance but different drifts have absolutely continuous distributions. In particular, qualitative properties such as existence of double points or Hausdorff dimension of paths are the same for radial and chordal SLE. $U_t$ is a driftless Brownian motion if $a = 1/3$, $\kappa = 6$.

Whole-plane $SLE_\kappa$ from 0 to $\infty$ is a path $\gamma : (-\infty, \infty) \to \mathbb{C}$ with $\gamma(-\infty) = 0$, $\gamma(\infty) = \infty$, such that given $\gamma(-\infty, t]$, the distribution of $\gamma(t, \infty)$ is that of radial $SLE_\kappa$ from boundary point $\gamma(t)$ to interior point $\infty$ in the domain $\mathbb{C} \setminus \gamma[-\infty, t]$. One can define whole-plane $SLE_\kappa$ connecting two distinct points in $\mathbb{C}$ by conformal transformation.

## Locality and Restriction

There are two special values of $\kappa : \kappa = 6, a = 1/3$ that satisfies the "locality" property and $\kappa = 8/3$, $a = 3/4$ that satisfies the "restriction" property. Suppose $\gamma$ is a chordal $SLE_\kappa$ curve from 0 to $\infty$ in $\mathbb{H}$ parametrized as in [2]. Suppose $\Phi : \mathcal{N} \to H$ is a conformal map taking a neighborhood $\mathcal{N}$ of 0 in $\mathbb{H}$ to $\Phi(\mathcal{N})$ and that locally maps $\mathbb{R}$ into $\mathbb{R}$. Let $\tilde{\gamma}(t) = \Phi \circ \gamma(t)$, which is defined for sufficiently small $t$. Let $g_t^*$ be the conformal transformation of $\mathbb{H} \setminus \tilde{\gamma}[0, t]$ onto $\mathbb{H}$ with

$$g_t^*(z) = z + \frac{a^*(t)}{z} + \cdots$$

and let $\tilde{U}_t$ be the driving function such that

$$\dot{g}_t^*(z) = \frac{\dot{a}^*(t)}{g_t^*(z) - \tilde{U}_t}$$

Here $a^*(t) = \mathrm{hcap}[\tilde{\gamma}[0, t]]$. If we change time, $\gamma_t^* = \tilde{\gamma}_{\sigma(t)}$, so that $a^*(\sigma(t)) = at$, then an application of Itô's formula shows that $U_t^* := \tilde{U}_{\sigma(t)}$ satisfies

$$dU_t^* = \frac{1}{2}(3a - 1)\frac{\Phi''_{\sigma(t)}(W_{\sigma(t)})}{\Phi'_{\sigma(t)}(W_{\sigma(t)})^2}dt + d\tilde{W}_t$$

Here $\tilde{W}_t$ is a standard Brownian motion, $\Phi_t = g_t^* \circ \Phi \circ g_t^{-1}$, and $g_t$ is the conformal map associated to $\gamma$. In particular, if $a = 1/3$, $\kappa = 6$, $U_t^*$ is a standard Brownian motion; hence, $\tilde{\gamma}^*$ has the distribution of $SLE_6$. The locality property for $SLE_6$ can be stated as "the conformal image of $SLE_6$ is (a time change of) $SLE_6$." Intuitively, the $SLE_6$ path in a restricted domain does not feel the boundary of the domain until it reaches it. Radial $SLE_6$ satisfies a similar locality property. Moreover, [5] can be used to show that the image of chordal $SLE_6$ under the exponential map is the same (for small time $t$) as radial $SLE_6$. The locality property explains why

$SLE_6$ is a natural candidate for the boundary of percolation clusters.

If $\kappa \leq 4, SLE_\kappa$ paths are simple, that is, with no self-intersections. Suppose $A \subset \bar{\mathbb{H}} \backslash \{0\}$ is a compact set such that $\mathbb{H} \backslash A$ is simply connected. Let $\gamma$ denote a chordal $SLE_\kappa$ in $\mathbb{H}$ connecting 0 and $\infty$ and let $E_A$ be the event $E_A = \{\gamma(0, \infty) \cap A = \emptyset\}$. Let $\Phi_A : \mathbb{H} \backslash A \to \mathbb{H}$ be the unique conformal transformation with $\Phi_A(0) = 0$, $\Phi_A(\infty) = \infty$, $\Phi'_A(\infty) = 1$. On the event $E_A$, we can define $\tilde{\gamma}(t) = \Phi_A \circ \gamma(t)$. Chordal $SLE_\kappa$ is said to satisfy the restriction property if the conditional distribution of $\tilde{\gamma}$ given $E_A$ is the same as (a time change of) $\gamma$. The only $\kappa \leq 4$ that satisfies this property is $\kappa = 8/3$. The proof of this fact also establishes the formula: if $\gamma$ is a chordal $SLE_{8/3}$ curve in $\mathbb{H}$ from 0 to $\infty$, then

$$\boldsymbol{P}\{\gamma(0,\infty) \cap A = \emptyset\} = \Phi'_A(0)^{5/8} \qquad [6]$$

There is a similar formula for radial $SLE_{8/3}$, which establishes a radial restriction property. Suppose $A \subset \bar{\mathbb{D}} \backslash \{0, 1\}$ is a compact set such that $\mathbb{D} \backslash A$ is simply connected. Let $\Psi_A$ be the unique conformal transformation of $\mathbb{D} \backslash A$ onto $\mathbb{D}$ with $\Psi_A(0)$, $\Psi'_A(0) > 0$. Then, if $\gamma$ is a radial $SLE_{8/3}$ curve from 1 to 0 in $\mathbb{D}$, then

$$\boldsymbol{P}\{\gamma(0,\infty) \cap A = \emptyset\} = \Psi'_A(0)^{5/48} |\Psi'_A(1)|^{5/8}$$

The restriction property makes $SLE_{8/3}$ the candidate for the scaling limit of self-avoiding walks.

## Relation to Conformal Field Theory

The Schramm–Loewner evolution is one of the tools used to rigorously prove predictions made using powerful, yet nonrigorous, arguments of conformal field theory. In conformal field theory, there is a parameter $c$, called the central charge, which classifies theories. To each $c \leq 1$, there corresponds a $\kappa \leq 4$ and a "dual" $\kappa' = 16/\kappa \geq 4$:

$$c = c_\kappa = \frac{(8 - 3\kappa)(\kappa - 6)}{2\kappa}$$

In particular, $\kappa = 8/3$, $\kappa' = 6$ corresponds to central charge zero. It is expected, and has been proved in a number of cases, that $SLE_\kappa$ or $SLE_{\kappa'}$ curves will appear in scaling limits of systems with central charge $c_\kappa$. These systems can also be parametrized by the boundary scaling exponent or conformal weight

$$\alpha = \alpha_\kappa = \frac{6 - \kappa}{2\kappa}$$

For $\kappa = 8/3$, $\alpha = 5/8$ which is the exponent in [6].

In studying the relationship between SLE and conformal field theories, two other probabilistic objects, restriction measures and the (Brownian) loop soup, arise. An $\mathbb{H}$-hull (connecting 0 and $\infty$) is an unbounded, connected, closed set $K \subset \bar{\mathbb{H}}$ with $K \cap \mathbb{R} = \{0\}$ and such that $\mathbb{H} \backslash K$ consists of two connected components, one whose boundary includes the positive reals and the other whose boundary includes the negative reals. A (chordal) restriction measure on hulls $K$ is a probability measure with the property that for any $A$ as in [6], the distribution of $\Phi_A \circ K$ given $\{K \cap A = \emptyset\}$ is the same as the original measure. The (Brownian) loop measure is a measure on unrooted loops derived from Brownian bridges. It is the scaling limit of the measure on random walk loops that gives each unrooted simple random walk loop of length $2n$ measure $4^{-2n}$. The loop measure in a bounded domain is obtained by restricting to loops that stay in that domain. We can consider this as a measure on "hulls" by filling in the bounded holes (so that the complement of the hull is connected). By doing this we get a family of infinite measures on hulls, indexed by domains $D$, and this family satisfies conformal invariance and the restriction property. The loop soup with parameter $\lambda$ is a Poissonian realization from this measure with parameter $\lambda$.

The set of all restriction measures is parametrized by $\alpha \geq 5/8$; the $\alpha$-restriction measure has the property that

$$\boldsymbol{P}\{K \cap A \neq \emptyset\} = \Phi'_A(0)^\alpha$$

For $\alpha = 5/8$, $K$ is given by the path of $SLE_{8/3}$. For integer $\alpha$, the hull $K$ can be constructed by taking $\alpha$-independent Brownian excursions in $\mathbb{H}$ (Brownian motions starting at 0 conditioned to stay in $\mathbb{H}$ for all times), and letting $K$ be the hull obtained by taking the union of the paths and filling in the bounded holes. If $\kappa \leq 8/3, c_\kappa \leq 0$, then the restriction measure with exponent $\alpha_\kappa \geq 5/8$ can also be constructed as follows: take a chordal $SLE_\kappa$ path and an independent realization of the loop soup with intensity $\lambda_\kappa = -c_\kappa$; add to the SLE path all the loops in the soup that intersect the $SLE_\kappa$ curve; and then fill in all the bounded hulls. The limiting case $\alpha = 5/8$, $\lambda = 0$ gives the only measure supported on simple curves that is also a restriction measure, $SLE_{8/3}$.

For $8/3 < \kappa \leq 4, 0 < c_\kappa \leq 1$, it is conjectured, and proved for small $c_\kappa$, that $SLE_\kappa$ curves can be found by taking a loop soup with parameter $\lambda = c_\kappa$ and looking at connected curves in the fractal set given by the complement of the union of all the hulls generated by the loops.

## Examples

The scaling limit of simple random walk, Brownian motion, is known to be conformally invariant. A two-dimensional Brownian bridge or loop is a Brownian motion, $B_t, 0 \leq t \leq 1$, conditioned so that $B_0 = B_1$. The frontier or outer boundary of the Brownian motion is the boundary of the unbounded component of the complement. Benoit Mandelbrot first observed numerically that the outer boundary of Brownian motion had fractal dimension $\sim 4/3$. Gregory Lawler, Oded Schramm, and Wendelin Werner used SLE to prove that the boundary has Hausdorff dimension 4/3. In fact, the outer boundary can be considered as an $SLE_{8/3}$ loop.

$SLE_6$ and $SLE_{8/3}$ arise in the scaling limit of critical percolation on the triangular lattice. Suppose that each vertex in the upper half-plane triangular lattice is colored black or white each with a probability 1/2. Suppose the real line gives a boundary condition of black on the negative real line and white on the positive real line. Then if we represent the vertices in the lattice as hexagons as in the figure, a curve is formed which is the boundary between the black and white clusters. This curve is called the "percolation exploration process." Stanislav Smirnov proved that the scaling limit of this curve is conformally invariant, and from this it can be concluded that the curve is chordal $SLE_6$. In particular, the Hausdorff dimension is 7/4 and the scaling limit has double points. In the scaling limit, the "outer boundary" of this curve has Hausdorff dimension 4/3 and its dimension is absolutely continuous with respect to that of $SLE_{8/3}$. While this result is expected for other critical percolation model, such as bond percolation in $\mathbb{Z}^2$ with critical probability 1/2, it has only been proved for the triangular lattice. Percolation has central charge 0 and the "locality" property can be seen in the lattice model. The outer boundary of the curve has the same distribution as the outer boundary of a Brownian motion that is reflected at angle $\pi/3$ off the real line. Locally, the outer boundary of percolation, the outer boundary of complex Brownian motion, and $SLE_{8/3}$ all look the same, and it is expected that this will also be true for the scaling limit of self-avoiding walks.

There are three models derived in some way from simple random walk that have been proved to have scaling limits of $SLE_\kappa$. The loop-erased random walk (LERW) in a finite subset $V$ of $\mathbb{Z}^2$ connecting two distinct points is obtained by taking a simple random walk from one point to the other and erasing loops chronologically. The LERW is closely related to uniform spanning trees; in fact, if one chooses a spanning tree of $V$ from the uniform distribution on all spanning trees, then the distribution of the unique path connecting the two points is exactly that of the LERW (see Figure 3). Another description of the LERW is as the Laplacian random walk: the LERW from $z$ to $w$ in $V$ chooses a new step weighted by the value of the function that is harmonic on the complement of $w$ and the path up to that point with boundary values 0 on the path and 1 on $w$. The LERW in the discrete upper half-plane can be obtained by erasing loops from a simple random walk excursion. The LERW and the uniform spanning tree are systems with central charge $c = -2$. It has been proved that the scaling limit of the LERW is $SLE_2$; hence, the paths have Hausdorff dimension 5/8.

There is another path associated to spanning trees given by the one-to-one correspondence between spanning trees and Hamiltonian walks on a corresponding directed (Manhattan) lattice on the dual graph (see Figure 4). If the spanning trees, or equivalently the Hamiltonian walks, are chosen using the uniform distribution, then the scaling limit of this walk is the space-filling curve $SLE_8$. Note that 2 and 8 are the dual values of $\kappa$ associated to $c = -2$.

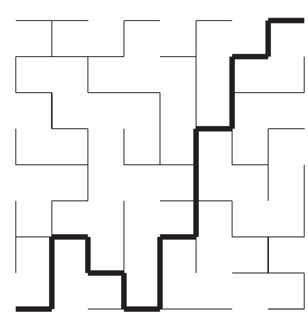

**Figure 3** A spanning tree and the path between two vertices. If the tree has the uniform distribution, the path has the distribution of the LERW.

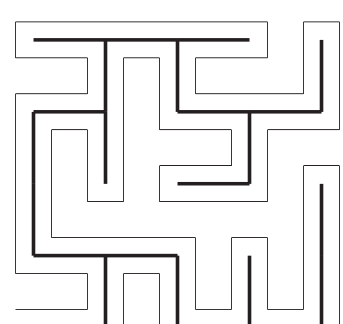

**Figure 4** A spanning tree and the corresponding Hamiltonian walk.

Another discrete process derived from simple random walk, the harmonic explorer, has a scaling limit of $SLE_4$. There is a particular property of $SLE_\kappa$ that leads to the definition of this discrete process. Consider a chordal $SLE_\kappa$ curve, let $z \in \mathbb{H}$, and let $Z_t^z$ be as in [3] with $a = 2/\kappa$. Itô's formula shows that $\Theta_t := \arg(Z_t^z)$ satisfies

$$d\Theta_t = \left(\frac{1}{2} - a\right) \frac{\sin(2\Theta_t)}{|Z_t^z|^2}\, dt - \frac{\sin\Theta_t}{|Z_t^z|}\, dW_t$$

In particular, $\Theta_t$ is a martingale if and only if $a = 1/2$, $\kappa = 4$. The probability that a complex Brownian motion starting at $z \in \mathbb{H}$ first hits $\mathbb{R}$ on the negative half-line can be shown to be $\arg(z)$. If $\kappa \le 4$, then we can see that $\Theta_\infty$ equals 0 or $\pi$, depending on whether $z$ is on the right or left side of the path $\gamma(0, \infty)$. For the martingale case $\kappa = 4$, $\Theta_t$ represents the probability that $z$ is on the left side of $\gamma(0, \infty)$, given $\gamma(0, t]$. The harmonic explorer is a process on the hexagonal lattice defined to have this property. In a way similar to the percolation process, the walk is defined as the boundary between black and white hexagons on the triangular lattice. However, when an unexplored hexagon is reached in the harmonic explorer, it is colored black with probability $q$, where $q$ is the probability that a simple random walk on the triangular lattice starting at that hexagon (considered as a vertex in the triangular lattice) hits a black hexagon before hitting a white hexagon. It is not difficult to show that this process has the property that for $z$ away from the curve, the "probability of $z$ ending on the left given the curve of $n$ steps" is a martingale.

There are many other models for which $SLE_\kappa$ curves are expected in the limit, but it has not been established. The most difficult part is to show the existence of a limit that is conformally invariant. One example is the self-avoiding walk (SAW). It is an open problem to establish that there exists a scaling limit of the uniform measure on SAWs and to establish conformal invariance of the limit. However, the nature of the discrete model is such that if the limit exists, it must satisfy the restriction property. Hence, under the assumption of conformal invariance, the only possible limit is $SLE_{8/3}$. Numerical simulations strongly support the conjecture that $SLE_{8/3}$ is the limit of SAWs, and this gives strong evidence for the conformal invariance conjecture for SAWs. Critical exponents for SAWs (as well as critical exponents for many other models) can be predicted nonrigorously from rigorous scaling exponents for the corresponding SLE paths.

## Generalizations

One of the reasons that the theory of SLE is nice for simply connected domains is that a simply connected domain with an arc connected to the boundary of the domain removed is again simply connected. For nonsimply connected domains, it is more difficult to describe because the conformal type of the slit domain changes as time evolves. In the case of a curve crossing an annulus, this can be done with an added parameter referring to the conformal type of the annulus (two annuli of the form $\{z : r_j < |z| < s_j\}$ are conformally equivalent if and only if $r_1/s_1 = r_2/s_2$). It is not immediately obvious what the correct definition of SLE should be in general domains and, more generally, on Riemann surfaces. One possibility for $\kappa \le 4$ is to consider a configurational (equilibrium statistical mechanics) view of SLE. Consider a family of measures $\{\mu_D(z, w)\}$, where $D$ ranges over domains and $z$, $w$ are distinct boundary points at $\partial D$ is locally analytic, supported on simple curves from $z$ to $w$ (modulo time change). Let $\mu_D^\#(z, w) = \mu_D(z, w)/|\mu_D(z, w)|$ be the corresponding probability measures, which may be defined even if $\partial D$ is not smooth at $z, w$. Then the following axioms should hold:

- *Conformal invariance*. If $f : D \to D'$ is a conformal transformation, $f \circ \mu_D^\#(z, w) = \mu_{D'}^\#(f(z), f(w))$.
- *Conformal Markov property*.
- *Perturbation of domains*. Suppose $D_1 \subset D$ and $\partial D_1, \partial D$ agree near $z$, $w$. Then $\mu_{D_1}(z, w)$ should be absolutely continuous with respect to $\mu_D(z, w)$. Let $Y$ denote the Radon–Nikodym derivative of $\mu_{D_1}(z, w)$ with respect to $\mu_D(z, w)$. Then

$$Y(\gamma) = 1\{\gamma(0, t_\gamma) \subset D_1\}\ F_c(D; \gamma, D\backslash D_1)$$

where $F_c$ is to be determined. In the case where $D, D_1$ are simply connected, $F_c(D; \gamma, D\backslash D_1) = J(\gamma, D, D_1)^{-c}$, where $J(\gamma, D, D_1)$ denotes the probability that there is a loop in the Brownian loop soup in $D$ that intersects both $\gamma$ and $D\backslash D_1$. (There is no problem defining this quantity in nonsimply connected domains, but it is not clear that it is the right quantity.) Here $c = c_\kappa$. The restriction property tells us that $F_0 \equiv 1$.

- *Conformal covariance*. If $f$ is as above, $\partial D$, $\partial D'$ are smooth near $z, w$ and $f(z), f(w)$, respectively, then

$$f \circ \mu_D(z, w) = |f'(z)|^\alpha |f'(w)|^\alpha \mu_{D'}(f(z), f(w))$$

Here $\alpha = \alpha_\kappa$ is the boundary scaling exponent.

# Stochastic Resonance

**S Herrmann**, Université Henri Poincaré, Nancy 1 Vandoeuvre-lès-Nancy, France
**P Imkeller**, Humboldt Universität zu Berlin, Berlin, Germany

## Introduction

The concept of stochastic resonance was introduced by physicists. It originated in a toy model designed for a qualitative description of periodicity phenomena in the recurrences of glacial eras in Earth's history. It spread its popularity over numerous areas of natural sciences: neuronal response to periodic stimuli, variations of magnetization in a ferromagnetic system, voltage variations in the simple Schmitt trigger electronic circuit or in more complicated devices, behavior of lasers in optical bi-stability, etc. The interest in this ubiquitous phenomenon is enhanced by signal analysis: an optimal dose of noise in some system can essentially boost signal transduction. Noise in this context does not enter the system as an impurity perturbing its performance, but on the contrary as a catalyst triggering amplified stochastic response to weak periodic signals.

## The Climate Paradigm

The phenomenon of stochastic resonance was first discovered in an elementary climate model serving in an explanation of major transitions in paleoclimatic time series confining glacial cycles. Data collected for instance from ice or deep sea cores allow one to deduce estimates of the average temperature on Earth over the last 700 000 years. They exhibit periodic switching between ice and warm ages with fast spontaneous transitions. The average periodicity of the glaciation time series obtained is $\sim 10^5$ years. In order to explain temperature variations, Benzi *et al.* (1981) introduced random perturbations into an energy balance model of the Budyko–Sellers type. This model describes the evolution of the seasonal and global average temperature $X$ caused by defects in the balance between incoming and outgoing radiation

$$c\frac{\mathrm{d}X(t)}{\mathrm{d}t} = E_{\mathrm{in}} - E_{\mathrm{out}}$$

where $c$ is the active thermal inertia of the system. The incoming energy is modeled as proportional to the "solar constant" $Q$:

$$E_{\mathrm{in}} = Q\left(1 + A\cos\frac{2\pi t}{T}\right), \quad \text{with } T \approx 92\,000 \text{ years}$$

and $A \approx 0.1\%$ of $Q$. This exceedingly small variation of the solar constant is caused by a modulation of the orbital eccentricity of the Earth's trajectory (Figure 1). The outgoing radiation $E_{\mathrm{out}}$ is composed

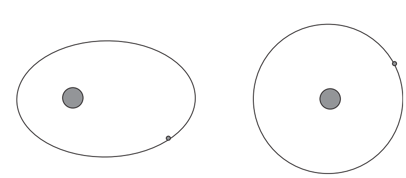

**Figure 1** Modulation of the orbital eccentricity.

of two essential parts. The first part $a(X)E_{\text{in}}$ is dominated by the albedo $a(X)$ representing the proportion of energy reflected back to space. It is a decreasing function of temperature, due to the higher rate of reflection from a brighter Earth at low temperatures implying a bigger volume of ice. The second part of the outgoing radiation comes from the fact that the Earth radiates energy like a black body, and is given by the Boltzmann law $\gamma X^4$, where $\gamma$ is the Stefan constant. Describing the balance of energy terms as a slowly and weakly time-varying gradient of a potential $U$, the balance model can be expressed by

$$\frac{\mathrm{d}X(t)}{\mathrm{d}t} = -\frac{\partial U}{\partial x}\left(\frac{t}{T}, X(t)\right)$$

where the time period 1 is blown up to (large) $T$ by time scaling. The roles of deep and shallow wells switch periodically (Figure 2). Since the variation of the solar constant is extremely small, we can assume that the height of the barrier between the two wells is lower-bounded by a positive constant. The system then admits three steady states two of which are stable and separated by roughly 10 K. As the solar constant, they fluctuate slowly and very weakly. Therefore, this deterministic system cannot account for climate changes with temperature variations of $\sim$10 K. They can only be explained by allowing transitions between the two steady states which become possible by adding noise to the system. In general, short timescale phenomena such as annual fluctuations in solar radiation are modeled by Gaussian white noise of intensity $\varepsilon$ and lead to equations of the type

$$\mathrm{d}X_t^\varepsilon = -\frac{\partial U}{\partial x}\left(\frac{t}{T}, X_t^\varepsilon\right)\mathrm{d}t + \sqrt{\varepsilon}\,\mathrm{d}W_t \qquad [1]$$

which are generic for studying stochastic resonance in numerous physical and biological models. Generally, the input of noise amplifies a weak periodic signal by creating trajectories fluctuating randomly periodically between meta-stable states. An optimal tuning of noise intensity to period length ("stochastic resonance") significantly enhances the response of the random system to weak perturbations with long periods.

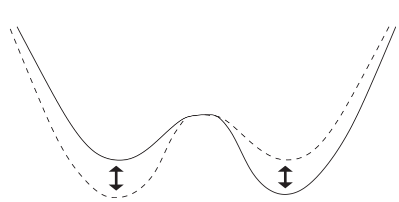

**Figure 2** Deep and shallow wells switching periodically.

## Strongly Damped Brownian Particle

It is useful to roughly compare solutions of stochastic differential equations and motions of Brownian particles in double-well landscapes (Figure 3) in order to understand properties of their trajectories (see Schweitzer 2003, Mazo 2002). As in the previous section, let us concentrate on a one-dimensional setting, remarking that we shall give a treatment that easily generalizes to the finite-dimensional setting. Due to Newton's law, the motion of a particle is governed by the impact of all forces acting on it. Let us denote $F$ the sum of these forces, $m$ the mass, $x$ the space coordinate, and $v$ the velocity of the particle. Then

$$m\dot{v} = F$$

Let us first assume the potential to be switched off. In their pioneering work at the turn of the twentieth century, Marian v. Smoluchowski and Paul Langevin introduced stochastic concepts to describe the Brownian particle motion by claiming that at time $t$

$$F(t) = -\gamma_0 v(t) + \sqrt{2k_{\mathrm{B}}T\gamma_0}\,\dot{W}_t$$

The first term results from friction $\gamma_0$ and is velocity dependent. An additional stochastic force represents random interactions between Brownian particles and their simple molecular random environment. The white noise $\dot{W}$ (formal derivative of the Wiener process) plays the crucial role. The diffusion coefficient (standard deviation of the random impact) is composed of Boltzmann's constant $k_{\mathrm{B}}$, friction, and environmental temperature $T$. It satisfies the condition of the fluctuation–dissipation theorem expressing the balance of energy loss due to friction and energy gain resulting from noise. The equation of motion becomes

$$\frac{\mathrm{d}x(t)}{\mathrm{d}t} = v(t)$$

$$\mathrm{d}v(t) = -\frac{\gamma_0}{m}v(t)\,\mathrm{d}t + \frac{\sqrt{2k_{\mathrm{B}}T\gamma_0}}{m}\,\mathrm{d}W_t$$

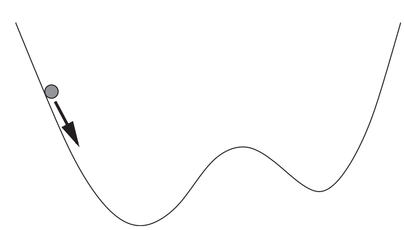

**Figure 3** Brownian particle in a double-well landscape.

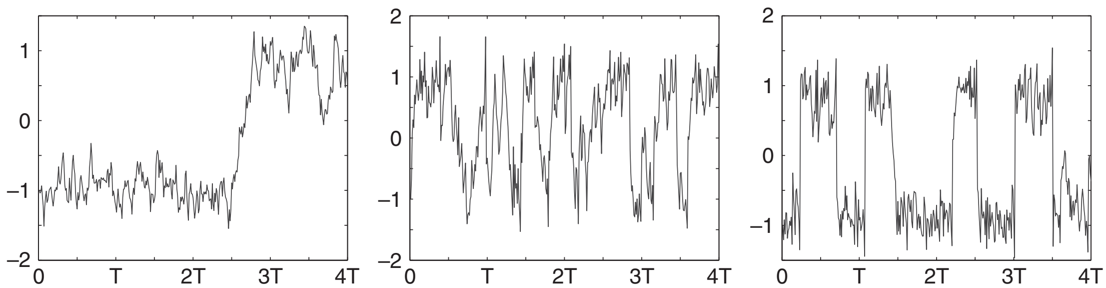

**Figure 4** Resonance pictures for diffusions.

In the stationary regime, the stationary Ornstein–Uhlenbeck process provides its solution

$$v(t) = v(0)\,\mathrm{e}^{-(\gamma_0/m)t} + \frac{\sqrt{2k_\mathrm{B}T\gamma_0}}{m}\int_0^t \mathrm{e}^{-(\gamma_0/m)(t-s)}\,\mathrm{d}W_s$$

The ratio $\beta := \gamma_0/m$ determines the dynamic behavior. Let us focus on the over-damped situation with large friction and very small mass. Then for $t >> 1/\beta = \tau$ (relaxation time), the first term in the expression for velocity can be neglected, while the stochastic integral represents a Gaussian process. By integrating, we obtain in the over-damped limit ($\beta \to \infty$) that $v$ and thus $x$ is Gaussian with almost constant mean

$$m(t) = x(0) + \frac{1-\mathrm{e}^{-\beta t}}{\beta}\,v(0) \approx x(0)$$

and covariance close to the covariance of white noise see Nelson (1967):

$$K(s,t) = \frac{2k_\mathrm{B}T}{\gamma_0}\min(s,t) + \frac{k_\mathrm{B}T}{\gamma_0\beta}(-2 + 2\mathrm{e}^{-\beta t} + 2\mathrm{e}^{-\beta s} - \mathrm{e}^{-\beta|t-s|} - \mathrm{e}^{-\beta(t+s)})$$
$$\approx \frac{2k_\mathrm{B}T}{\gamma_0}\min(s,t)$$

Hence, the time-dependent change of the velocity of the Brownian particle can be neglected, the velocity rapidly thermalizes ($\dot{v} \approx 0$), while the spactial coordinate remains far from equilibrium. In the so-called adiabatic transformation, the evolution of the particle's position is thus given by the transformed Langevin equation

$$\mathrm{d}x(t) = \frac{\sqrt{2k_\mathrm{B}T}}{\gamma_0}\,\mathrm{d}W_t$$

Let us next suppose that we have a Brownian particle in an external field of force (see Figure 3), generating a potential $U(t,x)$. This leads to the Langevin equation

$$\frac{\mathrm{d}x(t)}{\mathrm{d}t} = v(t)$$
$$m\,\mathrm{d}v(t) = -\gamma_0\,v(t)\mathrm{d}t - \frac{\partial U}{\partial x}(t,x(t)) + \sqrt{2k_\mathrm{B}T\gamma_0}\,\mathrm{d}W_t$$

In the over-damped limit, after relaxation time, the adiabatic elimination of the fast variables (Gardiner 2004) leads to an equation similar to the one encountered in the previous section:

$$\mathrm{d}x(t) = -\frac{1}{\gamma_0}\frac{\partial U}{\partial x}(t,x(t)) + \frac{\sqrt{2k_\mathrm{B}T}}{\gamma_0}\,\mathrm{d}W_t$$

In the particular case of some double-well potential $x \to U(t,x)$ with slow periodic variation, the following patterns of behavior of the solution trajectories will be experienced. If temperature is high, noise has a predominant influence on the motion, and the particle often crosses the barrier separating the two wells during one period. The behavior of the particle does not seem to be periodic but rather chaotic. If temperature is small, the particle stays for a very long time in the starting well, fluctuating weakly around the equilibrium position. It has too low energy to follow the periodic variation of the potential. So in this case too, the trajectories do not look periodic. Between these two extreme situations, there exists a regime of noise intensities for which the energy transmitted by the noise is sufficient to cross the barrier almost twice per period. The parameters are then near to the resonance point and the motion exhibits periodic switching (Figure 4).

## Transition Criteria and Quasideterministic Motion

Studying stochastic resonance accordingly means looking for the range of regimes for which periodic behavior is enhanced and eventually optimal. The optimal relation between period $T$ and noise

intensity $\varepsilon$ emerges in the small noise limit. To explain this, let us focus on the basic indicator for periodic transitions – the time the Brownian particle needs to exit from the starting well, say the left one. In the "frozen" case, that is, if the time variation of the potential term is eliminated just by freezing it at some time $s$, the asymptotics of the exit time is derived from the classical large deviation theory of randomly perturbed dynamical systems (see Freidlin and Wentzell 1998). Let us assume that $U$ is locally Lipschitz. We denote by $D_l$ (resp. $D_r$) the domain corresponding to the left (resp. right) well and $\chi$ their common boundary. The law of the first exit time $\tau^{\varepsilon}_{D_l} = \inf\{t \geq 0, X^{\varepsilon}_t \notin D_l\}$ is described by some particular functional related to large deviation. For $t > 0$, we introduce the "action functional" on the space of continuous functions $\mathcal{C}([0,t])$ on $[0,t]$ by

$$S^s_t(\varphi) = \begin{cases} \frac{1}{2}\int_0^t \left(\dot{\varphi}_u + \frac{\partial U}{\partial x}(s, \varphi_u)\right)^2 \mathrm{d}u, & \text{if } \varphi \text{ is abs. continuous} \\ +\infty & \text{otherwise} \end{cases}$$

which is non-negative and vanishes on the set of solutions of the ordinary differential equation $\dot{x} = -(\partial U/\partial x)(s,x)$. Let $x$ and $y \in \mathbb{R}$. In relation with the action functional, we define the quasipotential

$$V_s(x,y) = \inf\{S^s_t(\varphi) : \varphi \in \mathcal{C}([0,t]), \varphi_0 = x, \varphi_t = y, t \geq 0\}$$

It represents the minimal work the diffusion starting in $x$ has to do in order to reach $y$. To switch wells, the Brownian particle starting in the left well's bottom $x_l$ has to overcome the barrier. So we let

$$\overline{V}_s = \inf_{y \in \chi} V_s(x_l, y)$$

This minimal work needed to exit from the left well can be computed explicitly, and is seen to equal to twice its depth. The asymptotic behavior of the exit time is expressed by

$$\lim_{\varepsilon \to 0} \varepsilon \ln \mathbb{E}[\tau^{\varepsilon}_{D_l}] = \overline{V}_s$$

and

$$\lim_{\varepsilon \to 0} \mathbb{P}_x\left(\mathrm{e}^{(\overline{V}_s - \delta)/\varepsilon} < \tau^{\varepsilon}_{D_l} < \mathrm{e}^{(\overline{V}_s + \delta/\varepsilon)}\right) = 1 \quad \text{for any } \delta > 0$$

The prefactor for the exponential rate, derived by Freidlin and Wentzell (1998), was first given by Eyring and Kramers and then by Bovier *et al.* (2004).

Let us now assume that the left well is the deeper one at time $s$. If the Brownian particle has enough time to cross the barrier, that is, if $T > \mathrm{e}^{\overline{V}_s/\epsilon}$, then whatever the starting point is, Freidlin (2000) proved that it should stay near $x_l$ in the following sense:

$$\Lambda(t \in [0,1] : |X^{\varepsilon}_{tT} - x_l| > \delta) \to 0$$

in probability as $\varepsilon \to 0$. Here $\Lambda$ denotes Lebesgue measure on $\mathbb{R}$. If $T < \mathrm{e}^{\overline{V}_s/\epsilon}$, the time left is not long enough for crossings: the particle stays in the starting well, near the stable equilibrium point:

$$\Lambda(t \in [0,1] : |X^{\varepsilon}_{tT} - (x_l 1_{\{x \in D_l\}} + x_r 1_{\{x \in D_r\}})| > \delta) \to 0$$

This observation is at the basis of Freidlin's law of quasideterministic periodic motion discussed in the subsequent section. The lesson it teaches is this: to observe switching of the position to the energetically most favorable well, $T$ should be larger than some critical level $\mathrm{e}^{\lambda/\epsilon}$. Measuring time in exponential scales by $\mu$ through the equation $T^{\varepsilon} = \mathrm{e}^{\mu/\varepsilon}$, the condition becomes $\mu > \lambda$.

## Stochastic Resonance for Landscapes, Frozen on Half-Periods

This particular case has analytical advantages, since it allows one to employ classical techniques of semigroup and operator theory. The situation is the following: let $U$ be a double-well potential with minima $x_l = -1$ and $x_r = 1$ and a saddle point at the origin. We assume that $U(x) \to \infty$ as $|x| \to \infty$ and $U(-1) = -V/2 = -\overline{V}_l/2$, $U(1) = -v/2 = -\overline{V}_r/2$, $U(0) = 0$, and $0 < v < V$. We define the 1-periodic potential by $U(t,x) = U(t + 1/2, -x)$. Hence on each half-period the corresponding diffusion is time homogeneous. The critical level $\lambda$ is then easily defined by $\lambda = v$, that is, twice the depth of the shallow well. By letting

$$\phi(t) = \begin{cases} -1 & \text{for } t \in [k, k + \frac{1}{2}) \\ 1 & \text{for } t \in [k + \frac{1}{2}, k + 1), \quad k = 0, 1, 2, \ldots \end{cases}$$

the periodic function which describes the location of the global minimum of the potential, we get in the small noise limit

$$\Lambda(t \in [0,1] : |X^{\varepsilon}_{tT} - \phi(t)| > \delta) \to 0$$

in probability as $\varepsilon \to 0$. This result expresses Freidlin's law of quasideterministic motion: for large periods, the trajectories of the particle approach a periodic deterministic function. But the sense in which this notion measures periodicity does not take into account that for large periods short excursions to the wrong well may occur in an erratic way without counting much for Lebesgue measure of time. In fact, if the period is too large, that is, $\mu > V$, the time available in one period permits the exit of not only the shallow well but also that of the deep well. So, whatever the starting position of

the particle is, the number of observed transitions in one half period becomes very large. Indeed the first time $\xi$ the particle starting in $x_l$ hits again $x_l$ after visiting the position $x_r$ satisfies

$$\mathbb{E}(\xi) = e^{v/\varepsilon} + e^{V/\varepsilon} < T^\varepsilon = e^{\mu/\varepsilon}$$

The motion of the particle appears more chaotical than periodic: noise intensity is too large compared to period length. We avoid this range of chaotic spontaneous transitions by defining the resonance interval $I_R = [v, V]$, as the range of admissible energy parameters $\mu$ for randomly periodic behavior. In this regime, the trajectories possess periodicity properties. In these terms the resonance point describes the tuning rate $\mu_R \in I_R$ for which the stochastic response to weak external periodic forcing is optimal. To make sense, this point has to refer to some measure of quality for periodicity of random trajectories. In the huge physics literature concerning resonance, two families of criteria can be distinguished. The first one is based on invariant measures and spectral properties of the infinitesimal generator associated with the diffusion $X^\varepsilon$. Now, $X^\varepsilon$ is not Markovian and consequently does not admit invariant measures. But by taking into account deterministic motion of time in the interval of periodicity and considering the process $Z_t = (t \bmod(T^\varepsilon), X_t)$, we obtain a Markov process with an invariant measure $\nu_t(x)\mathrm{d}x$. In other words, the law of $X_t \sim \nu_t(x)\mathrm{d}x$ and the law of $X_{t+T} \sim \nu_{t+T}(x)\mathrm{d}x$, under this measure, are the same for all $t \geq 0$. Let us present the most important ones:

- the spectral power amplification (SPA) which plays an eminent role in the physics literature describes the energy carried by the spectral component of the averaged trajectories of $X^\varepsilon$ corresponding to the period:

$$M_{\mathrm{SPA}}(\varepsilon, T) = \left| \int_0^1 \mathbb{E}_\nu[X^\varepsilon_{sT}] e^{2\pi i s}\, \mathrm{d}s \right|^2$$

- the SPA-to-noise ratio, giving the ratio of the amplitude of the response and the noise intensity, which is also related to the signal-to-noise ratio:

$$M_{\mathrm{SPN}}(\varepsilon, T) = M_{\mathrm{SPA}}(\varepsilon, T)/\varepsilon^2$$

- the total energy of the averaged trajectories

$$M_{\mathrm{EN}}(\varepsilon, T) = \int_0^1 (\mathbb{E}_\nu[X_{sT}])^2\, \mathrm{d}s$$

The second family of criteria is more probabilistic. It refers to quality measures based on transition times between the domains of attraction of the local minima, residence times distributions measuring the time spent in one well between two transitions, or interspike times. This family is certainly less popular in the physics community.

However, measures related to invariant measures may suffer from robustness deficiency (Imkeller and Pavlyukevich 2002). To explain what we mean by robustness, let us introduce a model reduction first discussed by McNamara and Wiesenfeld (1989). Instead of studying the diffusion $X^\varepsilon$ in the double-well landscape, they introduce a two-state Markov chain $Y^\varepsilon$ (**Figure 5**) the dynamics of which just takes account of the domain of attraction the diffusion is in, and therefore with state space $\{-1, 1\}$. A reasonable choice of the infinitesimal generator should retain the dynamics of the diffusion's transitions characterized by Kramers' rate. We may take

$$Q(t) = \begin{pmatrix} -\varphi & \varphi \\ \psi & -\psi \end{pmatrix}, \quad 0 \leq t \leq \frac{T}{2}$$
$$Q(t) = \begin{pmatrix} -\psi & \psi \\ \varphi & -\varphi \end{pmatrix}, \quad \frac{T}{2} \leq t < T$$

periodically continued on $\mathbb{R}_+$. Here, $\varphi = p e^{-V/\varepsilon}$ and $\psi = q e^{-v/\varepsilon}$. The prefactors of subexponential order are beyond the scope of large deviation theory. They are related to the curvature of the potential in the

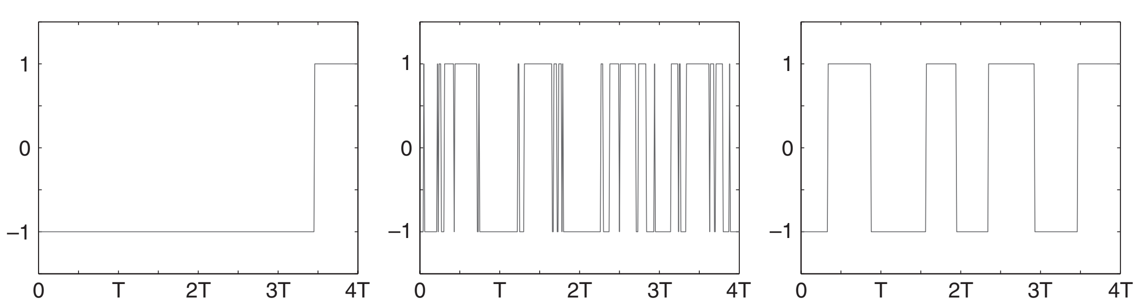

**Figure 5** Resonance pictures for Markov chain.

minima and the saddle point of the landscape and given by

$$p = \frac{1}{2\pi}\sqrt{U''(-1)|U''(0)|}$$
$$q = \frac{1}{2\pi}\sqrt{U''(1)|U''(0)|}$$

On the intervals $[kT/2,(k+1)T/2[, k \geq 0,$ the Markov chain $Y^\varepsilon$ is time-homogeneous and its transition probabilities can be expressed in terms of $\varphi$ and $\psi$. For instance, the probability with which the chain jumps from state –1 to state +1 in the time window $[t, t+h]$ equals $\varphi h + o(h)$, if this time interval is contained in $[kT/2,(k+1)T/2[$ for some even $k$. The stationary measure of the Markov chain denoted by $\nu$ can be explicitly calculated, and so can the classical quality measures based on the spectral notions. For instance, the spectral power amplification coefficient equals

$$M_{\text{SPA}}(\varepsilon, T) = \left| \int_0^1 \mathbb{E}_\nu[Y^\varepsilon_{st}]e^{2\pi is}\,ds \right|^2 = \frac{4}{\pi^2}\frac{T^2(\varphi-\psi)^2}{(\varphi+\psi)^2T^2+\pi^2}$$

This simple expression admits asymptotically a unique maximum which exhibits the resonance point:

$$T^\varepsilon_{\text{opt}} = \frac{\pi}{\sqrt{2pq}}\sqrt{\frac{v}{V-v}}e^{(V+v)/2\varepsilon}\left\{1+\mathcal{O}(e^{-(V-v)/\varepsilon})\right\}$$

The optimal period is then exponentially large – as was suggested by large deviation theory – and the growth rate is the sum of the two wells' depths. The simple Markov chain model is popular since the usual physical quantities are easy computable and since it is believed to mimic the dynamics of a Brownian particle in the corresponding double-well landscape. However, the models are not as similar as expected (Freidlin 2003). Indeed, in a reasonably large time window around the resonance point for $Y^\varepsilon$, the tuning picture of the spectral power amplification for the diffusion is different. Under weak regularity conditions on the potential, it exhibits strict monotonicity in the window. Hence, optimal tuning points for diffusion and Markov chain differ essentially. In other words, the SPA tuning behavior of the diffusion is not robust for passage to the reduced model. This strange deficiency is difficult to explain. The main reason of this subtle effect appears to be that the diffusive nature of the Brownian particle is neglected in the reduced model. In order to point out this feature, we may compute the SPA coefficient of $g(X^\varepsilon)$, where $g$ is a particular function designed to cut out the small fluctuations of the diffusion in the neighborhood of the bottoms of the wells, by identifying all states there. So $g(x) = -1$ (resp. 1) in some neighborhood of –1 (resp. 1) and otherwise $g$ is the identity. This results in

$$\widetilde{M}_{\text{SPA}}(\varepsilon, T) = \left| \int_0^1 \mathbb{E}_\nu g(X^\varepsilon_{sT})e^{2\pi is}\,ds \right|^2$$

In the small noise limit this quality function admits a local maximum close to the resonance point of the reduced model: the growth rate of $T^\varepsilon_{\text{opt}}$ is also given by the sum of the wells' depths. So the lack of robustness seems to be due to the small fluctuations of the particle in the wells' bottoms. In any case, this clearly calls for other quality measures to be used to transfer properties of the reduced model to the original one. Our discussion indicates that due to their emphasis on the pure transition dynamics, the second family of quality measures should be used. For these notions there is no need to restrict to landscapes frozen in time-independent potential states on half-period intervals.

## Stochastic Resonance for Continuously Varying Landscapes

From now on the potential $U(t, x)$ is supposed to be continuously varying in $(t, x)$. For simplicity, its local minima are assumed to be located at $\pm 1$, and its only saddle point at 0, independently of time. So the only meta-stable states on the whole time axis are $\pm 1$. Let us denote by $\Delta_-(t)$ (resp. $\Delta_+(t)$) the depth of the left (resp. right) well at time $t$. Together with $U$, these functions are continuous and 1-periodic. Assume that they are strictly monotonous between their global extrema. Let us now come back to the motion of a Brownian particle in this landscape. The exit time law by Eyring–Kramers–Freidlin entails that trajectories get close to the global minimum, if the period is large enough. Stated as before in exponential rates $T = e^{\mu/\varepsilon}$, with $\mu \geq \max_{i=\pm}\sup_{t\geq 0} 2\Delta_\pm(t)$, that is, $\mu$ exceeds the maximal work needed to cross the barrier, the particle often switches between the two wells and should stay close to the deepest position in the landscape. This position being described by the function $\phi(t) = 21_{\{\Delta_+(t)>\Delta_-(t)\}} - 1$, we get in the small noise limit

$$\Lambda(t \in [0,1] : |X^\varepsilon_{tT} - \phi(t)| > \delta) \to 0$$

in probability. But on these long timescales, many short excursions to the wrong well are observed, and trajectories look chaotical instead of periodic. So we

have to look at smaller periods even at the cost that the particle may not stay close to the global minimum. Let us study the transition dynamics. Assume that the starting point is –1 corresponding to the bottom of the deep well. If the depth of the well is always larger than $\mu = \varepsilon \log T^\varepsilon$, the particle has too little time during one period to climb the barrier, and should stay in the starting well. If, on the contrary, the minimal work to leave the starting well, given by $2\Delta_-(s)$, becomes smaller than $\mu$ at some time $s$, then the transition can and will happen. More formally, for $\mu \in [\inf_{t\geq 0} 2\Delta_-(t), \sup_{t\geq 0} 2\Delta_-(t)]$, we define (**Figure 6**).

$$a_\mu^-(s) = \inf\{t \geq s : 2\Delta_-(t) \leq \mu\}$$

The first transition time from –1 to 1 denoted $\tau_+$ has the following asymptotic behavior as $\varepsilon \to 0: \tau_+/T^\varepsilon \to a_\mu^-(0)$. At the second transition the particle returns to the starting well. If $a_\mu^+$ is defined analogously with respect to the depth function $\Delta_+$, this transition will occur near the deterministic time $a_\mu^+(a_\mu^-(s))T^\varepsilon$. In order to observe periodicity, and to exclude chaoticity from all parts of its trajectories, the particle has to stay for some time in the other well before returning. This will happen under the assumption $2\Delta_+(a_\mu(0)) > \mu$, that is, the right well is the deep one at transition time. In fact, we can define the resonance interval $I_R$ (**Figure 7**), as the set of all scales $\mu$ for which trajectories exhibit periodicity in the small noise limit, by

$$I_R = \left[\max_{i=\pm}\inf_{t\geq 0} 2\Delta_i(t), \inf_{t\geq 0}\max_{i=\pm} 2\Delta_i(t)\right]$$

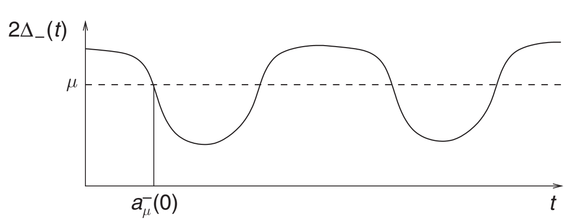

**Figure 6** Definition of $a_\mu^-$.

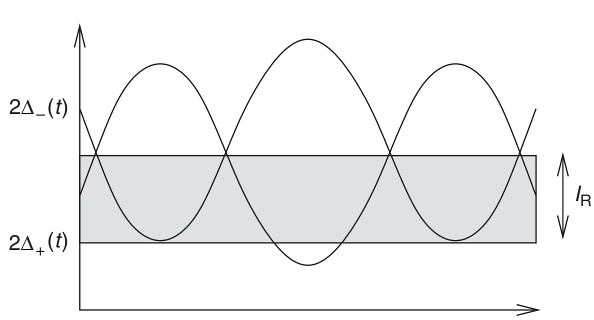

**Figure 7** Resonance interval.

On this interval they get close to deterministic periodic ones. Again, periodicity is quantified by a quality measure, to be maximized in order to obtain resonance as the best possible response to periodic forcing. One interesting measure is based on the probability that random transitions happen in some small time window around a deterministic time, in the small noise limit (Herrmann and Inkeller 2005). Formally, for $h > 0$, the measure gives

$$M_h(\varepsilon, T) = \min_{i=\pm} \mathbb{P}_i(\tau_\mp/T^\varepsilon \in [a_\mu^i - h, a_\mu^i + h])$$

where $\mathbb{P}_i$ is the law of the diffusion starting in $i$. In the small noise limit, this quality measure tends to 1, and optimal tuning can be related to the exponential rate at which this happens. This is due to the following large deviations principle:

$$\lim_{\varepsilon\to 0} \varepsilon \log(1 - M_h(\varepsilon, T)) = \max_{i=\pm}\{\mu - 2\Delta_i(a_\mu^i - h)\}$$

for $\mu \in I_R$, with uniform convergence on each compact subset of $I_R$. The result is established using classical large-deviation techniques applied to locally time homogeneous approximations of the diffusion. Maximizing the transition probability in the time window position means minimizing the default rate obtained by the large deviations principle. This can be easily achieved. In fact, if the window length $2h$ is small, then $\mu - 2\Delta_i(a_\mu^i - h) \approx 2h\Delta_i'(a_\mu^i)$, since $2\Delta_i(a_\mu^i) = \mu$ by definition. The value $\Delta_i'(a_\mu^i)$ is negative, so we have to find the position where its absolute value is maximal. In this position the depth of the starting well has the most rapid drop under the level $\mu$, characterizing the link between the noise intensity and the period. So the transition time is best concentrated around it.

It is clear that a good candidate for the resonance point is given by the eventually existing limit of the global minimizer $\mu_R(h)$ as the window length $h$ tends to 0. This limit is therefore called the resonance point of the diffusion with time-periodic landscape $U$. Let us note that for sinusoidal depth functions

$$\Delta_-(t) = \frac{V+v}{4} + \frac{V-v}{4}\cos(2\pi t)$$

and

$$\Delta_+(t) = \Delta_-(t+\pi)$$

the optimal tuning is given by $T^\varepsilon = \exp \mu_R/\varepsilon$ with $\mu_R = (v+V)/2$. This optimal rate is equivalent to the optimal rate given by the SPA coefficient of the reduced dynamics' Markov chain in the preceding section.

The big advantage of the quality measure $M_h$ is its robustness. Indeed, consider the reduced model

consisting of a two-state Markov chain with infinitesimal generator

$$Q(t) = \begin{pmatrix} -\varphi(t) & \varphi(t) \\ \psi(t) & -\psi(t) \end{pmatrix}$$

where $\varphi(t) = \exp -2\Delta_-(t/T)/\varepsilon$ and $\psi(t) = \exp -2\Delta_+(t/T)/\varepsilon$. The law of transition times of this Markov chain is readily computed from Laplace transforms. Normalized by $T^\varepsilon$ it converges to $a^i_\mu$. This calculation even reveals a rigorous underlying pattern for the second- and higher-order transition times interpreting the interspike distributions of the physics literature. The dynamics of diffusion and Markov chain are similar. Resonance points provided by $M_b$ for the diffusion and its analog for the Markov chain agree.

## Related Notions: Synchronization

In the preceding sections, we interpreted stochastic resonance as optimal response of a randomly perturbed dynamical system to weak periodic forcing, in the spirit of the physics literature (see Gammaitoni *et al.* (1998)). Our crucial assumption concerned the barrier heights a Brownian particle has to overcome in the potential landscape of the dynamical system: it is uniformly lower bounded in time. Measures for the quality of tuning were based on essentially two concepts: one concerning spectral criteria, with the spectral power amplification as most prominent member, the other one concerning the pure transitions dynamics between the domains of attraction of the local minima. A number of different criteria can be used to create an optimal tuning between the intensity of the noise perturbation and the large period of the dynamical system. The relations have to be of an exponential type $T = \exp \mu/\varepsilon$, since the Brownian particle needs exponentially long times to cross the barrier separating the wells according to the Eyring–Kramers–Freidlin transition law. Our barrier height assumption seems natural in many situations, but can fail in others. If it becomes small periodically, and eventually scales with the noise-intensity parameter, the Brownian particle does not need to wait an exponentially long time to climb it. So periodicity obtains for essentially smaller timescales. In this setting, the slowness of periodic forcing may also be assumed to be essentially subexponential in the noise intensity.

If it is fast enough to allow for substantial changes before large deviation effects can take over, we are in the situation of Berglund and Gentz (2002). They in fact consider the case in which the barrier between the wells becomes low twice per period, to the effect of modulating periodically a bifurcation parameter: at time zero the right-hand well becomes almost flat, and at the same time the bottom of the well and the saddle approach each other; half a period later, a spatially symmetric scenario is encountered. In this situation, there is a threshold value for the noise intensity under which transitions become unlikely. Above this threshold, the trajectories typically contain two transitions per period. Results are formulated in terms of concentration properties for random trajectories. The intuitive picture is this: with overwhelming probability, sample paths will be concentrated in spacetime sets scaling with the small parameters of the problem. In higher dimensions, these sets may be given by adiabatic or center manifolds of the deterministic system, which allow model reduction of higher-dimensional systems to lower-dimensional ones. Asymptotic results hold for any choice of the small parameters in a whole parameter region. A passage to the small noise limit as for optimal tuning in the preceding sections is not needed.

Related problems studied by Berglund and Gentz in the multidimensional case concern the noise-induced passage through periodic orbits, where unexpected phenomena arise. Here, as opposed to the classical Freidlin–Wentzell theory, the distribution of first-exit points depends nontrivially on the noise intensity. Again aiming at results valid for small but nonvanishing parameters in subexponential scale ranges, they investigate the density of first-passage times in a large regime of parameter values, and obtain insight into the transition from the stochastic resonance regime into the synchronization regime.

# String Field Theory

**L Rastelli**, Princeton University, Princeton, NJ, USA

## Introduction

String field theory (SFT) is the second-quantized approach to string theory. In the usual, first-quantized, formulation of string perturbation theory, one postulates a recipe for the string $S$-matrix in terms of a sum over two-dimensional (2D) world sheets embedded in spacetime. Very schematically,

$$\langle\langle V_1(k_1)\ldots V_n(k_n)\rangle\rangle = \sum_{\text{topologies}} g_s^{-\chi}\int [d\mu_\alpha]\,\langle V_1(k_1)\ldots V_n(k_n)\rangle_{\{\mu_\alpha\}} \qquad [1]$$

Here the left-hand side stands for the $S$-matrix of the physical string states $\{V_a(k_a)\}$. The symbol $\langle\ldots\rangle_{\{\mu_\alpha\}}$ denotes a correlation function on the 2D world sheet, which is a punctured Riemann surface of Euler number $\chi$ and given moduli $\{\mu_\alpha\}$. In SFT, one aims to recover this standard prescription from the Feynman rules of a second-quantized spacetime action $S[\Phi]$. The string field $\Phi$, the fundamental dynamical variable, can be thought of as an infinite-dimensional array of spacetime fields $\{\phi^i(x^\mu)\}$, one field for each basis state in the Fock space of the first-quantized string.

The most straightforward way to construct $S[\Phi]$ uses the unitary light-cone gauge. Light-cone SFT is an almost immediate transcription of Mandelstam's light-cone diagrams in a second-quantized language. While often useful as a bookkeeping device, light-cone SFT seems unlikely to represent a real improvement over the first-quantized approach. By contrast, from our experience in ordinary quantum field theory, we should expect Poincaré-covariant SFTs to give important insights into the issues of vacuum selection, background independence and the nonperturbative definition of string theory.

Covariant SFT actions are well established for the open (Witten 1986), closed (Zwiebach 1993) and open/closed (Zwiebach 1998) bosonic string. These theories are based on the BRST formalism, where the world sheet variables include the $bc$ ghosts introduced in gauge-fixing the world sheet metric to the conformal gauge $g_{ab}\sim\delta_{ab}$. (An alternative approach (Hata *et al.*), based on covariantizing light-cone SFT, will not be described in this article.) Much less is presently known for the superstring: classical actions have been established for the Neveu-Schwarz sector of the open superstring (Berkovits 2001) and for the heterotic string (Berkovits *et al.* 2004).

During the first period of intense activity in SFT (1985–1992), the covariant bosonic actions were constructed and shown to pass the basic test of reproducing the $S$-matrix [1] to each order in the perturbative expansion. The more recent revival of the subject (since 1999) was triggered by the realization that SFT contains nonperturbative information as well: D-branes emerge as solitonic solutions of the classical equations of motion in

open SFT (OSFT). We can hope that the nonperturbative string dualities will also be understood in the framework of SFT, once covariant SFTs for the superstring are better developed.

In this article, we review the basic formalism of covariant SFT, using for illustration purposes the simplest model – cubic bosonic OSFT. We then briefly sketch the generalization to bosonic SFTs that include closed strings. Finally, we turn to the subjects of classical solutions in OSFT and the physics of the open-string tachyon.

## Open Bosonic SFT

The standard formulation of string theory starts with the choice of an on-shell spacetime background where strings propagate. In the bosonic string, the closed string background is described by a conformal field theory of central charge 26 (the "matter" CFT). The total world sheet CFT is the direct sum of this matter CFT and of the universal ghost CFT, of central charge –26. To describe open strings, we must further specify boundary conditions for the string endpoints. The open-string background is encoded in a boundary CFT (BCFT), a CFT defined in the upper-half plane, with conformal boundary conditions on the real axis (see Boundary Conformal Field Theory in this encyclopedia). In modern language, the choice of BCFT corresponds to specifying a D-brane state.

In classical OSFT, we fix the closed-string background (the bulk CFT) and consider varying the D-brane configuration (the boundary conditions). To lowest order in $g_s$, we can neglect the backreaction of the D-brane on the closed-string fields, since this is a quantum effect from the open-string viewpoint. Let us prepare the ground by recalling the standard $\sigma$-model philosophy. To describe off-shell open-string configurations, we should allow for general (not necessarily conformal) boundary conditions. We can imagine to proceed as follows:

1. We choose an initial open-string background, a reference BCFT that we shall call $\text{BCFT}_0$. For example, a D$p$ brane in flat 26 dimensions (Neumann boundary conditions on $p+1$ coordinates, Dirichlet on $25-p$ coordinates).
2. We then write a basis of boundary perturbations around this background. Taking, for example, $\text{BCFT}_0$ to be a D25 brane in flat space, the world sheet action $S_{\text{WS}}$ takes the schematic form

$$S_{\text{WS}} = \frac{1}{2\pi\alpha'}\int_{\text{UHP}} \partial X_\mu \bar{\partial} X^\mu + \int_{\boldsymbol{R}} \tilde{T}(x^\mu) + \tilde{A}_\nu(x^\mu)\partial X^\nu + \tilde{B}_\nu(x^\mu)\partial^2 X^\nu + \cdots \qquad [2]$$

Here to the standard free bulk action (integrated over the upper-half complex plane UHP) we have added perturbation localized on the real axis $\boldsymbol{R}$. Notice that the basis of perturbations depends on the chosen $\text{BCFT}_0$.
3. We interpret the coefficients $\{\tilde{\phi}^i(x^\mu)\}$ of the perturbations as spacetime fields. (The tilde on $\tilde{\phi}^i(x)$ serves as a reminder that these fields are not quite the same as the fields $\phi^i(x)$ that will appear in the OSFT action). We are after a spacetime action $S[\{\tilde{\phi}^i\}]$ such that solutions of its classical equations of motion correspond to conformal boundary conditions:

$$\frac{\delta S}{\delta \tilde{\phi}^i} = 0(\text{spacetime}) \leftrightarrow \beta_i[\{\tilde{\phi}^j\}] = 0 \text{ (world sheet)} \qquad [3]$$

We recognize in [2] the familiar open-string tachyon $\tilde{T}(x)$ and gauge field $\tilde{A}_\mu(x)$, which are the lowest modes in an infinite tower of fields. Relevant perturbations on the world sheet (with conformal dimension $h<1$) correspond to tachyonic fields in spacetime ($m^2<0$), whereas marginal world sheet perturbations ($h=1$) give massless spacetime fields. To achieve a complete description, we must include all the higher massive open-string modes as well, which correspond to nonrenormalizable boundary perturbations ($h>1$). In the traditional $\sigma$-model approach, this appears like a daunting task. The formalism of OSFT will automatically circumvent this difficulty.

### The Open-String Field

In covariant SFT the reparametrization ghosts play a crucial role. The ghost CFT consists of the Grassmann odd fields $b(z), c(z), \bar{b}(\bar{z}), \bar{c}(\bar{z})$, of dimensions $(2,0), (-1,0), (0,2), (0,-1)$, respectively. The boundary conditions on the real axis are $b=\bar{b}, c=\bar{c}$. The state space $\mathcal{H}_{\text{BCFT}_0}$ of the full matter + ghost BCFT can be broken up into subspaces of definite ghost number,

$$\mathcal{H}_{\text{BCFT}_0} = \bigoplus_{G=-\infty}^{\infty} \mathcal{H}^{(G)}_{\text{BCFT}_0} \qquad [4]$$

We use conventions where the SL(2, $\boldsymbol{R}$) vacuum $|0\rangle$ carries zero ghost number, $G(|0\rangle)=0$, while $G(c)=+1$ and $G(b)=-1$. As is familiar from the first-quantized treatment, physical open-string states are identified with $G=+1$ cohomology classes of the BRST operator,

$$Q|V_{\text{phys}}\rangle = 0, \quad |V_{\text{phys}}\rangle \sim |V_{\text{phys}}\rangle + Q|\Lambda\rangle \qquad [5]$$
$$G(|V_{\text{phys}}\rangle) = +1$$

where the nilpotent BRST operator $Q$ has the standard expression

$$Q = \frac{1}{2\pi i}\oint (c\,T_{\text{matter}} + :bc\partial c:) \qquad [6]$$

Though not *a priori* obvious, it turns out that the simplest form of the OSFT action is achieved by taking as the fundamental off-shell variable an arbitrary $G = +1$ element of the first-quantized Fock space,

$$|\Phi\rangle \in \mathcal{H}^{(1)}_{\text{BCFT}_0} \qquad [7]$$

By the usual state–operator correspondence of CFT, we can also represent $|\Phi\rangle$ as a local (boundary) vertex operator acting on the vacuum,

$$|\Phi\rangle = \Phi(0)|0\rangle \qquad [8]$$

The open-string field $|\Phi\rangle$ is really an infinite-dimensional array of spacetime fields. We can make this transparent by expanding it as

$$|\Phi\rangle = \sum_i \int d^{p+1}k|\Phi_i(k)\rangle\,\phi^i(k_\mu) \qquad [9]$$

where $\{|\Phi_i(k)\rangle\}$ is some convenient basis of $\mathcal{H}^{(1)}_{\text{BCFT}_0}$ that diagonalizes the momentum $k_\mu$. The fields $\phi^i$ are *a priori* complex. This is remedied by imposing a suitable reality condition on the string field, which will be stated momentarily. Notice that there are many more elements in $\{|\Phi_i(k)\rangle\}$ than in the physical subspace (the cohomology classes of $Q$). Some of the extra fields will turn out to be nondynamical and could be integrated out, but at the price of making the OSFT action look much more complicated.

It is often useful to think of the string field in terms of its Schrödinger representation, that is, as a functional on the configuration space of open strings. Consider the unit half-disk in the upper-half plane, $D_H \equiv \{|z| \leq 1, \Im z \geq 0\}$, with the vertex operator $\Phi(0)$ inserted at the origin. Impose $\text{BCFT}_0$ open string boundary conditions for the fields $X(z,\bar{z})$ on the real axis (here $X(z,\bar{z})$ is a short-hand notation for all matter and ghost fields), and boundary conditions $X(\sigma) = X_b(\sigma)$ on the curved boundary of $D_H, z = \exp(i\sigma), 0 \leq \sigma \leq \pi$. The path integral over $X(z,\bar{z})$ in the interior of the half-disk assigns a complex number to any given $X_b(\sigma)$, so we obtain a functional $\Phi[X_b(\sigma)]$. This is the Schrödinger wave function of the state $\Phi(0)|0\rangle$. Thus, we can think of open-string functionals $\Phi[X_b(\sigma)]$ as the fundamental variables of OSFT. This is as it should be: the first-quantized wave functions are promoted to dynamical fields in the second-quantized theory. Finally, let us quote the reality condition for the string field, which takes a compact form in the Schrödinger representation:

$$\begin{aligned}\Phi[X^\mu(\sigma), b(\sigma), c(\sigma)]\\ = \Phi^*[X^\mu(\pi-\sigma), b(\pi-\sigma), c(\pi-\sigma)]\end{aligned} \qquad [10]$$

where the superscript $*$ denotes complex conjugation.

### The Classical Action

With all the ingredients in place, it is immediate to write the quadratic part of the OSFT action. The linearized equations of motion must reproduce the physical-state condition [5]. This suggests

$$S \sim \langle\Phi|Q|\Phi\rangle \qquad [11]$$

Here $\langle|\rangle$ is the usual BPZ inner product of $\text{BCFT}_0$, which is defined in terms of a two-point correlator on the disk, as we review below. The ghost anomaly implies that on the disk we must have $G_{\text{tot}} = +3$, which happily is the case in [11]. Moreover, since the inner product is nondegenerate, variation of [11] gives

$$Q|\Phi\rangle = 0 \qquad [12]$$

as desired. The equivalence relation $|V_{\text{phys}}\rangle \sim |V_{\text{phys}}\rangle + Q|\Lambda\rangle$ is interpreted in the second-quantized language as the spacetime gauge invariance

$$\delta_\Lambda|\Phi\rangle = Q|\Lambda\rangle, \quad |\Lambda\rangle \in \mathcal{H}^{(0)}_{\text{BCFT}_0} \qquad [13]$$

valid for the general off-shell field. This equation is a very compact generalization of the linearized gauge invariance for the massless gauge field. Indeed, focusing on the level-zero components, $|\Phi\rangle \sim A_\mu(x)(c\partial X^\mu)(0)|0\rangle$ and $|\Lambda\rangle \sim \lambda(x)|0\rangle$, we find $\delta A_\mu(x) = \partial_\mu\lambda(x)$. It is then plausible to guess that the nonlinear gauge invariance should take the form

$$\delta_\Lambda|\Phi\rangle = Q|\Lambda\rangle + |\Phi\rangle * |\Lambda\rangle - |\Lambda\rangle * |\Phi\rangle \qquad [14]$$

where $*$ is some suitable product operation that conserves ghost number

$$* : \mathcal{H}^{(n)}_{\text{BCFT}_0} \otimes \mathcal{H}^{(m)}_{\text{BCFT}_0} \to \mathcal{H}^{(n+m)}_{\text{BCFT}_0} \qquad [15]$$

Based on a formal analogy with 3D nonabelian Chern–Simons theory, Witten proposed the cubic action

$$S = -\frac{1}{g_o^2}\left(\frac{1}{2}\langle\Phi|Q|\Phi\rangle + \frac{1}{3}\langle\Phi|\Phi * \Phi\rangle\right) \qquad [16]$$

The string field $|\Phi\rangle$ is analogous to the Chern–Simons gauge potential $A = A_i dx^i$, the $*$ product to the $\wedge$ product of differential forms, $Q$ to the exterior derivative $d$, and the ghost number $G$ to the degree

of the form. The analogy also suggests a number of algebraic identities:

$$
\begin{aligned}
Q^2 &= 0 \\
\langle QA|B\rangle &= -(-1)^{G(A)}\langle A|QB\rangle \\
Q(A*B) &= (QA)*B + (-1)^{G(A)}A*(QB) \\
\langle A|B\rangle &= (-1)^{G(A)G(B)}\langle B|A\rangle \\
\langle A|B*C\rangle &= \langle B|C*A\rangle \\
A*(B*C) &= (A*B)*C
\end{aligned} \qquad [17]
$$

Note in particular the associativity of the $*$-product. It is straightforward to check that this algebraic structure implies the gauge invariance of the cubic action under [14]. A $*$-product satisfying all required formal properties can indeed be defined. The most intuitive presentation is in the functional language. Given an open-string curve $X(\sigma), 0 \le \sigma \le \pi$, we single out the string mid-point $\sigma = \pi/2$ and define the left and right "half-string" curves

$$
\begin{aligned}
X_{\mathrm{L}}(\sigma) &\equiv X(\sigma) && \text{for } 0 \le \sigma \le \frac{\pi}{2} \\
X_{\mathrm{R}}(\sigma) &\equiv X(\pi - \sigma) && \text{for } \frac{\pi}{2} \le \sigma \le \pi
\end{aligned} \qquad [18]
$$

A functional $\Phi[X(\sigma)]$ can, of course, be regarded as a functional of the two half-strings, $\Phi[X] \to \Phi[X_{\mathrm{L}}, X_{\mathrm{R}}]$. We define

$$
(\Phi_1 * \Phi_2)[X_{\mathrm{L}}, X_{\mathrm{R}}] \equiv \int [\mathrm{d}Y]\Phi_1[X_{\mathrm{L}}, Y]\Phi_2[Y, X_{\mathrm{R}}] \qquad [19]
$$

where $\int [\mathrm{d}Y]$ is meant as the functional integral over the space of half-strings $Y(\sigma)$, with $Y(\pi/2) = X_{\mathrm{L}}(\pi/2) = X_{\mathrm{R}}(\pi/2)$. Figure 1a shows two open strings interacting (to form a single open string) if and only if the right half of the first string precisely overlaps with the left half of the second string. Associativity is transparent (Figure 1b).

We can now translate this formal construction in the precise CFT language. Very generally, an $n$-point vertex of open strings can be defined by specifying an $n$-punctured disk, that is, a disk with marked points on the boundary (punctures) and a choice of local coordinates around each puncture. Local coordinates are essential since we are dealing with off-shell open-string states. The BPZ inner product (two-point vertex) is given by

$$
\begin{aligned}
\langle \Phi_1|\Phi_2\rangle &\equiv \langle I \circ \Phi_1(0)\ \Phi_2(0)\rangle_{\mathrm{UPH}} \\
I(z) &= -\frac{1}{z}
\end{aligned} \qquad [20]
$$

The symbol $f \circ \Phi(0)$, where $f$ is a complex map, means the conformal transform of $\Phi(0)$ by $f$. For example, if $\Phi$ is a dimension-$d$ primary field, then $f \circ \Phi(0) = f'(0)^d \Phi(f(0))$. If $\Phi$ is nonprimary, the transformation rule will be more complicated and involve extra terms with higher derivatives of $f$. By performing the $\mathrm{SL}(2, \mathbf{C})$ transformation

$$
w = h(z) \equiv \frac{1 + \mathrm{i}z}{1 - \mathrm{i}z} \qquad [21]
$$

we can represent the two-point vertex as a correlator on the unit disk $D = \{|w| \le 1\}$,

$$
\begin{aligned}
\langle \Phi_1|\Phi_2\rangle &= \langle f_1 \circ \Phi_1(0),\ f_2 \circ \Phi_2(0)\rangle_D \\
f_1(z_1) &= -h(z_1), \quad f_2(z_2) = h(z_2)
\end{aligned} \qquad [22]
$$

The vertex operators are inserted as $w = -1$ and $w = +1$ on $D$ (see Figure 2a) and correspond to the two open strings at (Euclidean) world sheet time $\tau = -\infty$ (we take $z = \exp(\mathrm{i}\sigma + \tau)$). The left half of $D$ is the world sheet of the first open string; the right half of $D$ is the world sheet of the second string. The two strings meet at $\tau = 0$ on the imaginary $w$ axis. The three-point Witten vertex is given by

$$
\begin{aligned}
&\langle \Phi_1, \Phi_2, \Phi_3\rangle \\
&\quad \equiv \langle g_1 \circ \Phi_1(0) g_2 \circ \Phi_2(0) g_3 \circ \Phi_3(0)\rangle_D
\end{aligned} \qquad [23]
$$

where

$$
\begin{aligned}
g_1(z_1) &= \mathrm{e}^{2\pi\mathrm{i}/3}\left(\frac{1 + \mathrm{i}z_1}{1 - \mathrm{i}z_1}\right)^{2/3} \\
g_2(z_2) &= \left(\frac{1 + \mathrm{i}z_2}{1 - \mathrm{i}z_2}\right)^{2/3} \\
g_3(z_3) &= \mathrm{e}^{-2\pi\mathrm{i}/3}\left(\frac{1 + \mathrm{i}z_3}{1 - \mathrm{i}z_3}\right)^{2/3}
\end{aligned} \qquad [24]
$$

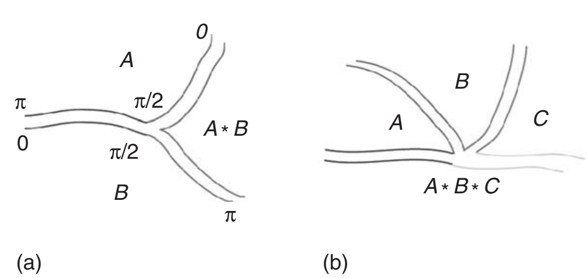

**Figure 1** Midpoint overlaps of open strings.

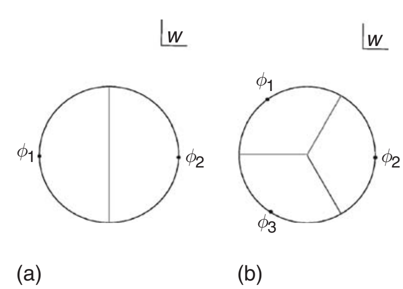

**Figure 2** Representation of the quadratic and cubic vertices as 2- and 3-punctured unit disks.

The 3-punctured disk is depicted in **Figure 2b**, and describes the symmetric mid-point overlap of the three strings at $\tau = 0$. Finally, the relation between the three-point vertex and the $*$-product is

$$\langle \Phi_1 | \Phi_2 * \Phi_3 \rangle \equiv \langle \Phi_1, \Phi_2, \Phi_3 \rangle \quad [25]$$

Knowledge of the right-hand side (RHS) in [25] for all $\Phi$ allows to reconstruct the $*$-product. All formal properties [17] are easily shown to hold in the CFT language. This completes the definition of the OSFT action.

Evaluation of the classical action is completely algorithmic and can be carried out for arbitrary massive states, with no fear of divergences, since in all required correlators the operators are inserted well apart from each other.

#### Quantization

Quantization is defined by the path integral over the second-quantized string field. The first step is to deal with the gauge invariance [14] of the classical action. The gauge symmetry is reducible: not all gauge parameters $\Lambda^{(0)}$ (the superscript labels ghost number) lead to a gauge transformation. This is clear at the linearized level; indeed, if $\Lambda^{(0)} = Q\Lambda^{(-1)}$, then $\delta_{\Lambda^{(0)}}\Phi^{(1)} = Q^2\Lambda^{(0)} = 0$. Thus, the set $\{\Lambda^{(0)}\}$ gives a redundant parametrization of the gauge group. Characterizing this redundancy is somewhat subtle, since fields of the form $\Lambda^{(-1)} = Q\Lambda^{(-2)}$ do not really lead to a redundancy in $\Lambda^{(0)}$, and so on, *ad infinitum*. It is clear that we need to introduce an infinite tower of (second-quantized) ghosts for ghosts.

The Batalin–Vilkovisky formalism is a powerful way to handle the problem. The basic object is the master action $S(\phi^s, \phi^*_s)$, which is a function of the "fields" $\phi^s$ and of the "antifields" $\phi^*_s$. Each field is paired with a corresponding antifield of opposite Grassmanality. ("Grassmanality" is defined to be even or odd: a Grassmann even (odd) field is a commuting (anticommuting) field). The master action must obey the boundary condition of reducing to the classical action when the antifields are set to zero. (Note that in general the set of fields $\phi^s$ will be larger than the set of fields $\phi^i$ that appear in the classical action). Independence of the $S$-matrix on the gauge-fixing procedure is equivalent to the BV master equation

$$\tfrac{1}{2}\{S, S\} = -\hbar \Delta S \quad [26]$$

The antibracket $\{,\}$ and the $\Delta$ operator are defined as

$$\{A, B\} \equiv \frac{\partial_r A}{\partial \phi^s}\frac{\partial_l B}{\partial \phi^*_s} - \frac{\partial_r A}{\partial \phi^*_s}\frac{\partial_l B}{\partial \phi^s}$$
$$\Delta \equiv \frac{\partial_r}{\partial \phi^s}\frac{\partial_l}{\partial \phi^*_s} \quad [27]$$

where $\partial_l$ and $\partial_r$ are derivatives from the left and from the right. It is often convenient to expand $S$ in powers of $\hbar$, $S = S_0 + \hbar S_1 + \hbar^2 S_2 + \cdots$, with

$$\{S_0, S_0\} = 0$$
$$\{S_0, S_1\} + \{S_0, S_1\} = -2\hbar\Delta S_0, \ldots \quad [28]$$

With these definitions in place, we shall simply describe the answer, which is extremely elegant. In OSFT the full set of fields and antifields is packaged in a single string field $|\Phi\rangle$ of unrestricted ghost number. If we write

$$|\Phi\rangle = |\Phi_-\rangle + |\Phi_+\rangle$$
$$\text{with } G(\Phi_-) \leq 1 \text{ and } G(\Phi_+) \geq 2 \quad [29]$$

all the fields are contained in $|\Phi_-\rangle$ and all the antifields in $|\Phi_+\rangle$. To make the pairing explicit, we pick a basis $\{|\Phi_s\rangle\}$ of $\mathcal{H}_{\mathrm{BCFT}_0}$, and define a conjugate basis $\{|\Phi^C_s\rangle\}$ by

$$\langle \Phi^C_r | \Phi_s \rangle = \delta_{rs} \quad [30]$$

Clearly, $G(\Phi^C_s) + G(\Phi_s) = 3$. Then

$$|\Phi_-\rangle = \sum_{G(\Phi_s)\leq 1} |\Phi_s\rangle \phi^s, \quad |\Phi_+\rangle = \sum_{G(\Phi_s)\leq 1} |\Phi^C_s\rangle \phi^*_s \quad [31]$$

Basis states $|\Phi_s\rangle$ with even (odd) ghost number $G(\Phi_s)$ are defined to be Grassmann even (odd). The full string field $|\Phi\rangle$ is declared to be Grassmann odd. It follows that $\phi^s$ is Grassmann even (odd) for $G(\Phi_s)$ odd (even), and that the corresponding antifield $\phi^*_s$ has the opposite Grassmanality of $\phi^s$, as it must be. With this understanding of $|\Phi\rangle$, the classical master action $S_0$ is identical in form to the Witten action [16]! The boundary condition is satisfied; indeed, setting $|\Phi_+\rangle = 0$, the ghost number anomaly implies that only the terms with $G = +1$ survive. The equation $\{S_0, S_0\} = 0$ follows from straightforward manipulations using the algebraic identities [17]. On the other hand, the issue of whether $\Delta S_0 = 0$, or whether instead quantum corrections are needed to satisfy full BV master equation, is more subtle and has never been fully resolved. The $\Delta$ operator receives singular contributions from the same region of moduli space responsible for the appearance of closed-string poles, which are discussed below. (See Thorn (1989) for a classic statement of this issue). It seems possible to choose a basis in $\mathcal{H}_{\mathrm{BCFT}_0}$ such that there are no quantum corrections to $S_0$ (Erler and Gross 2004). In the following we shall derive the Feynman rules implied by $S_0$ alone.

### SFT Diagrams and Minimal Area Metrics

Imposing the Siegel gauge condition $b_0\Phi = 0$, one finds the gauge-fixed action

$$S_{\rm gf} = -\frac{1}{g_o^2}\left(\frac{1}{2}\langle\Phi|c_0L_0|\Phi\rangle + \frac{1}{3}\langle\Phi|\Phi * \Phi\rangle + \langle\beta|\, b_0|\Phi\rangle\right) \qquad [32]$$

where $\beta$ is a Lagrangian multiplier. The propagator reads

$$\frac{b_0}{L_0} = b_0\int_0^\infty {\rm d}T\, {\rm e}^{-TL_0} \qquad [33]$$

Since $L_0$ is the first-quantized open-string Hamiltonian, ${\rm e}^{-TL_0}$ is the operator that evolves the open-string wave functions $\Psi[X(\sigma)]$ by Euclidean world sheet time $T$. It can be visualized as a flat rectangular strip of "horizontal" width $\pi$ and "vertical" height $T$. Each propagator comes with an antighost insertion

$$b_0 = \int_0^\pi b(\sigma) \qquad [34]$$

integrated on a horizontal trajectory.

The only elementary interaction vertex is the mid-point three-string overlap, visualized in Figure 3. We are instructed to draw all possible diagrams with given external legs (represented as semi-infinite strips), and to integrate over all Schwinger parameters $T_i \in [0,\infty)$ associated with the internal propagators. The claim is that this prescription reproduce precisely the first-quantized result [1]. This follows if we can show that (1) the OSFT Feynman rules give a unique cover of the moduli space of open Riemann surfaces; (2) the integration measure agrees with the measure $[{\rm d}\mu_\alpha]$ in [1]. The latter property holds because the antighost insertion [34] is precisely the one prescribed by the Polyakov formalism for integrating over the moduli $T_i$. To show point (1), we introduce the concept of minimal-area metrics, which has proved very fruitful. (Here and below, our discussion of minimal-area metrics will summarize ideas developed mainly by Zwiebach.) Quite generally, the Feynman rules of an SFT provide us with a cell decomposition of the appropriate moduli space of Riemann surfaces, a way to construct surfaces in terms of vertices and propagators. Given a Riemann surface (for fixed values of its complex moduli), the SFT must associate with it one and only one string diagram. The diagram has more structure than the Riemann surface: it defines a metric on it. In all known covariant SFTs, this is the metric of minimal area obeying suitable length conditions. Consider the following:

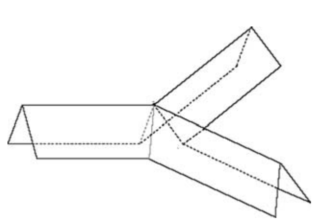

**Figure 3** The cubic vertex represented as the mid-point gluing of three strips.

**Minimal-area problem for open SFT** Let $\mathcal{R}_o$ be a Riemann surface with at least one boundary component and possibly punctures on the boundary. Find the (conformal) metric of minimal area on $\mathcal{R}_o$ such that all nontrivial Jordan open curves have length greater than or equal to $\pi$. (A curve is said to be nontrivial if it cannot be continuously shrunk to a point without crossing a puncture.)

An OSFT diagram (for fixed values of its $T_i$), defines a Riemann surface $\mathcal{R}_o$ endowed with a metric solving this minimal-area problem. This is the metric implicit in its picture: flat everywhere except at the conical singularities of defect angle $(n-2)\pi$ when $n$ propagators meet symmetrically. (For $n = 3$, these are the elementary cubic vertices; for $n > 3$, they are effective vertices, obtained when propagators joining cubic vertices collapse to zero length.) It is not difficult to see both that the length conditions are obeyed, and that the metric cannot be made smaller without violating a length condition. Conversely, any surface $\mathcal{R}_o$ endowed with a minimal-area metric, corresponds to an OSFT diagram. The idea is that the minimal-area metric must have open geodesics ("horizontal trajectories") of length $\pi$ foliating the surface. The geodesics intersect on a set of measure zero – the "critical graph" where the propagators are glued. Bands of open geodesics of infinite height are the external legs of the diagram, while bands of finite height are the internal propagators.

The single cover of moduli space is then ensured by an existence and uniqueness theorem for metrics solving the minimal-area problem for OSFT. These metrics are seen to arise from Jenkins–Strebel quadratic differentials. Existence shows that the Feynman rules of OSFT generate each Riemann surface $\mathcal{R}_o$ at least once. Uniqueness shows that there is no overcounting: since different diagrams correspond to different metrics (by inspection of their picture), no Riemann surface can be generated twice.

### Closed Strings in OSFT

As is familiar, the open-string $S$-matrix contains poles due to the exchange of on-shell open and closed strings. The closed-string poles are present in nonplanar loop amplitudes. We have seen that OSFT reproduces the standard $S$-matrix. Factorization over the open-string poles is manifest, it corresponds to propagator lengths $T_i$ going to infinity. Surprisingly, the closed-string poles are also correctly reproduced, despite the fact that OSFT treats only the open strings as fundamental dynamical variables. In some sense, closed strings must be considered as derived objects in OSFT. Factorizing the amplitudes over the closed-string poles, one finds that on-shell closed-string states can be represented, at least formally, as certain singular open-string fields with $G = +2$, closely related to the (formal) identity string field. The picture is that of a folded open string, whose left and right halves precisely overlap, with an extra closed-string vertex operator inserted at the mid-point. The corresponding open/closed vertex is given by

$$\langle \Psi_{\text{phys}} | \Phi \rangle_{\text{OC}} \equiv \langle \Psi_{\text{phys}}(0) \mathcal{I} \circ \Phi(0) \rangle_D \qquad \mathcal{I} = \left( \frac{1 + iz}{1 - iz} \right)^2 \tag{35}$$

and describes the coupling to the open-string field of a nondynamical, on-shell closed string $|\Psi_{\text{phys}}\rangle$. It is possible to add this open/closed vertex to the OSFT action. Remarkably, the resulting Feynman rules give a single cover of the moduli space of Riemann surfaces with at least one boundary, with open and closed punctures. This is shown using the same minimal-area problem as above, but now allowing for surfaces with closed punctures as well.

We should finally mention that the structure of OSFT emerges frequently in topological string theory, in contexts where open/closed duality plays a central role. Two examples are the interpretation of Chern–Simons theory as the OSFT for the $A$-model on the conifold, and the intepretation of the Kontsevich matrix integral for topological gravity as the OSFT on FZZT branes in $(2, 1)$ minimal string theory.

## Closed Bosonic SFT

The generalization to covariant closed SFT is nontrivial, essentially because the requisite closed-string decomposition of moduli space is much more complicated.

The free theory parallels the open case, with a minor complication in the treatment of the CFT zero modes. The closed-string field is taken to live in a subspace of the matter + ghost state space, $|\Psi\rangle \in \tilde{\mathcal{H}}_{\text{CFT}_0}$, where the tilde means that we impose the subsidiary conditions

$$b_0^- |\Psi\rangle = L_0^- |\Psi\rangle = 0, \quad b_0^- \equiv b_0 - \bar{b}_0, \quad L_0^- \equiv L_0 - \bar{L}_0 \tag{36}$$

In the classical theory, the string field carries ghost number $G = +2$, since it is the off-shell extension of the familiar closed-string physical states, and the quadratic action reads

$$S \sim \langle \Psi, Q_c \Psi \rangle \tag{37}$$

Here $Q_c$ is the usual closed BRST operator. The inner product $\langle \, , \rangle$ is defined in terms of the BPZ inner product, with an extra insertion of $c_0^- \equiv c_0 - \bar{c}_0$,

$$\langle A, B \rangle \equiv \langle A | c_0^- | B \rangle \tag{38}$$

In [37] $G_{\text{top}} = +6$, as it should be. Without the extra ghost insertion and the subsidiary conditions [36] it would not be possible to write a quadratic action. The linearized equations of motion and gauge invariance,

$$Q_c |\Psi\rangle = 0, \quad |\Psi\rangle \sim |\Psi\rangle + Q_c |\Lambda\rangle, \quad |\Lambda\rangle \in \tilde{\mathcal{H}}^{(1)}_{\text{CFT}_0} \tag{39}$$

give the expected cohomological problem. The fact that the cohomology is computed in the semirelative complex, $b_0^- |\Psi\rangle = b_0^- |\Lambda\rangle = 0$, well known from the operator formalism of the first-quantized theory, is recovered naturally in the second-quantized treatment.

The interacting action is constructed iteratively, by demanding that the resulting Feynman rules give a (unique) cover of moduli space. This requires the introduction of infinitely many elementary string vertices $\mathcal{V}_{g,n}$, where $n$ is the number of closed-string punctures and $g$ the genus. This decomposition of moduli space is more intricate than the decomposition that arises in OSFT, but is in fact analogous to it, when characterized in terms of the following.

**Minimal-area problem for closed SFT** Let $\mathcal{R}_c$ be a closed Riemann surface, possibly with punctures. Find the (conformal) metric of minimal area on $\mathcal{R}$ such that all nontrivial Jordan closed curves have length greater than or equal to $2\pi$.

The minimal-area metric induces a foliation of $\mathcal{R}_c$ by closed geodesics of length $2\pi$. In the classical theory ($g = 0$), the minimal-area metrics arise from Jenkins–Strebel quadratic differentials (as in the open case), and geodesics intersect on a measure-zero set. For $g > 0$, however, there can be foliation bands of geodesics that cross. By staring at the foliation, we can break up the surface into vertices and propagators. In correspondence with each puncture, there is a band of

infinite height, a flat semi-infinite cylinder of circumference $2\pi$, which we identify as an external leg of the diagram. We mark a closed geodesic on each semi-infinite cylinder, at a distance $\pi$ from its boundary. Bands of finite height (internal bands not associated to punctures) correspond to propagators if their height is greater than $2\pi$, otherwise they are considered part of an elementary vertex. Along any internal cylinder of height greater than $2\pi$, we mark two closed geodesics, at a distance $\pi$ from the boundary of the cylinder. If we now cut open all the marked curves, the surface decomposes into a number of semi-infinite cylinders (external legs), finite cylinders (internal propagators) and surfaces with boundaries (elementary interactions). Each elementary interaction of genus $g$ and with $n$ boundaries is an element of $\mathcal{V}_{g,n}$. A crucial point of this construction is that we took care of leaving a "stub" of length $\pi$ attached to each boundary. Stubs ensure that sewing of surfaces preserves the length condition on the metric (no closed curve shorter than $2\pi$).

These geometric data can be translated into an iterative algebraic construction of the full quantum action $S[\Psi]$. The $\mathcal{V}_{g,n}$ satisfy geometric recursion relations whose algebraic counterpart is the quantum BV master equation for $S[\Psi]$. Remarkably, the singularities of the $\Delta$ operator encountered in OSFT are absent here, precisely because of the presence of the stubs. We refer to Zwiebach (1993) for a complete discussion of closed SFT.

#### Open/Closed SFT

There is also a covariant SFT that includes both open and closed strings as fundamental variables. The Feynman rules arise from the following problem.

**Minimal-area problem for open/closed SFT** Let $\mathcal{R}_{oc}$ be a Riemann surface, with or without boundaries, possibly with open and closed punctures. Find the (conformal) metric of minimal area on $\mathcal{R}_{oc}$ such that all nontrivial Jordan open curves have length greater than or equal to $l_o = \pi$, and all nontrivial Jordan closed curves have length greater than or equal to $l_c = 2\pi$.

The surface $\mathcal{R}_{oc}$ is decomposed in terms of elementary vertices $\mathcal{V}^{g,n}_{b,m}$ (of genus $g$, $b$ boundary components, $n$ closed-string punctures and $m$ open-string punctures) joined by open and closed propagators. Degenerations of the surface correspond always to propagators becoming of infinite length – factorization is manifest both in the open and in the closed channel.

The SFT described in the section "Closed strings in OSFT" (Witten OSFT augmented with the single open/closed vertex [35]) corresponds to taking $l_o = \pi$ and $l_c = 0$. Varying $l_c \in [0, 2\pi]$, we find a whole family of interpolating SFTs. This construction clarifies the special status of the Witten theory: moduli space is covered by a single cubic open overlap vertex, with no need to introduce dynamical closed strings, but at the price of a somewhat singular formulation.

### Classical Solutions in Open SFT

In the present formulation of SFT, a background (a classical solution of string theory) must be chosen from the outset. The very definition of the string field requires to specify a (B)CFT$_0$. Intuitively, the string field lives in the "tangent" to the "theory space" at a specific point – where "theory space" is some notion of a "space of 2D (boundary) quantum field theories," not necessarily conformal. In the early 1990s independence from the choice of background was demonstrated for infinitesimal deformations: the SFT actions written using neighboring (B)CFTs are indeed related by a field redefinition. In recent years, it has become apparent that at least the open-string field reaches out to open-string backgrounds a finite distance away – possibly covering the whole of theory space. (Classical solutions of closed SFT are beginning to be investigated at the time of this writing (2005)).

The OSFT action written using BCFT$_0$ data is just the full world volume action of the D-brane with BCFT$_0$ boundary conditions. Which classical solutions should we expect in this OSFT? In the bosonic string, D$p$ branes carry no conserved charge and are unstable. This instability is reflected in the presence of a mode with $m^2 = -1/\alpha'$, the open-string tachyon $T(x^\mu), \mu = 0, \ldots, p$. From this physical picture, Sen argued that:

1. the tachyon potential, obtained by eliminating the higher modes of the string field by their equations of motion, must admit a local minimum corresponding to the vacuum with no D-brane at all (henceforth, the tachyon vacuum, $T(x^\mu) = T_0$);
2. the value of the potential at $T_0$ (measured with respect to the BCFT$_0$ point $T = 0$) must be exactly equal to minus the tension of the brane with BCFT$_0$ boundary conditions;
3. there must be no perturbative open-string excitations around the tachyon vacuum; and
4. there must be space-dependent "lump" solutions corresponding to lower-dimensional branes. For example, a lump localized along one world volume direction, say $x^1$, such that $T(x^1) \to T_0$ as $x^1 \to \pm\infty$, is identified with a D$(p-1)$ brane.

Sen's conjectures have all been verified in OSFT. (See Sen (2004) and Taylor and Zwiebach (2003) for reviews). The deceptively simple-looking equations of motion (in Siegel gauge)

$$L_0|\Phi\rangle + b_0(|\Phi\rangle * |\Phi\rangle) = 0 \qquad [40]$$

are really an infinite system of coupled equations, and no analytic solutions are known. Turning on a vacuum expectation value (VEV) for the tachyon drives into condensation an infinite tower of modes. Fortunately, the approximation technique of "level truncation" is surprisingly effective. The string field is restricted to modes with an $L_0$ eigenvalue smaller than a prescribed maximal level $L$. For any finite $L$, the truncated OSFT contains a finite number of fields and numerical computations are possible. Numerical results for various classical solutions converge quite rapidly as the level $L$ is increased.

The most important solution is the string field $|\mathcal{T}\rangle$ that corresponds to the tachyon vacuum. A remarkable feature of $|\mathcal{T}\rangle$ is universality: it can be written as a linear combination of modes obtained by acting on the tachyon $c_1|0\rangle$ with ghost oscillators and matter Virasoro operators,

$$|\mathcal{T}\rangle = T_0\, c_1|0\rangle + u\, L^m_{-2} c_1|0\rangle + v\, c_{-1}|0\rangle + \cdots$$

This implies that the properties of $|\mathcal{T}\rangle$ are independent of any detail of $\mathrm{BCFT}_0$, since all computations involving $|\mathcal{T}\rangle$ can be reduced to purely combinatorial manipulations involving the ghosts and the Virasoro algebra. The numerical results strongly confirm Sen's conjectures, and indicate that the tachyon vacuum is located at a non-singular point in configuration space. Numerical solutions describing lower-dimensional branes and exactly marginal deformations are also available. For example, the full family of solutions interpolating between a D1 and a D0 brane at the self-dual radius has been found. There is increasing evidence that the open-string field provides a faithful map of the open-string landscape.

### Vacuum SFT: D-branes as Projectors

In the absence of a closed-form expression for $|\mathcal{T}\rangle$, we are led to guesswork. When expanded around $|\mathcal{T}\rangle$, the OSFT is still cubic, only with a different kinetic term $\mathcal{Q}$,

$$S = -\kappa_0 \left[\frac{1}{2}\langle\Phi|\mathcal{Q}|\Phi\rangle + \frac{1}{3}\langle\Phi|\Phi * \Phi\rangle\right] \qquad [41]$$

The operator $\mathcal{Q}$ must obey all the formal properties [17], must be universal (constructed from ghosts and matter Virasoro operators), and must have trivial cohomology at $G = +1$. Another constraint comes from requiring that [41] admits classical solutions in Siegel gauge. The choice

$$\begin{aligned}\mathcal{Q} &= \frac{1}{2\mathrm{i}}(c(i) - \bar{c}(i)) \\ &= c_0 - (c_2 + c_{-2}) + (c_4 + c_{-4}) - \cdots\end{aligned} \qquad [42]$$

satisfies all these requirements. The conjecture (Rastelli *et al.* 2001) is that, by a field redefinition, the kinetic term around the tachyon vacuum can be cast into this form. This "purely ghost" $\mathcal{Q}$ is somewhat singular (it acts at the delicate string mid-point), and presumably should be regarded as the leading term of a more complicated operator that includes matter pieces as well. The normalization constant $\kappa_0$ is formally infinite. Nevertheless, a regulator (e.g., level truncation) can be introduced, and physical observables are finite and independent of the regulator. The vacuum SFT ([41]–[42]) appears to capture the correct physics, at least at the classical level. Taking a matter/ghost factorized ansatz

$$|\Phi_{\mathrm{g}}\rangle \otimes |\Phi_{\mathrm{m}}\rangle \qquad [43]$$

and assuming that the ghost part is universal for all D-branes solutions, the equations of motion reduce to following equations for the matter part:

$$|\Phi_{\mathrm{m}}\rangle * |\Phi_{\mathrm{m}}\rangle = |\Phi_{\mathrm{m}}\rangle \qquad [44]$$

A solution $|\Phi_{\mathrm{m}}\rangle$ can be regarded as a projector acting in "half-string space." Recall that the $*$-product looks formally like a matrix multiplication [19]: the matrices are the string fields, whose "indices" run over the half-string curves. These projector equations have been exactly solved by many different techniques (see Rastelli (2004) for a review). In particular, there is a general BCFT construction that shows that one can obtain solutions corresponding to any D-brane configuration, including multiple branes – the rank of the projector is the number of branes. A rank-one projector corresponds to an open-string functional which is left/right split, $\Phi[X(\sigma)] = F_{\mathrm{L}}(X_{\mathrm{L}})F_{\mathrm{R}}(X_{\mathrm{R}})$. There is also clear analogy between these solutions and the soliton solutions of noncommutative field theory. The analogy can be made sharper using a formalism that rewrites the open-string $*$-product as the tensor product of infinitely many Moyal products. (See Bars (2002) and references therein).

It is unclear whether or not multiple-brane solutions (should) exist in the original OSFT – they are yet to be found in level truncation. Understanding this and other issues, like the precise role of closed strings in the quantum theory seems to require a precise characterization of the allowed

space of open-string functionals. In principle, the path integral over such functionals would define the theory at the full nonperturbative level. This remains a challenge for the future.

**Note Added in Proof** Very recently, M Schnabl, building on previous work on star algebra projectors and related surface states (Rastelli L (2004) and references therein) was able to find the exact solution for the universal tachyon condensate in OSFT. This breakthrough is likely to lead to rapid new developments in SFT.

# String Theory: Phenomenology

**A M Uranga**, Consejo Superior de Investigaciones Cientificas, Madrid, Spain

## String Theory and Compactification

The string theory provides a setup in which gauge and gravitational interactions can be described in a unified framework consistently at the quantum level. As such, it provides a candidate theory in which to describe the standard model of particle physics (describing quarks and leptons and their strong and electroweak interactions) and gravity within the same quantum theory.

The string theory has a unique fundamental scale $M_s$, fixed by the string tension, often encoded in the parameter $\alpha'$ of dimension $(\text{length})^{-2}$. All other scales are derived from this one and are background dependent.

Most of the string theory phenomenological model building has centered on the critical superstrings, which are ten dimensional (10D) and involve spacetime (as well as world-sheet) supersymmetry. There are five such different 10D theories: type IIA, type IIB, type I, and the $E_8 \times E_8$ and SO(32) heterotic theories. The heterotic theories include nonabelian gauge fields and charged fermions in ten dimensions; hence, they constitute a promising setup to embed the standard model. On the other hand, the possibility of including D-branes

(which carry nonabelian gauge symmetries and charged matter) in compactifications of type II theories (and orientifolds thereof, like the type I theory itself) makes the latter reasonable alternative setups to embed the standard model as a brane world. The different 10D theories (as well as the 11D M-theory) are related by diverse dualities, also upon compactification. This suggests that they are just different limits of a unique underlying theory. For 4D models, this implies that the different classes of constructions are ultimately related by dualities, and that often a given model may be realized using different string theory constructions as starting points.

In order to recover 4D physics at low energies, compactification of the theory is required. In geometrical terms, the theory is required to propagate on a spacetime with geometry $M_4 \times X_6$, where $M_4$ is a 4D Minkowski space, and $X_6$ is a compact manifold. This description is valid in the regime of a large compactification volume, $\alpha'/R^2 \ll 1$ (where $R$ is the overall scale of the compact manifold), where $\alpha'$ string theory corrections are negligible. Other 4D string models may be constructed using abstract conformal field theories. They may often be regarded as extrapolations of geometric compactifications to the regime of sizes comparable with the string length, where string theory corrections are relevant and the classical geometric picture does not hold.

In the simplest situation of geometrical compactification, not including additional backgrounds beyond the metric, the requirement of 4D spacetime supersymmetry (useful for the stability of the model, as well as of phenomenological interest) implies that the space $X_6$ is endowed with an SU(3) holonomy metric. Existence of such metrics is guaranteed for Calabi–Yau spaces, namely Kähler manifolds with vanishing first Chern class.

There are a very large number of 4D supersymmetric string models that can be constructed using different starting string theories and different compactification manifolds. They lead to different 4D spectra, often including nonabelian gauge symmetries and charged chiral fermions (but only rarely resembling the actual standard model). In addition, for each given model, there exist, in general, a large number of massless 4D scalars, known as moduli, whose vacuum expectation values are not fixed. They parametrize different choices of the compactification data in a given topological sector (e.g., Kähler and complex structure moduli of the internal Calabi–Yau space). All physical parameters of the 4D theory vary continuously with the vacuum expectation values of these scalars.

All such models are on equal footing from the point of view of the theory. Hence, 4D string models suffer from a large arbitrariness. Although the breaking of supersymmetry clearly changes the picture qualitatively (e.g., flat directions associated to moduli are lifted by radiative corrections), it is difficult to evaluate this impact.

In this situation, most of the research in string theory phenomenology has centered on the study of generic properties of certain classes of compactifications, with the potential to lead to realistic structures (such as $N=1$ or no supersymmetry, nonabelian gauge symmetries with replicated sets of charged chiral fermions). Within each class, explicit models (as close as possible to the standard model) have also been constructed. Generic predictions or expectations for phenomenology can be obtained within each setup, but quantitative results, even for explicit models, are always functions of undetermined moduli vacuum expectation values. Tractable mechanisms for moduli stabilization are under active research, although only preliminary results are available presently.

The better-studied classes of models are compactifications of heterotic theories on Calabi–Yau spaces, and compactifications of type II theories (or orientifolds thereof) with D-branes. Other possibilities include the heterotic M-theory, the M-theory on $G_2$ holonomy varieties, the F-theory on Calabi–Yau 4-folds, etc. As already mentioned, different classes (or even explicit models) are often related by string duality.

## Heterotic String Phenomenology

A large class of phenomenologically interesting string vacua, which has been explored in depth, is provided by 4D compactifications of (any of the two) perturbative heterotic string theories. Compactification on large volume manifolds can be described in the supergravity approximation. As described by Candelas, Horowitz, Strominger, and Witten, the requirement of 4D $N=1$ supersymmetry requires the internal manifold to be of SU(3) holonomy, a condition which is satisfied by Calabi–Yau manifolds. In the presence of a curvature, the Bianchi identity for the Kalb–Ramond 2-form $B$ is modified, so that, in general, it reads

$$\mathrm{d}H = \mathrm{tr}\, R^2 - \frac{1}{30}\mathrm{tr}\, F^2 \qquad [1]$$

where $H$ is the field strength 3-form, $R$ is the Ricci 2-form, and $F$ is the field strength, in the adjoint representation, of the 10D gauge fields. Regarding the above equation in cohomology leads to a

consistency condition, forcing the background gauge bundle $V$ to be topologically nontrivial, with

$$c_2(V) = c_2(TX_6) \qquad [2]$$

where $c_2$ denotes the second Chern class, and $TX_6$ is the compactification tangent space.

The condition of supersymmetry implies that the gauge fields must be solutions of the Donaldson–Uhlenbeck–Yau equations. Existence of such a solution is guaranteed for holomorphic and stable gauge bundles. The simplest solution to these conditions is the so-called standard embedding, where the gauge connection is locally identical to the spin connection, but more general solutions exist and have been characterized for particular classes of Calabi–Yau manifolds (e.g., when they are elliptically fibered). The gauge background bundle $V$, with structure group $H$, breaks the 10D gauge symmetry $G$ to its commutant subgroup $G_{4\mathrm{D}}$. The latter corresponds to the 4D gauge symmetry. Moreover, the background bundle modifies the Kaluza–Klein reduction of the 10D charged fermions, leading to a nonzero number of replicated 4D chiral fermions. Decomposing the adjoint representation of $G$ (in which 10D fermions transform) with respect to $G_{4\mathrm{D}} \times H$,

$$\mathrm{Adj}\, G = \bigoplus_i (R_{G_{4\mathrm{D}},i}, R_{H,i}) \qquad [3]$$

the net number of 4D chiral fermions in the representation $R_{G_{4\mathrm{D}}}$ is given by the index of the Dirac operator coupled to $V$ in the representation $R_{H,i}$. Condition [1] implies proper cancellation of chiral anomalies in the resulting theory. A simple and well-studied class is provided by standard embedding compactifications of the $E_8 \times E_8$ heterotic string theory, whose unbroken 4D gauge group is $E_6 \times E_8$. The number of families (i.e., chiral multiplets in the representation 27 of $E_6$ ) and conjugate families (in the $\overline{27}$) are given by the Hodge numbers

$$n_{27} = h_{1,1}(X_6), \quad n_{\overline{27}} = h_{2,1}(X_6) \qquad [4]$$

More specifically, the harmonic representatives in each cohomology class represent the internal profile of the corresponding 4D fields. The net number of families is thus determined by the Euler characteristic $\chi(X_6)$

$$n_{\mathrm{fam}} = |h_{1,1} - h_{2,1}| = \tfrac{1}{2}|\chi(X_6)| \qquad [5]$$

Recently, much progress in heterotic model building has been achieved in nonstandard embedding compactifications by the detailed construction of holomorphic stable bundles and the computation of the diverse indexes. In particular, explicit models with just the minimal supersymmetric standard model spectrum have been constructed.

The above geometric approach has several limitations. On the technical side, the construction of explicit holomorphic and stable gauge bundles is nontrivial from the mathematical viewpoint. On the more fundamental side, it allows one to explore only the large volume limit of heterotic compactifications.

Further insight into the latter aspect can be obtained via constructions based on exactly solvable conformal field theories (CFTs), which describe the world-sheet string dynamics in compactifications, including all $\alpha'$ corrections, and, therefore, allowing one to enter the small volume regime. The simplest such compactifications are provided by toroidal orbifolds, which describe string propagation in quotients of toroidal compactifications by a discrete group $\Gamma$. From the world-sheet viewpoint, they are described by 2D free CFT, but which include sectors of closed strings with boundary conditions twisted by elements of $\Gamma$. The resulting 4D theory contains chiral fermions, arising from the untwisted and twisted sectors. In the former, the nonchiral spectrum of toroidal compactification suffers a projection onto the $\Gamma$-invariant states and leads to chirality. Twisted sectors are localized at the fixed points of the orbifold action, where the local supersymmetry is reduced, leading naturally to chiral fermions.

Many of these models can be regarded as limits of compactifications on Calabi–Yau spaces in the limit in which they become locally flat and develop conical singularities (and similarly, their gauge bundles become locally flat and with curvature localized near the singular points). Indeed, flat directions involving moduli fields in the twisted sector often exist, which correspond to geometric blow-ups of the singular point that resolve the conical singularities to yield a smooth Calabi–Yau.

The theories remain simple and solvable for any value of the untwisted moduli (namely moduli of the underlying toroidal compactification). This allows the discussion of their low-energy effective action including the explicit dependence on the untwisted moduli, while only partial results for the dependence on twisted moduli are known.

Other approaches, such as free fermion constructions or Gepner models, also provide exact descriptions of compactifications, although only at a point of the moduli space, deep inside the small volume regime.

Exact CFT constructions provide a small volume description of Calabi–Yau compactifications, at least for particular models. Moreover, their consistency conditions (modular invariance of the partition function) provide a stringy version of the large volume geometric condition implied by eqn [2]. The

constructions also show the existence of full-fledged string theory constructions with properties similar to geometric compactifications, but incorporating all $\alpha'$ corrections.

Within the general class of perturbative heterotic string models, a certain number of phenomenologically interesting statements are quite generic.

- The 4D Planck scale $M_{\rm P}$ and gauge couplings $g_{YM}$ (at the string scale) are related to the fundamental string scale by

$$M_{\rm s} = M_{\rm P} g_{YM} \qquad [6]$$

  This implies that the string scale is close to the 4D Planck scale. In this situation, supersymmetry can stabilize the electroweak scale against radiative corrections.
- 4D heterotic models contain certain U(1) symmetries, whose gauge bosons actually get Stuckelberg masses due to $B \wedge F$ couplings to components of the 2-form. Such U(1)'s would correspond to global symmetries, but are violated at tree level by $\alpha'$ nonperturbative effects, namely world-sheet instantons. Hence, no continuous global symmetries exist, even perturbatively, in these models. Proton decay might, however, be avoided by discrete global symmetries. In any event, even without such symmetries, the large fundamental scale suppresses the processes mediating proton decay. Thus, the proton lifetime is naturally larger than present experimental bounds.
- Gauge coupling constants for the different gauge factors in the standard model unify at the string scale. This agrees with extrapolation from their electroweak values, assuming the minimal supersymmetric standard model content between the electroweak and string scale, up to a mismatch of scales (by a factor of 20). The latter may be addressed in diverse ways, such as threshold corrections, intermediate scales, or in the heterotic M-theory.
- Yukawa couplings are, in principle, computable. Explicit computations have been carried out in standard embedding geometric compactifications (where they amount to the overlap integral of the internal profiles of the 4D fields, namely a topological intersection number), and in orbifold models. They are in general moduli dependent, so their quantitative analysis is involved. Qualitatively, however, interesting patterns, such as hierarchical structures, are possible, for example, in specific orbifold models.

Heterotic models have been studied beyond the perturbative regime. For instance, the construction of compactifications including nonperturbative objects, namely 5-branes, has been pursued; so has been the strong coupling limit of the $E_8 \times E_8$ heterotic, described by compactifications of the M-theory on an interval (the so-called heterotic M-theory or Horava–Witten theory). The strong coupling phenomena of the SO(32) heterotic theory can be addressed using dual type I (or other type II orientifold) constructions.

## D-Brane Phenomenology

A different setup for realistic string theory compactifications, within the so-called brane-world constructions, is provided by compactifications of type II string theories containing D-branes, or quotients thereof. A particularly relevant class of quotients involves quotienting out by world-sheet parity, accompanied by some $Z_2$ geometric action. The resulting theories are denoted type II orientifolds, and contain orientifold planes, subspaces fixed under the geometric action, corresponding to regions where the orientation of a string can flip. Type II compactifications with D-branes filling the noncompact dimensions must satisfy a set of consistency conditions, known as RR tadpole cancellation. This is the condition that, in the compact space, the charge of D-branes and orientifold planes under the different RR forms must cancel. For the $Z$-valued charges, the conditions read

$$\sum_a N_a Q_a + Q_{\rm Op} = 0 \qquad [7]$$

where $N_a$ denotes the multiplicity of D-branes with charge vector and $Q_a$ under the RR fields, $Q_{\rm Op}$ is the charge vector of the orientifold planes. Additional discrete conditions may be present if the relevant K-theory group (classifying D-brane charges in the corresponding background) contains torsion pieces.

The most familiar example of these constructions is provided by the type I string theory, which is an orientifold quotient of the type IIB theory by world-sheet parity (with no geometric action). The model can be regarded as containing one orientifold 9-plane and 32 D9 branes (all filling out 10D spacetime), such that their RR charges with respect to the (nondynamical) RR 10-form cancel.

Supersymmetric geometric compactifications of type II theories and orientifolds must correspond to compactification on Calabi–Yau spaces in order to have a preserved spinor. Models with D-branes filling the noncompact dimensions may be broadly classified into two classes: type IIB compactifications with $D(3 + 2p)$-branes, wrapped on holomorphic $2p$-cycles, and carrying holomorphic and stable

world-volume gauge bundles, and type IIA compactifications with D6 branes wrapped on special Lagrangian 3-cycles (in general, models with D4 and D8 branes are not allowed since Calabi–Yau spaces do not have nontrivial 1- or 5-cycles on which to wrap the branes). This classification is a large volume realization of the general classification of supersymmetric configurations of D-branes into two classes, denoted A and B.

### Intersecting Brane Worlds

Type IIA compactifications with A-branes correspond to compactifications of type IIA theory (or orientifolds thereof) with D6 branes wrapped on 3-cycles of the internal Calabi–Yau space. In these models, each stack of $N$ D6 branes generically leads to a U($N$) gauge factor. Chirality arises from open strings stretched between pairs of branes at the corresponding intersections. The chiral fermions from an open string stretched between branes $a$ and $b$ transform in the bifundamental representation $(\square_a, \overline{\square}_b)$ of the gauge factors $U(N_a) \times U(N_b)$ of the intersecting D6 brane stacks. In general, two 3-cycles in a 6D manifold intersect at points of the internal space. Hence, such fermions arise in several families, whose (net) number is given by the (net) number of intersections of the corresponding 3-cycles $\Pi_a, \Pi_b$, namely the topological invariant intersection number of their homology classes

$$I_{ab} = [\Pi_a] \cdot [\Pi_b] \qquad [8]$$

Simple modifications of the above rules arise in some sectors in the presence of orientifold planes (e.g., the reduction of the gauge symmetry from unitary to orthogonal or symplectic factors for branes on top of orientifold planes).

The RR tadpole cancellation conditions specify that the total homological charge carried by the D6 branes (and the orientifold 6-planes) cancel. They imply automatic cancellation of cubic nonabelian anomalies, and the cancellation of mixed U(1) anomalies by a Green–Schwarz mechanism mediated by 4D scalars from the RR closed-string sector.

Explicit models with SM spectrum have been constructed in orientifolds of toroidal compactifications in the nonsupersymmetric case, and in orbifolds thereof in supersymmetric cases. The generalization of the above construction beyond toroidal situations is, in principle, possible, but difficult, due to the mathematically challenging task of constructing special Lagrangian submanifolds for general Calabi–Yau manifolds.

Certain phenomenologically interesting quantities, such as gauge couplings and their threshold corrections, Yukawa couplings, and other diverse correlation functions have been computed in toroidal cases, where the corresponding correlators are computable exactly in $\alpha'$. Particularly interesting is the computation of Yukawa couplings, or, in general, of couplings involving only fields at intersections. These couplings arise from open-string world-sheet instantons, namely disks with boundaries on the D-branes corresponding to those intersections.

### Type IIB Orientifolds

Type IIB compactifications with B-type branes contain several familiar classes of 4D models, for instance, compactifications of type I string theory on smooth Calabi–Yau spaces (whose description may be carried out using the effective supergravity action, in close analogy with the heterotic compactifications). Compactifications of type I string theory on orbifolds can be regarded as a particular realization of this, easily described using exact CFTs (although from the viewpoint of the general description as B-branes, the appearance of lower-dimensional branes requires their mathematical description to involve coherent sheaves). Since open strings at orbifolds do not have twisted boundary conditions, chirality arises from the orbifold projection of the toroidally compactified theory on the spectrum.

Another example within this kind is provided by the so-called magnetized D-brane models. These correspond to toroidal compactifications of type I theory, with D9 branes carrying constant magnetic backgrounds for the internal components of the world-volume gauge fields. In this kind of model, although the closed-string sector is highly supersymmetric, the open-string spectrum has reduced supersymmetry, or no supersymmetry (if the bundle stability condition is relaxed). Chirality arises from the nontrivial index of the Dirac operator for open strings ending on D-branes with different world-volume magnetic fields. Explicit models have mainly centered on nonsupersymmetric models from orientifolds of $T^6$, and on supersymmetric models from orientifolds of the $T^6/(Z_2 \times Z_2)$ orbifold. In both contexts, models with semirealistic spectra have been obtained: concretely nonsupersymmetric models with just the standard model spectrum, or supersymmetric models with the minimal supersymmetric standard model spectrum, plus nonchiral matter. Further, properties of the gauge coupling constants and the computation of the Yukawa couplings have been studied as functions of undetermined moduli.

Finally, a second large class of models constructed using B-type branes are given by lower-dimensional D-branes, for example, D3 branes, located at singular points in the internal compactification space. Since the massless sector of open strings is determined only in terms of the local structure of the singularity, these models have been mostly studied in noncompact setups. Resulting spectra can be encoded in quiver diagrams, related to those in the mathematical literature on the McKay correspondence. Semirealistic three-family models have been constructed based on systems of D3 and D7 branes at the $C^3/Z_3$ orbifold singularity.

Type IIB orientifold compactifications are also intimately related to F-theory compactifications on Calabi–Yau 4-folds, which provide a nonperturbative completion for such models.

Mirror symmetry exchanges type IIB and IIA compactifications with B- and A-type branes. Hence, it provides a map between the above two kinds of compactifications. This shows that type IIB orientifold models lead to spectra with structure similar to that of intersecting-branes worlds, and that they share many of their general properties.

As a particular example, toroidal models of intersecting D6 branes are mapped under mirror symmetry to models of magnetized D9 branes. This mirror map has been exploited to construct the same theories from both starting points and to recover certain quantities, such as the $\alpha'$-exact Yukawa couplings in the IIA picture from a purely classical (no $\alpha'$ corrections) computation in the mirror IIB model. This is a particular application of the general proposal of homological mirror symmetry in compactifications with branes.

Type II orientifold compactifications with D-branes have also been explored beyond the geometric regime, using exact CFTs to describe the (analog of the) internal space, and crosscap and boundary states to describe (the analogs of) orientifold planes and D-branes. Formal developments in the construction of the latter in Gepner models have been successfully applied to obtain large classes of semirealistic 4D string models in this setup.

As compared with heterotic compactifications, the setup of D-brane models leads to several generic features:

- Since gauge sectors are localized on D-branes, and have a dilaton dependence different from gravitational interactions, the relation between the fundamental string scale and the 4D Planck scale and gauge coupling reads

$$M_{\mathrm{P}}^2 g_{YM}^2 = \frac{M_{\mathrm{s}}^{11-p} V_{\mathrm{T}}}{g_{\mathrm{s}}} \qquad [9]$$

  where $V_{\mathrm{T}}$ is a measure of the volume in the directions transverse to the brane, and $g_{\mathrm{s}}$ is the 10D string coupling. The above relation shows that it is possible to achieve large 4D Planck mass with a lower fundamental string scale by adjusting the transverse volume and the string coupling. This has been proposed by Antoniadis, Arkani-Hamed, Dimopoulos, and Dvali as an alternative to explain the Planck/weak hierarchy without supersymmetry.
- The compactifications contain several U(1) gauge symmetries. For some of the corresponding gauge bosons, the 4D effective theory contains Stuckelberg masses of order $M_{\mathrm{s}}$, due to $B \wedge F$ couplings to fields in the RR sector. These couplings make the U(1) gauge bosons massive; hence, they are absent from the low-energy physics. Nevertheless, the U(1)'s remain as global symmetries exact in $\alpha'$ and to all orders in the perturbation theory in $g_{\mathrm{s}}$. They are violated by D-brane instantons, which are nonperturbative in $g_{\mathrm{s}}$. In many realistic models, the baryon number is one such global symmetry, and it prevents proton decay, even if the string scale is not large.
- In general, each gauge factor in the standard model arises from a different brane stack, and their gauge couplings at the string scale are controlled by different moduli. This implies that, generically, it is not natural to have gauge coupling unification in D-brane models. Particular models may enjoy enhanced discrete global symmetries at special points in moduli space where unification is achieved, thus making unification appear more natural in such examples. Similar statements apply for constructions which realize complete or partial unification of gauge groups at large scales (like string models of grand unification or of Pati–Salam type).
- As already mentioned, important quantities such as Yukawa couplings are, in principle, computable, although quantitative expressions have been derived only in a few examples, mostly in toroidal compactifications or quotients thereof. The results are moduli dependent, making it difficult to derive model-independent patterns.

## M-Theory Phenomenology

Most of the phenomenological models from the M-theory have been constructed using the Horava–Witten theory (compactification of M-theory on $S^1/Z_2$) as starting point. This theory provides a description of the strong coupling regime of the $E_8 \times E_8$ heterotic theory, and many of its basic features are similar to those in the perturbative regime. In particular, the techniques used in model

building involve the construction of stable and holomorphic vector bundles and the computation of the relevant indexes to obtain the 4D gauge group and charge matter content. An important difference is that gauge interactions propagate only over the 10D boundaries of spacetime, while gravity propagates over the 11 dimensions. This makes the setup share some features of brane-world constructions, and, in particular, it allows one to lower the fundamental scale of the theory (the 11D Planck scales) to reconcile it with the traditional unification scale.

A different setup for M-theory phenomenology involves the compactification of the 11D theory on a 7-manifold of $G_2$ holonomy $X_7$, in order to lead to $N=1$ supersymmetry in four dimensions. Although a fundamental formulation of the M-theory is lacking, duality arguments and indirect evidence can be used to show that nonabelian gauge symmetries of the A–D–E classical groups arise if $X_7$ contains 3-cycles of codimension-4 singularities, locally of the form $C^2/\Gamma$, with $\Gamma$ an A–D–E Kleinian subgroup of SU(2). Similarly, it can be shown that chiral multiplets charged under these gauge symmetries arise if $X_7$ contains certain codimension-7 singularities. The local geometry of the latter has been explicitly described, and can be regarded as lying at the intersections of codimension-4 singularities.

The direct construction of such singular $G_2$ holonomy manifolds is very difficult, and there are no known topological conditions that guarantee existence of such a metric for a fixed topology. However, the existence of large classes of such models can be indirectly shown by using duality arguments. Namely, any type IIA models of intersecting D6 branes and O6 planes, preserving $N=1$ supersymmetry, lifts to an M-theory compactification on a singular $G_2$ holonomy manifold. In fact, the local structure of the codimension-4 and -7 singularities agrees in particular cases with the local structure of D6 branes on 3-cycles and D6 brane intersections.

## Further Topics

Some additional topics related to the phenomenology of the string theory, but not covered by the above model building description are discussed in the following.

### Effective Actions

The construction of effective actions for such classes of models has been carried out in general in supersymmetric compactifications, using the parametrization of the general 4D $N=1$ supergravity action in terms of the Kähler potential for the moduli and matter fields, the gauge kinetic functions, and the superpotential. The moduli action is quite universal, at least for geometric compactifications and for untwisted moduli in orbifold compactifications. For instance, the Kähler potential for the 4D dilaton multiplet $S$ and the modulus $T$ controlling the size of the internal manifold, in the large volume and weak coupling regime, reads

$$K = -\log(S+S^*) - 3\log(T+T^*) \qquad [10]$$

The corresponding expression including matter fields is more model dependent, but known within each particular class.

### Moduli Stabilization and Supersymmetry Breaking

Both issues are often related. Although moduli stabilization preserving supersymmetry is possible, it often occurs that the potential stabilizing moduli has its origin in mechanisms related to supersymmetry breaking.

The description of purely string theoretical mechanisms to break supersymmetry is difficult, and most approaches rely on field-theoretical mechanisms in the effective action. One of the better-studied mechanisms, mostly in the heterotic string setup (but also in type II compactifications), is gaugino condensation in a strongly coupled hidden sector, interacting with the standard model sector via gravitational (or perhaps additional gauge) interactions. Although explicit models with such hidden sectors and strong dynamics exist, they often result in runaway potentials for moduli. Racetrack scenarios where several condensates balance each other are possible but contrived.

A second mechanism to break supersymmetry, mostly explored in type IIB/F-theory compactifications, is the introduction of field-strength fluxes for $p$-form fields. Interestingly, such fluxes lead to nontrivial potentials depending on moduli, and generically breaking supersymmetry. The existence of several remnant flat directions in the leading $\alpha', g_s$ approximation, leaves unanswered the question of possible runaway moduli potentials in those directions. However, evidence for nonperturbative contributions stabilizing the remaining moduli at finite distance has been proposed. Preliminary results in the analysis of flux stabilized vacua have been obtained in simple examples of (still unrealistic) Calabi–Yau compactifications with small number of moduli.

Most explored mechanisms propose supersymmetry breaking below the Kaluza–Klein compactification

scale, and, therefore, can be described in the 4D effective theory. They can be nicely parametrized in terms of vacuum expectation values for the dilaton and geometric moduli of the compactification. This description allows for a computation of the soft terms using the expansion of the $N = 1$ supergravity formulas in components. Concrete patterns, such as the universality of squark masses, or the complex phases of diverse soft terms, can be explored using this approach.

Alternative mechanisms of breaking supersymmetry at higher scales, such as the introduction of antibranes or nonsupersymmetric compactifications, lead to generic difficulties with stability.

Related to the question of supersymmetry breaking is the question of the cosmological constant. Unfortunately, there is no manifest mechanism in the string theory that explains the smallness of the observed value of this scale. Given that many aspects of both quantum gravity in the string theory and realistic model building (with proper supersymmetry breaking and moduli stabilization) are still under progress, an open-minded point of view on this problem and the proposed solutions is kept.

### Cosmology

Although somewhat different from the traditional focus of string phenomenology, recent progress in observational cosmology has triggered much interest in string theory realizations of inflationary models (or alternatives such as pre-big bang scenarios). Most inflationary models have centered on using moduli as the inflaton field, due to their flat potentials. A simple setup in type II compactifications, known as brane inflation models, uses the modulus controlling a brane position as the inflaton field, which has a flat enough potential with a moderate fine-tuning. Such setups may lead to interesting additional features, such as a moderate but potentially observable density of cosmic strings created in the reheating process.

On the other hand, many interesting questions in string cosmology await further understanding of time-dependent backgrounds in the string theory.

## Retrospect

It is remarkable that the formal framework of the string theory admits tractable solutions with reasonable resemblance to the structure of the standard model. In particular, generic features such as nonabelian gauge symmetry and chirality, coupled to gravity, are generic in 4D compactifications. This is already a success. In addition, much progress has been made in the general description of the relevant mathematical tools, and physical mechanisms and ingredients involved in these vacua, as well as in the explicit construction of models with the standard model spectrum (or supersymmetric extensions of it). Yet, many questions remain open and much more work is needed in order to make contact with the physics observed in nature.

# String Topology: Homotopy and Geometric Perspectives

**R L Cohen**, Stanford University, Stanford, CA, USA

String topology is a new field of study involving the geometric and algebraic topology of spaces of loops and paths in manifolds. The subject was initiated in the important work of Chas and Sullivan (1999) who uncovered previously unknown algebraic structure in the homology and equivariant homology of loop spaces. While the structure is purely topological, it was motivated by formalisms in quantum field theory and string theory. Since that time this subject has attracted the attention of many mathematicians, but one of the main lines of research continues to be motivated by the attempt to understand the relation between this structure (and its generalizations) with topological and conformal field theories.

In order to describe some of the recent advances in this field, we begin with some notation. Throughout this article $M^n$ will denote a closed, $n$-dimensional, oriented manifold. $LM$ will denote the free loop space,

$$LM = \mathrm{Map}(S^1, M)$$

For $D_1, D_2 \subset M$ closed submanifolds, $\mathcal{P}_M(D_1, D_2)$ will denote the space of paths in $M$ that start at $D_1$ and end at $D_2$,

$$\mathcal{P}_M(D_1, D_2) = \{\gamma : [0,1] \to M, \gamma(0) \in D_1, \gamma(1) \in D_2\}$$

The paths and loops we consider will always be assumed to be piecewise smooth. Such spaces of paths and loops are well known to be infinite-dimensional manifolds, and roughly speaking, string topology is the study of the intersection theory in these manifolds.

Recall that for closed, oriented manifolds, there is an intersection pairing,

$$H_r(M) \times H_s(M) \to H_{r+s-n}(M)$$

which is defined to be Poincaré dual to the cup product,

$$H^{n-r}(M) \times H^{n-s}(M) \xrightarrow{\cup} H^{2n-r-s}(M)$$

The geometric significance of this pairing is that if the homology classes are represented by submanifolds, $P^r$ and $Q^s$ with transverse intersection, then the image of the intersection pairing is represented by the geometric intersection, $P \cap Q$.

The remarkable result of Chas and Sullivan says that even without Poincaré duality, there is an intersection type product

$$\mu : H_p(LM) \times H_q(LM) \to H_{p+q-n}(LM)$$

that is compatible with both the intersection product on $H_*(M)$ via the map $ev : LM \to M (\gamma \to \gamma(0))$, and with the Pontrjagin product in $H_*(\Omega M)$.

The construction of this pairing involves consideration of the diagram,

$$LM \xleftarrow{\gamma} \mathrm{Map}(8, M) \xrightarrow{e} LM \times LM \qquad [1]$$

Here $\mathrm{Map}(8, M)$ is the mapping space from the figure 8 to $M$, which can be viewed as the subspace of $LM \times LM$ consisting of those pairs of loops that agree at the basepoint. $\gamma : \mathrm{Map}(8, M) \to LM$ is the map on mapping spaces induced by the pinch map $S^1 \to S^1 \vee S^1$.

Chas and Sullivan constructed this pairing by studying intersections of chains in loop spaces. A more homotopy-theoretic viewpoint was taken by Cohen and Jones (2002) who viewed $e : \mathrm{Map}(8, M) \to LM \times LM$ as an embedding, and showed there is a tubular neighborhood homeomorphic to a normal given by the pullback bundle, $ev^*(TM)$, where $ev : LM \to M$ is the evaluation map mentioned above. They then constructed a Pontrjagin–Thom collapse map whose target is the Thom space of the normal bundle, $\tau_e : LM \times LM \to \mathrm{Map}(8, M)^{ev^*(TM)}$. Computing $\tau_e$ in homology and applying the Thom isomorphism defines an "umkehr map,"

$$e_! : H_*(LM \times LM) \to H_{*-n}(\mathrm{Map}(8, M))$$

The Chas–Sullivan loop product is defined to be the composition

$$\mu_* = \gamma_* \circ e_! : H_*(LM \times LM) \to H_{*-n}(\mathrm{Map}(8, M)) \to H_{*-n}(LM)$$

Notice that the umkehr map $e_!$ can be defined for a generalized homology theory $h_*$ whenever one has a Thom isomorphism of the tangent bundle, $TM$, which is to say a generalized homology theory $h_*$ for which the representing spectrum is a ring spectrum, and which supports an orientation of $M$.

By twisting the Pontrjagin–Thom construction by the virtual bundle $-TM$, one obtains a map of spectra,

$$\tau_e : LM^{-TM} \wedge LM^{-TM} \to \mathrm{Map}(8, M)^{ev^*(-TM)}$$

where $LM^{-TM}$ is the Thom spectrum of the pullback of the virtual bundle $ev^*(-TM)$. Now we can compose, to obtain a multiplication,

$$LM^{-TM} \wedge LM^{-TM} \xrightarrow{\tau_e} \mathrm{Map}(8, M)^{ev_0^*(-TM)} \xrightarrow{\gamma} LM^{-TM}$$

The following was proved by Cohen and Jones (2002).

**Theorem 1** *Let M be a closed manifold, then $LM^{-TM}$ is a ring spectrum. If M is orientable the ring structure on $LM^{-TM}$ induces the Chas–Sullivan loop product on $H_*(LM)$ by applying homology and the Thom isomorphism.*

The ring structure on the spectrum $LM^{-TM}$ was also observed by Dwyer and Miller using different methods.

Cohen and Godin (2004) generalized the loop product in the following way. Observe that the figure 8 is homotopy equivalent to the pair of pants surface $P$, which we think of as a genus 0 cobordism between two circles and one circle.

Furthermore, **Figure 1** is homotopic to the diagram of mapping spaces,

$$LM \xleftarrow{\rho_{\text{out}}} \text{Map}(P, M) \xrightarrow{\rho_{\text{in}}} (LM)^2$$

where $\rho_{\text{in}}$ and $\rho_{\text{out}}$ are restriction maps to the "incoming" and "outgoing" boundary components of the surface $P$. So the loop product can be viewed as a composition,

$$\begin{aligned}\mu &= \mu_P \\ &= (\rho_{\text{out}})_* \circ (\rho_{\text{in}})_! : (H_*(LM))^{\otimes 2} \to H_*(\text{Map}(P, M)) \\ &\quad \to H_*(LM)\end{aligned}$$

where using the figure 8 to replace the surface $P$ can be viewed as a technical device that allows one to define the umkehr map $(\rho_{in})_!$.

In general if one considers a surface of genus $g$, viewed as a cobordism from $p$ incoming circles to $q$ outgoing circles, $\Sigma_{g,p+q}$, one gets a similar diagram (**Figure 2**)

$$(LM)^q \xleftarrow{\rho_{\text{out}}} \text{Map}(\Sigma_{g,p+q}, M) \xrightarrow{\rho_{\text{in}}} (LM)^p$$

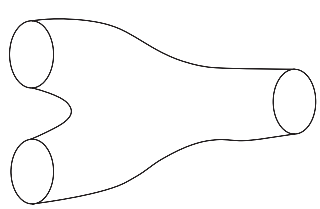

**Figure 1** Pair of pants *P*.

Cohen and Godin (2004) used the theory of "fat" or "ribbon" graphs to represent surfaces as developed by Harer (1985), Penner (1987), and Strebel (1984), in order to define Pontrjagin–Thom maps,

$$\tau_{\Sigma_{g,p+q}} : (LM)^p \to \text{Map}(\Sigma_{g,p+q}, M)^{\nu(\Sigma_{g,p+q})}$$

where $\nu(\Sigma_{g,p+q})$ is the appropriately defined normal bundle of $\rho_{\text{in}}$. By applying (perhaps generalized) homology and the Thom isomorphism, they defined the umkehr map,

$$(\rho_{\text{in}})_! : H_*((LM)^p) \to H_{*+\chi(\Sigma_{g,p+q})\cdot n}(\text{Map}(\Sigma_{g,p+q}, M))$$

where $\chi(\Sigma_{g,p+q}) = 2 - 2g - p - q$ is the Euler characteristic. Cohen and Godin then defined the string topology operation to be the composition,

$$\begin{aligned}\mu_{\Sigma_{g,p+q}} = \rho_{\text{out}} \circ (\rho_{\text{in}})_! : H_*((LM)^p) \to H_{*+\chi(\Sigma_{g,p+q})\cdot n} \\ \times (\text{Map}(\Sigma_{g,p+q}, M)) \to H_{*+\chi(\Sigma_{g,p+q})\cdot n}((LM)^q)\end{aligned}$$

They proved that these operations respect gluing of surfaces,

$$\mu_{\Sigma_1 \# \Sigma_2} = \mu_{\Sigma_2} \circ \mu_{\Sigma_1}$$

where $\Sigma_1 \# \Sigma_2$ is the glued surface as shown in **Figure 3**.

The coherence of these operations is summarized in the following theorem.

**Theorem 2** (Cohen and Godin 2004). *Let $h_*$ be any multiplicative generalized homology theory that supports an orientation of M. Then the assignment*

$$\Sigma_{g,p+q} \to \mu_{\Sigma_{g,p+q}} : h_*((LM)^p) \to h_*((LM)^q)$$

*is a positive boundary topological quantum field theory. "Positive boundary" refers to the fact that the number of outgoing boundary components, q, must be positive.*

A theory with open strings was initiated by Sullivan (2004) and developed further by A Ramirez (2005) and by Harrelson (2004). In this

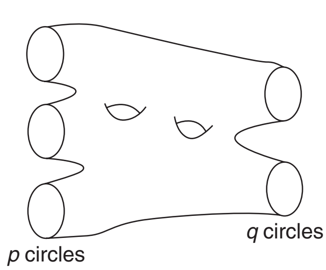

**Figure 2** $\Sigma_{g,p+q}$.

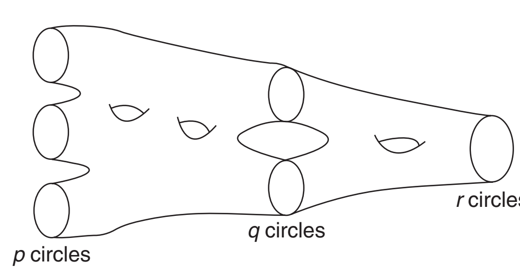

**Figure 3** $\Sigma_1 \# \Sigma_2$.

setting one has a collection of submanifolds, $D_i \subset M$, referred to as "D-branes." This theory studies intersections in the path spaces $P_M(D_i, D_j)$.

A theory with D-branes involves "open–closed cobordisms" which are cobordisms between compact one-dimensional manifolds whose boundary is partitioned into three parts:

1. Incoming circles and intervals.
2. Outgoing circles and intervals.
3. The rest is the "free boundary" which is itself a cobordism between the boundary of the incoming and boundary of the outgoing intervals. Each connected component of the "free boundary" is labeled by a D-brane (see **Figure 4**).

In a topological field theory with D-branes, one associates to each boundary circle a vector space $V_{S^1}$ (in our case $V_{S^1} = H_*(LM)$) and to an interval whose endpoints are labeled by $D_i, D_j$, one associates a vector space $V_{D_i,D_j}$ (in our case $V_{D_i,D_j} = H_*(P_M(D_i, D_j))$).

To an open–closed cobordism as above, one associates an operation from the tensor product of these vector spaces corresponding to the incoming boundaries to the tensor product of the vector spaces corresponding to the outgoing boundaries. Of course, these operations have to respect the relevant gluing of open–closed cobordisms.

By developing a theory of fat graphs that encode the open–closed boundary data, Ramirez was able to prove that there are string topology operations that form a positive boundary, topological quantum field theory with D-branes (Ramirez 2005).

We end these notes by a discussion of three applications of string topology to classifying spaces of groups.

**Example 1** Application to Poincaré duality groups – (Abbaspour *et al.* to appear). For $G$ any discrete group, one has that the loop space of the classifying space satisfies

$$LBG \simeq \coprod_{[g]} BC_g$$

where $[g]$ is the conjugacy class determined by $g \in G$, and $C_g < G$ is the centralizer of $g$.

When $BG$ is represented by a closed manifold, or more generally, when $G$ is a Poincaré duality group, the Chas–Sullivan loop product then defines pairings among the homologies of the centralizer subgroups. Abbaspour *et al.* describe this loop product entirely in terms of group homology, thus giving structure to the homology of Poincaré-duality groups that previously had not been known.

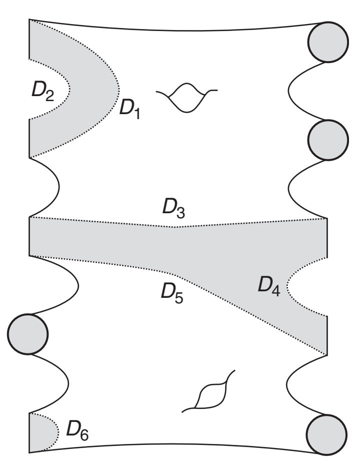

**Figure 4** Open–closed cobordism.

**Example 2** Applications to 3-manifolds. (Abbaspour 2005). Let $\iota : H_*M \to H_*(LM)$ be induced by inclusion of constant loops. This is a split injection of rings. Write $H_*(LM) = H_*(M) \oplus A_M$. We say $H_*(LM)$ has nontrivial extended loop products if the composition

$$A_M \otimes A_M \hookrightarrow H_*(LM) \otimes H_*(LM) \xrightarrow{\mu} H_*(LM)$$

is nontrivial.

Let $M$ be a closed, irreducible 3-manifold. In a remarkable piece of work, Abbaspour showed the relationship between having a trivial extended loop product and $M$ being "algebraically hyperbolic." This means that $M$ is a $K(\pi, 1)$ and its fundamental group has no rank-2 abelian subgroup. (If geometrization conjecture is true, this is equivalent to $M$ admitting a complete hyperbolic metric.)

**Example 3** The string topology of classifying spaces of compact Lie groups (Gruher (to appear) and of Gruher and Salvatore (to appear)). The goal of Gruher's work is to construct string topological invariants of $LBG \simeq EG \times_G G$, where $G$ acts on itself via conjugation. Ultimately, one would like to understand the relationship between this structure and the work of Freed (2003) on twisted equivariant $K$-theory, $K_G^\tau(G)$ and the Verlinde algebra.

The first observation in this program was to notice that the key ingredient in the forming of the Chas–Sullivan loop product is that the fibration $ev : LM \to M$ is a fiberwise monoid over a closed oriented manifold. The fiber is $\Omega M$, which has the usual Pontrjagin product.

The following was proved by Gruher and Salvatore:

**Lemma 3** *Let $G \to E \to M$ be a fiberwise monoid over a closed manifold $M$. Then $E^{-TM}$ is a ring spectrum.*

The following construction gives a large supply of examples of such fiberwise monoids over manifolds.

Let $G \to P \to M$ be a principal $G$ bundle over a closed manifold $M$. We can construct the corresponding adjoint bundle,

$$\mathrm{Ad}(P) = P \times_G G \to M$$

It is an easy observation that $G \to \mathrm{Ad}(P) \to M$ is a fiberwise monoid.

**Theorem 4** $\mathrm{Ad}(P)^{-TM}$ *is a ring spectrum. This ring structure is natural with respect to maps of principal G-bundles.*

Let $BG$ be classifying space of compact Lie groups. It is possible to construct a filtration of $BG$,

$$M_1 \hookrightarrow M_2 \hookrightarrow \cdots \hookrightarrow M_i \subset M_{i+1} \hookrightarrow \cdots \hookrightarrow BG$$

where the $M_i$'s are compact, closed manifolds. An example of this is filtering $BU(n)$ by Grassmannians.

Let $G \to P_i \to M_i$ be the restriction of $EG \to BG$. By the above theorem one obtains an inverse system of ring spectra

$$P_1^{-TM_1} \leftarrow P_2^{-TM_2} \leftarrow \cdots \leftarrow P_i^{-TM_i} \leftarrow P_{i+1}^{-TM_{i+1}} \leftarrow \cdots$$

**Theorem 5** *The homotopy type of this pro-ring-spectrum is a well-defined invariant of BG. It is referred to as the "string topology of BG."*

## Potential Application: Twisted K-theory and the Verlinde Algebra

Let $G$ be a connected, compact Lie group. Using the observation that the loop space of a classifying space is the classifying space of the loop group, $L(BG) \simeq B(LG)$, the string topology gives new structure on the classifying space of these loop groups. In particular, one has new structure on the $K$-theory of these classifying spaces. Now classical results of Atiyah and Segal suggest that $K$-theory of classifying spaces should be related to the representation theory of the group. In this case, the representation theory of loop groups has been widely studied and is very important in conformal field theory.

Understanding the precise relationship between the string topology of the classifying space and this representation theory is an interesting area of current research. To motivate this, first recall that the loop space, $LBG$, has a well-known description as

$$LBG \simeq EG \times_{\mathrm{Ad}} G$$

where the right-hand side refers to the homotopy orbit space of the conjugation (or adjoint) action of $G$ on itself. Thus, the homology $H_*(LBG)$ is the equivariant homology $H_*^G(G)$. Similarly, the $K$-theory $K^*(LBG)$ maps to the equivariant $K$-theory, $K_G^*(G)$. Now in recent work of Freed (2003) twisted equivariant $K$-homology, $K_G^\tau(G)$ was shown to be isomorphic to the Verlinde algebra. This algebra is a space of representations of the loop group, $LG$. The multiplication in this algebra is the "fusion product," coming from conformal field theory. One topic of current research is to understand the relationship between multiplicative structure coming from the string topology of $BG$, and this fusion product in the Verlinde algebra. More generally, the goal is to bring to bear the considerable calculational techniques of algebraic topology that are available in string topology, to understand the recently uncovered field theoretic structure of twisted $K$-theory (Freed 2003), and its applications to string theory.

# Superfluids

**D Einzel**, Bayerische Akademie der Wissenschaften, Garching, Germany

## Introduction

Superfluidity has been known to exist since the 1930s. This widespread phenomenon occurs in many-particle Bose and Fermi systems as different as liquid $^4$He, liquid $^3$He, atomic gases like Rb and Li, atomic nuclei, pulsars and last, but not least, in metals, where the itinerant electrons may become superfluid. This article is devoted to a unifying theoretical description of Bose and Fermi superfluidity. The mechanisms leading to superfluidity include Bose–Einstein condensation (BEC) and Bardeen, Cooper, and Schrieffer (BCS)–Leggett pairing correlations. We hope to be able to demonstrate why this fascinating phenomenon is – even roughly 80 years after its experimental discovery and its first theoretical explanation – still a subject of intensive research.

The phenomenon of superfluidity is closely connected with the apparent lack of any measurable flow resistance, which scales with the shear viscosity of the fluid. Its complete absence implies that the system is frictionless moving with zero viscosity. The observation of superfluidity is usually precluded by the solidification of most liquids as the temperature is lowered. Only systems with particularly light atoms (like the helium isotopes $^4$He and $^3$He) stay liquid down to the lowest temperatures. These systems are referred to as "quantum liquids," since their liquid state is caused by the quantum-mechanical zero-point motion of the atoms. It should be noted that the Helium isotopes belong to two different kinds of elementary particles which can be distinguished by their statistics: $^4$He is a spin-0 boson and $^3$He a spin-1/2 fermion.

In 1924, Satyendra Nath Bose and Albert Einstein proposed that below a characteristic degeneracy temperature $T_B$, a macroscopic number of bosons can condense into the state of lowest energy $\epsilon_k = 0$. In the 1930s, Fritz London and Heinz London showed that this so-called Bose–Einstein condensate can be described by a macroscopic quantum-mechanical wave function like the one for a single elementary particle, but with the probability density replaced by the density of the condensed particles. By the end of the 1930s, the experimental results of Allen, Kamerlingh–Onnes, Keesom, Kapitza, Miesener, Wolfke, and others accumulated the evidence that liquid $^4$He undergoes a second-order phase transition at $T_\lambda = 2.17\,K$ to a state referred to as a superfluid, since the liquid could flow without any sign of a flow resistance. This superfluid state was interpreted in terms of Bose condensation of the $^4$He atoms in the liquid (London 1938).

In Figure 1 the $P$–$T$ phase diagram of liquid $^4$He is shown with a normal liquid phase, a solid phase and the superfluid phase below the $\lambda$-line at about 2 K.

Fermions cannot condense in a way similar to the BEC, due to the Pauli exclusion principle. In 1957 Bardeen, Cooper, and Schrieffer came up with their ingenious proposal that the superfluidity of the electron system (usually referred to as superconductivity) comes about through the formation of fermion pairs (quasibosons) in $\boldsymbol{k}$-space in a spin-singlet state. In 1971, several superfluid phases of liquid $^3$He at a few mK were discovered by Lee, Osheroff, and Richardson at Cornell University. Experimental aspects connected with the spin degrees of freedom of the quantum liquid gave strong evidence for Cooper pairing of the $^3$He atoms in a spin-triplet state. In Figure 2 the zero-field $P$–$T$ phase diagram of liquid $^3$He is shown with a normal (Fermi) liquid phase, a solid phase and the superfluid A and B phases.

Immediately after this discovery, Anthony J Leggett applied the BCS ideas to liquid $^3$He and introduced a generalized scheme, that allowed for triplet-pairing correlations. His theory turned out to describe a large variety of experimental results accurately. A new and exciting development set in when Bose–Einstein condensates were discovered for the first time in dilute gases of alkali atoms in 1995 by Cornell and Wiemann *et al.* (Rb), Ketterle *et al.* (Na), and Hulet *et al.* (Li).

## Boson and Fermion Degeneracy

In what follows, the energy dispersion of Bose and Fermi systems is denoted as $\epsilon_{\boldsymbol{k}}$ (free bosons/fermions would be represented by $\epsilon_{\boldsymbol{k}} = \hbar^2 \boldsymbol{k}^2/2m$). A large number of bosons can occupy Bose quantum states $|\boldsymbol{k}\rangle$, the average occupation is dictated by the Bose–Einstein distribution

$$n_{\boldsymbol{k}} = \frac{1}{e^{(\epsilon_{\boldsymbol{k}}-\mu)/k_B T} - 1} \qquad [1]$$

For Bose systems, the chemical potential is negative $\mu = -k_B T\alpha$ and $\alpha$ is fixed by the condition

$$n = \frac{1}{V}{\sum_{\boldsymbol{k}}}' n_{\boldsymbol{k}} = \frac{1}{\lambda_T^3} B_{\frac{3}{2}}(\alpha) \qquad [2]$$

where the prime indicates the summation over excited states $|\boldsymbol{k}| > 0$. In [2], $\lambda_T = h/\sqrt{2\pi m k_B T}$ denotes the thermal de Broglie wavelength which provides a criterion for the importance of quantum effects or degeneracy through $n\lambda_T^3 \geq O(1)$. The Bose integrals $B_\sigma(\alpha)$ originate from the conversion of the momentum sum into an energy integral and read for parabolic dispersion:

$$B_\sigma(\alpha) = \frac{1}{\Gamma(\sigma)} \int_0^\infty \frac{dy\, y^{\sigma-1}}{e^{y+\alpha} - 1} = \sum_{\nu=1}^{\infty} \frac{e^{-\nu\alpha}}{\nu^\sigma} \qquad [3]$$

with $B_\sigma(0) = \zeta(\sigma), \Gamma$ the Euler $\Gamma$-function and $\zeta$ denoting the Riemann $\zeta$-function. It is important to understand that in order to have a constant total density $n, B_{3/2}(\alpha)$ has to increase $\propto T^{-3/2}$ in the same way as $\lambda_T^3$. This is, however, impossible at all temperatures since the chemical potential of the Bose gas vanishes $(\alpha \to 0)$ at a finite temperature $T_B$ given by

$$T_B = \frac{2\pi\hbar^2}{mk_B}\left[\frac{n}{\zeta(3/2)}\right]^{2/3} \qquad [4]$$

for which $n\lambda_{T_B}^3 = B_{3/2}(0) = \zeta(3/2) = 2.612\ldots$.

In sharp contrast, fermions obey the Pauli exclusion principle, which states that only one fermion can occupy a quantum state $|\boldsymbol{k}, \sigma\rangle$ specified in addition by the spin projection $\sigma$. The average statistical occupation is given by the Fermi–Dirac distribution

$$f_{\boldsymbol{k}} = \frac{1}{e^{(\epsilon_{\boldsymbol{k}}-\mu)/k_B T} + 1} \qquad [5]$$

Figure 3 shows a comparison of Bose–Einstein and Fermi–Dirac momentum distributions $n_{\boldsymbol{k}}$ plotted vs. $\epsilon_{\boldsymbol{k}}$. The chemical potential is shown for fermions only, $\mu_F = k_B T\alpha$ is always positive and the total density can be expressed as

$$n = \frac{1}{V}\sum_{\boldsymbol{k},\sigma} f_{\boldsymbol{k}} = \frac{2}{\lambda_T^3} F_{\frac{3}{2}}(\alpha) \qquad [6]$$

where the factor of 2 originates from the spin degeneracy. For parabolic dispersion, the Fermi integral reads:

$$F_\sigma(\alpha) = \frac{1}{\Gamma(\sigma)} \int_0^\infty \frac{dy\, y^{\sigma-1}}{e^{y-\alpha} + 1} \overset{T\to 0}{=} \frac{(\mu/k_B T)^\sigma}{\Gamma(\sigma+1)} \qquad [7]$$

One recognizes that the degeneracy condition $n\lambda_T^{3/2} \geq 1$ corresponds to the limit $T \leq T_F = \mu(0)/k_B$, which is connected with the formation of a "Fermi sea," with $\mu(0) \equiv E_F$ the Fermi energy:

$$\mu \overset{T\to 0}{=} \frac{\hbar^2}{2m}(3\pi^2 n)^{\frac{2}{3}} = E_F \qquad [8]$$

To summarize, quantum behavior in Bose and Fermi system sets in below the degeneracy temperature $T^*$, defined through $n\lambda_{T^*}^3 = O(1)$. For bosons, $T^* = T_B$ is the temperature at which the chemical potential vanishes, whereas for fermions $T^* = T_F$ is the Fermi temperature.

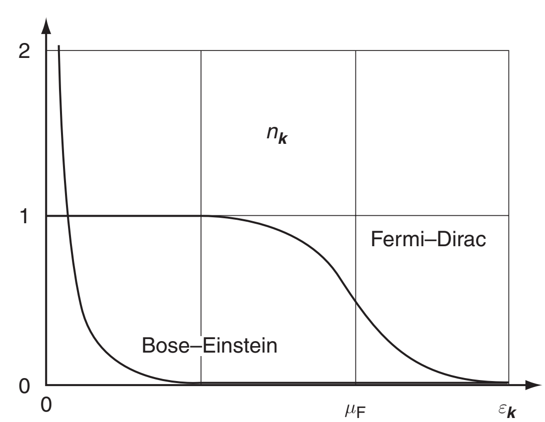

**Figure 3** The Fermi and Bose momentum distribution.

## London Quantum Hydrodynamics

For a general treatment of the quantum-mechanical origin of the equations describing Bose and Fermi superfluidity, it is convenient to introduce a parameter $\nu$ which describes single bosons ($\nu = 1$) or Fermion pairs ($\nu = 2$) of mass $M = \nu m$. The basic assumption (London 1938) is that the laws of quantum mechanics are applicable also to a macroscopic number of single ($\nu = 1$) or composite ($\nu = 2$) particles of density $\rho^s/\nu m$, the so-called condensate, which is represented by a macroscopic wave function $\psi(\boldsymbol{r}, t)$. $\psi$ has the property

$$\psi(\boldsymbol{r}, t)\psi^*(\boldsymbol{r}, t) = \frac{\rho^s(\boldsymbol{r}, t)}{\nu m}; \quad \nu = 1, 2$$

The dynamics of the condensate is governed by the Schrödinger equation

$$\mathrm{i}\frac{\hbar}{\nu}\frac{\partial\psi}{\partial t} = \left(-\frac{\hbar^2\nabla^2}{2\nu^2 m} + \mu\right)\psi \qquad [9]$$

in which $\mu$ represents the condensate's chemical potential. After performing a Madelung transformation (Madelung 1926):

$$\psi = a\mathrm{e}^{\mathrm{i}\varphi}, \quad a^2 = \frac{\rho^s}{\nu m}$$

one arrives at two coupled hydrodynamic equations, the first of which reads

$$\begin{gathered}\frac{\partial\rho^s}{\partial t} + \nabla\cdot\boldsymbol{j}^s_m = 0 \\ \boldsymbol{j}^s_m = \rho^s\boldsymbol{v}^s, \quad \boldsymbol{v}^s = \frac{\hbar}{\nu m}\nabla\varphi\end{gathered} \qquad [10]$$

Equation [10] can be interpreted as a continuity equation, which represents the conservation law for the condensate mass density $\rho^s$. The second equation

$$-\frac{\hbar}{\nu}\frac{\partial\varphi}{\partial t} = \frac{1}{2}m v^{s2} + \mu + \mathrm{O}(\hbar^2\nabla^2) \qquad [11]$$

assumes the form of the Hamilton–Jacobi equation for the action field of classical mechanics $\hbar\varphi$, if the quasiclassical limit (terms $\propto \mathrm{O}(\hbar^2\nabla^2) \to 0$) is taken.

From [10] and [11] a condensate acceleration equation can be derived, which resembles the Euler equation of classical hydrodynamics ($\mu = \mu_0 + \delta\mu$):

$$\frac{\partial\boldsymbol{v}^s}{\partial t} + (\boldsymbol{v}^s\cdot\nabla)\boldsymbol{v}^s = -\frac{1}{m}\nabla\delta\mu \qquad [12]$$

The physical nature of the driving force becomes evident after applying the Gibbs–Duhem relation $n\delta\mu = \delta P - \sigma_0\delta T$. Finally, the acceleration of the mass supercurrent $\boldsymbol{j}^s_m$ is of the form

$$\frac{\partial\boldsymbol{j}^s_m}{\partial t} = -\frac{\rho^s}{\rho}\nabla(\delta P - \sigma_0\delta T) \qquad [13]$$

It turns out that the London equations [10] and [13], in which $\rho^s$ is an unknown phenomenological parameter, explain many experimental observations such as persistent currents, U-tube oscillations, thermomechanical (e.g., fountain-) effects, beaker flow phenomena, and many others.

## Bose–Einstein Condensation (BEC)

In order to understand the macroscopic quantum state in case of Bose systems, we consider first the simple case of a Bose gas. Let us decompose the energy eigenstates $\epsilon_{\boldsymbol{k}}$ into those with $\epsilon_{\boldsymbol{k}} = \epsilon_0 = 0$ (condensate) and average occupation number

$$n_0 = \frac{N_0}{V} = \frac{1}{V}\frac{1}{\mathrm{e}^{\alpha} - 1} \qquad [14]$$

and those with $\epsilon_{\boldsymbol{k}} > 0$ (excited states) and average occupation number

$$n_{ex} = \frac{N_{ex}}{V} = \sum_{\boldsymbol{k}}{}' n_{\boldsymbol{k}} = n\frac{B_{3/2}(\alpha)}{B_{3/2}(0)}\left(\frac{T}{T_B}\right)^{3/2} \qquad [15]$$

with the total density $n = n_{ex} + n_0$. The consequence of the chemical potential vanishing at $T_B$ clearly is a macroscopic occupation of the ground state of the Bose gas:

$$N_0 \overset{\alpha\to 0}{=} \frac{1}{1 + \alpha + \cdots - 1} = \frac{1}{\alpha} \to \infty \qquad [16]$$

This phenomenon is referred to as BEC. Below $T_B, \alpha = 0$ and from [15] we see that

$$n_{ex} \overset{\text{free bosons}}{=} n\left(\frac{T}{T_B}\right)^{3/2}, \quad T < T_B \qquad [17]$$

The average occupation of the ground state is given by

$$n_0(T) = n - n_{ex}(T), \quad T < T_B \qquad [18]$$

It is important to understand that the number density of condensed particles $n_{ex}$ has nothing to do with the current response function $\rho^s$ (eqn [10]). A derivation of $\rho^s$ will be given in the section "Local response of condensates and excitation gases."

Let us now discuss the structure of the excitation spectrum, which will turn out to be crucial for the observability of superfluidity, in some more detail. Suppose that a macroscopic object of mass $M$ moves through the superfluid. Then one may ask the question, at what velocity does this motion cause the creation of an excitation of energy $E_{\boldsymbol{p}}$ and momentum $\boldsymbol{p}$. The condition can be formulated in terms of the velocity

difference $v_i - v_f$ as $E_p = M(v_i^2 - v_f^2)/2$ and $p = M(v_i - v_f)$. Eliminating $v_f$ yields $\epsilon_p = p \cdot v_i + O(M^{-1})$ so that condition for the creation of an excitation leads to the so-called Landau critical velocity

$$v_L = \min\left\{\frac{E_p}{|p|}\right\} > 0 \qquad [19]$$

It is immediately clear that for free bosons $v_L = 0$. This means that a free Bose gas can never be a superfluid, since drag forces on moving objects will start to act even at smallest velocities.

It turns out that interaction effects can drastically modify the nature of the elementary excitations. In 1947, Nikolai Bogoliubov showed (for the first time using the method of second quantization) that even in the limit of weak repulsive interactions the excitation spectrum is phonon-like $E_p = c|p|$, with $c$ the sound velocity. Lev Landau and Richard Feynman investigated the situation for superfluid $^4$He, where the interactions between the atoms are far from weak. Landau (1947) postulated the following form for the excitation spectrum, for which Feynman (1953) gave the microscopic justification. At low momenta, the spectrum is phonon-like and linear in $p$:

$$\lim_{p \to 0} E_p = E_p^{\text{phon}} = c|p| \qquad [20]$$

At higher momenta, the spectrum is reminiscent of that of crystal phonons in that $E_p$ passes though a maximum, and then, at a characteristic momentum $p_0$ approaches the next minimum, which, however, is located at a finite energy $\Delta$. Feynman called this part of the spectrum the "roton" (mass $m_r$) in an analogy with a "smoke ring," since it is connected with the forward motion of a particle accompanied by a ring of back-flowing other particles:

$$\lim_{|p| \to p_0} E_p = E_p^{\text{rot}} = \Delta + \frac{(|p| - p_0)^2}{2m_r} \qquad [21]$$

Figure 4 shows a sketch of the phonon–roton spectrum of superfluid $^4$He. Clearly, the Landau critical velocity for the phonon–roton spectrum is characterized by the roton minimum and is given by $v_L \approx \Delta/p_0$.

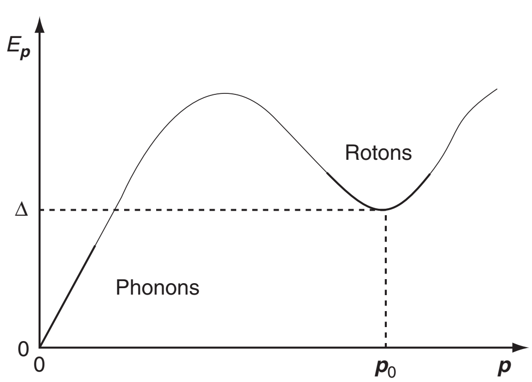

**Figure 4** The phonon–roton spectrum.

## BCS–Leggett Pair Condensation

The key assumptions of the weak-coupling mean-field BCS–Leggett pairing model can be summarized as follows: one first assumes that at sufficiently low temperatures it is energetically favorable that a temperature-dependent part of the fermions forms so-called Cooper pairs. This pair formation is caused by an attractive interaction in $k$-space near the Fermi surface:

$$\Gamma_{kp}^{(s)} < 0, \qquad |\xi_k|, |\xi_p| < \epsilon_c$$

Here $\xi_k = \epsilon_k - \mu$ measures the energy from the chemical potential. The index $s$ denotes the total spin of the pair. Classical superconductors have pairs in a relative singlet state $s = 0, m_s = 0$ whereas the superfluid phases of liquid $^3$He have pairs in a relative spin-triplet state $s = 1, m_s = 0, \pm 1$, with $m_s$ the magnetic quantum number. The amplitude of spontaneous pair formation is

$$g_{k\sigma_1\sigma_2} \equiv \langle \hat{c}_{-k\sigma_1} \hat{c}_{k\sigma_2} \rangle \neq 0, \qquad T \leq T_c \qquad [22]$$

with $k = k_1 - k_2$ the relative momentum of the pair. The attractive interaction that drives the Cooper-pair formation connects the pairing amplitude $g_{k\sigma_1\sigma_2}$ with a new energy scale, the so-called pair potential

$$\Delta_{k\sigma_1\sigma_2} = \sum_p \Gamma_{kp}^{(s)} g_{p\sigma_1\sigma_2} \qquad [23]$$

As a consequence of triplet pairing the spin part of the pair potential is "even" upon interchange of $\sigma_1$ and $\sigma_2$: $\Delta_{k\sigma_2\sigma_1} = \Delta_{k\sigma_1\sigma_2}$. Then the Pauli principle requires that $\Delta_{k\sigma_1\sigma_2}$ must be "odd" with respect to the interchange of $k_1$ and $k_2$ or, equivalently, $k \to -k$. The $k$-dependence can now be classified by an orbital quantum number $\ell$ with the special cases of $\ell = 1$ ($p$-wave) pairing, $\ell = 3$ ($f$-wave) pairing, etc. All superfluid phases of $^3$He are characterized by $p$-wave orbital symmetry.

The transition temperature $T_c$ from [23] reads

$$k_B T_c = \frac{2e^\gamma}{\pi} \epsilon_c e^{-1/(N_F \Gamma^{(s)})}$$

with $N_F = 3n/2E_F$ the density of states at the Fermi level and $\gamma = 0.577\ldots$ the Euler constant. The energies $\xi_k$ can trivially be divided into particle-like ($\xi_k > 0$) and hole-like ($\xi_k < 0$) terms. The presence of the pair potential $\Delta_k$ leads to a mixing of particle- and hole-like contributions to the energy, which

becomes a matrix in particle–hole, or Nambu space (Nambu 1960), and generates what is referred to as off-diagonal long-range order (ODLRO):

$$\underline{\xi}_{k} = \begin{pmatrix} \xi_k \mathbf{1} & \Delta_k \\ \Delta_k^\dagger & -\xi_k \mathbf{1} \end{pmatrix} \quad [24]$$

As usual, the diagonalization of $\underline{\xi}_k$ (Bogoliubov 1958) leads to the energy dispersion of the relevant thermal excitations of the superfluid state, the so-called Bogoliubov quasiparticles or "bogolons":

$$E_k = \sqrt{\xi_k^2 + \Delta_k^2}, \quad \Delta_k^2 = \Delta_k \cdot \Delta_k^\dagger \quad [25]$$

In Figure 5, the dispersion $E_p$ of Bogoliubov quasiparticles vs. $|\boldsymbol{p}|$ is shown. It turns out that the superfluid phases (A and B) of liquid $^3$He in zero magnetic field are characterized by unitary matrices $\Delta_k$, so that the scalar quantity $\Delta_k$ can be interpreted as the energy gap in the bogolon spectrum, which, in general, may be anisotropic in $\boldsymbol{k}$-space.

The energy gap $\Delta_k$ of the superfluid B-phase can be represented in the simple nodeless (pseudoisotropic) and BCS-like form (Balian and Werthamer, (BW), 1963):

$$\Delta_k = \Delta(T), \qquad \frac{\Delta(0)}{k_B T_c} = \frac{\pi}{e^\gamma} \quad [26]$$

Its spin structure is characterized by the presence of all three triplet components $m_s = 0, \pm 1$ and will be discussed further with respect to the magnetization response (see next section). The gap symmetry of $^3$He-A is uniaxial with respect to an axis $\hat{\ell}$ (Anderson and Morel 1960; Anderson and Brinkman 1973)

$$\Delta_k = \Delta_0(T)\sin\phi_k, \qquad \frac{\Delta_0(0)}{k_B T_c} = \frac{\pi e^{5/6}}{2e^\gamma} \quad [27]$$

where $\cos\phi_k = \boldsymbol{k}\cdot\hat{\ell}$, and characterized by two point nodes of $\Delta_k$ at the zeros ($\phi_k = 0, \pi$) on the Fermi surface. It has furthermore turned out that only the $m_s = \pm 1$ components of the spin triplet contribute to its spin dependence (equal spin pairing (ESP)).

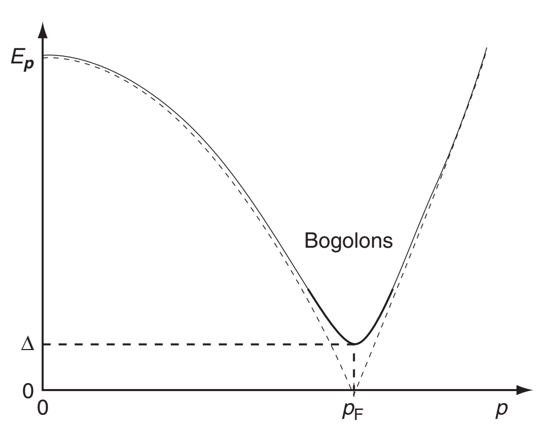

Figure 5 The bogolon energy dispersion.

## Local Response of Condensates and Excitation Gases

In the previous sections we have seen that the structure (energy dispersion, statistics, critical flow velocity) of the relevant thermal excitations is of crucial importance for the superfluidity. We can now aim at a generalized statistical description of bosonic (phonons, rotons) and fermionic (bogolons) excitation gases, by introducing a generalized momentum distribution

$$n_\theta\{E_k\} = \frac{1}{e^{E_k/k_B T} - \theta} \quad [28]$$

and its energy derivative

$$\varphi_{k,\theta} = -\frac{\partial n_\theta\{E_k\}}{\partial E_k} = \frac{1}{2k_B T[\cosh(E_k/k_B T) - \theta]} \quad [29]$$

Special cases are

$$\theta = \begin{cases} 1, & \text{Bose (phonons, rotons)} \\ -1, & \text{Fermi (bogolons)} \end{cases}$$

Introducing the spin $s = (1-\theta)/4$, the total momentum density response to the presence of a superfluid velocity

$$\boldsymbol{v}^s = \frac{\hbar\nabla\varphi}{(2s+1)m}, \quad s = 0, \frac{1}{2}$$

and a normal fluid velocity $\boldsymbol{v}^n$ can be written in the general form

$$\boldsymbol{j}_m = \frac{2s+1}{V}\sum_k \boldsymbol{p} n_\theta\{E_k + \delta E_k\} + \rho\boldsymbol{v}^s \quad [30]$$

After Taylor-expanding $n_\theta$ with respect to the small energy shifts $\delta E_k = \boldsymbol{p}\cdot(\boldsymbol{v}^s - \boldsymbol{v}^n)$, one may introduce the so-called normal fluid density tensor

$$\rho_{ij}^n = \frac{2s+1}{V}\sum_k \varphi_{k,\theta} p_i p_j \quad [31]$$

and the momentum density assumes the form

$$\boldsymbol{j}_m = \rho^s\cdot\boldsymbol{v}^s + \rho^n\cdot\boldsymbol{v}^n, \quad \rho^s = \rho\mathbf{1} - \rho^n \quad [32]$$

Equation [32] forms the central result of this essay because it represents the microscopic counterpart of the generalized London equation [10]. It is clearly seen how the phenomenon of superfluidity originates from $\rho^s > 0$ due to a qualitative change in the dispersion of the elementary excitations, which may in particular be characterized by a gap in

the excitation spectrum. Equation [32] is more general than [10] in that it introduces a two-fluid picture in which the mass supercurrent $\boldsymbol{j}_{\mathrm{m}}^{\mathrm{s}} = \rho^{\mathrm{s}}\boldsymbol{v}^{\mathrm{s}}$ (eqn [10]) is complemented by a normal (excitation) mass current $\boldsymbol{j}_{\mathrm{m}}^{\mathrm{n}} = \rho^{\mathrm{n}}\boldsymbol{v}^{\mathrm{n}}$ in the presence of a macroscopic velocity field $\boldsymbol{v}^{\mathrm{n}}$ of the excitation gas obeying arbitrary statistics. The temperature dependence of $\rho^{\mathrm{s}}(T)$ can now be computed via [31] and the result depends on the dispersion of the thermal excitation under consideration. **Figure 6** shows the temperature dependence of the normal and superfluid density of superfluid $^4$He. The normal fluid density of superfluid $^3$He is, in general, a tensor quantity

$$\rho_{ij}^{\mathrm{n}} = \begin{cases} \rho_{\|}^{\mathrm{n}}\hat{\ell}_i\hat{\ell}_j + \rho_{\perp}^{\mathrm{n}}(\delta_{ij} - \hat{\ell}_i\hat{\ell}_j), & {}^3\text{He-A} \\ \rho^{\mathrm{n}}\delta_{ij}, & {}^3\text{He-B} \end{cases} \qquad [33]$$

The short-range Fermi liquid interaction leads to a quasiparticle mass enhancement $m^*/m = 1 + F_1^{\mathrm{s}}/3$ characterized by the pressure-dependent dimensionless Landau parameter $F_1^{\mathrm{s}}$. In **Figure 7**, the normal fluid density ($\rho_{\|,\perp}^{\mathrm{n}}$ for $^3$He-A, $\rho^{\mathrm{n}}$ for $^3$He-B) is shown as a function of reduced temperature at a pressure of 27 bar, where $F_1^{\mathrm{s}} = 12.53$. The entropy density of an excitation system of arbitrary statistics below the transition can be written as

$$\sigma_0 = k_{\mathrm{B}}\frac{(2s+1)}{V}\sum_{\boldsymbol{k}} P_{\boldsymbol{k}\theta}$$
$$P_{\boldsymbol{k}\theta} = \theta(1+\theta n_\theta)\ln(1+\theta n_\theta) - n_\theta \ln n_\theta \qquad [34]$$

with $n_\theta = n_\theta\{E_{\boldsymbol{k}}\}$, from which one may derive the specific heat capacity

$$T\delta\sigma = \frac{2s+1}{V}\sum_{\boldsymbol{k}} E_{\boldsymbol{k}} n_\theta \left\{ \frac{E_{\boldsymbol{k}} + \frac{\partial E_{\boldsymbol{k}}}{\partial T}\delta T}{k_{\mathrm{B}}(T+\delta T)} \right\}$$
$$= c_V \delta T \qquad [35]$$

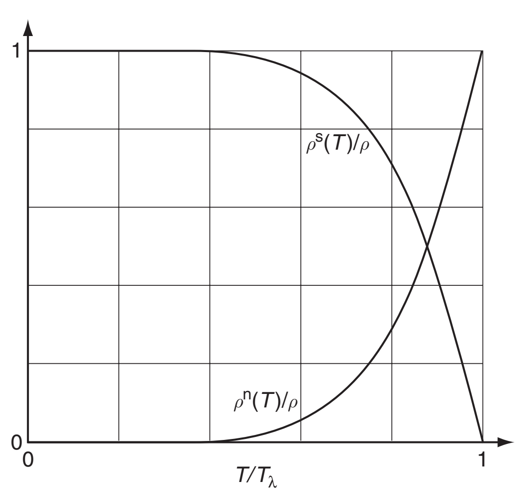

**Figure 6** The normal and superfluid density for He-II.

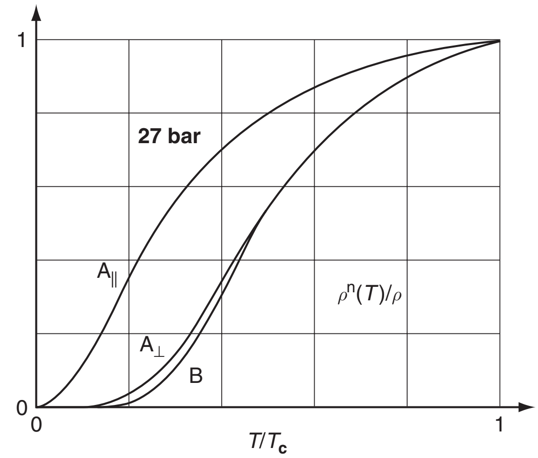

**Figure 7** The normal fluid density for $^3$He-A, B.

After a Taylor expansion of $n_\theta$ with respect to the small local temperature change $\delta T$, the result for $c_V(T)$ reads

$$c_V = \frac{2s+1}{V}\sum_{\boldsymbol{k}} \varphi_{\boldsymbol{k},\theta}\left(\frac{E_{\boldsymbol{k}}^2}{T} - E_{\boldsymbol{k}}\frac{\partial E_{\boldsymbol{k}}}{\partial T}\right) \qquad [36]$$

In **Figures 8 and 9** we show the cusp-like specific heat of a Bose gas as compared with the specific heat of $^3$He-A, B, which display discontinuities at $T_{\mathrm{c}}$.

Finally, the superfluid phases of $^3$He are characterized in addition by the spin degrees of freedom, reflected by the bogolon spin magnetization response to an external magnetic field $B$:

$$M^{\mathrm{n}} = \frac{\gamma\hbar}{2V}\sum_{\boldsymbol{k},\sigma} \sigma n_{-1}\{E_{\boldsymbol{k}} - \gamma\hbar\sigma B/2\} = \chi_0 B \qquad [37]$$

where $\gamma$ denotes the gyromagnetic ratio of the fermions. The bogolon spin susceptibility $\chi_0$ is obtained after a Taylor expansion of $n_{-1}$ with respect to $B$ as

$$\chi_0 = \left(\frac{\gamma\hbar}{2}\right)^2 \frac{1}{V}\sum_{\boldsymbol{k},\sigma}\varphi_{\boldsymbol{k},-1} \equiv \left(\frac{\gamma\hbar}{2}\right)^2 N_{\mathrm{F}} Y(T) \qquad [38]$$

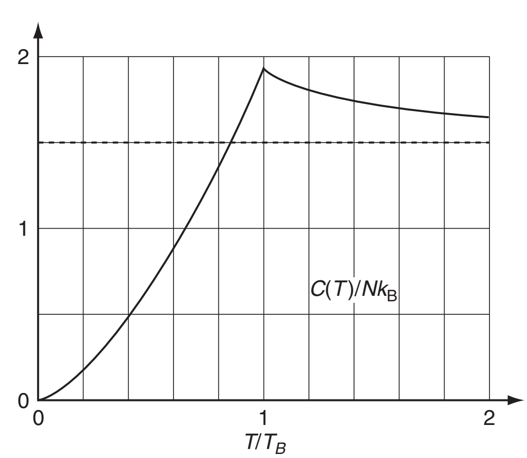

**Figure 8** The specific heat capacity of a Bose gas.

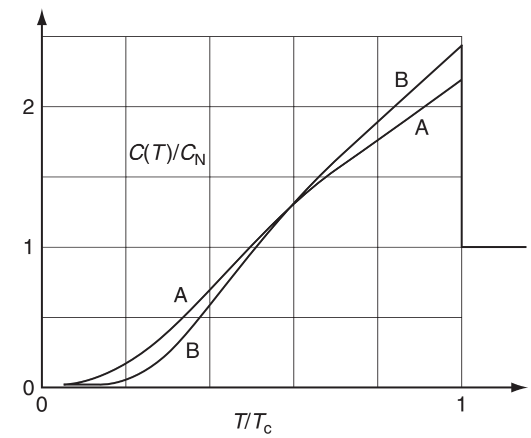

**Figure 9** The specific heat of $^3$He-A, B.

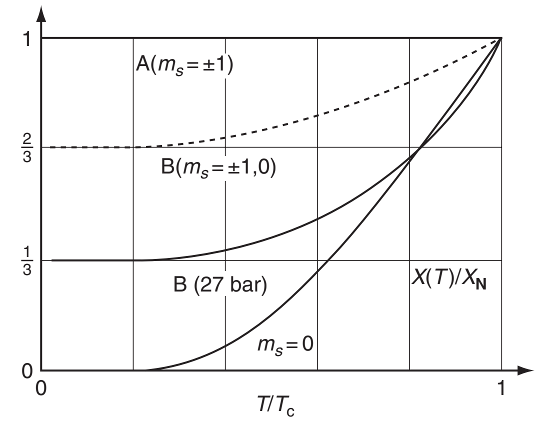

**Figure 10** The spin susceptibility of $^3$He-A, B.

Note that eqn [38] accounts only for the $m_s = 0$ (bogolon) contribution to the spin-triplet susceptibility, the temperature dependence of which is given by the so-called Yosida function $Y(T) = N_F^{-1} \sum_{k\sigma} \varphi_{k,-1}$. The total susceptibility reads

$$\chi_{\text{tot}} = \underbrace{\chi_0}_{\text{bogolons}} + \underbrace{\chi_1 + \chi_{-1}}_{\text{condensate}} \qquad [39]$$

with the condensate contributing through $\chi_{m_s=\pm 1}$ a fraction of 2/3 of the normal state Pauli susceptibility. In Figure 10, the reduced spin susceptibility $\chi/\chi_N$ of $^3$He-A, B is plotted vs. reduced temperature. While the constant susceptibility is characteristic of the ESP pairing state, the reduction of the B-phase susceptibility is due to the lack of the nonmagnetic $m_s = 0$ contribution to the spin triplet in the low-temperature limit. Exchange interaction effects, characterized by the dimensionless Landau parameter $F_0^a$, lead to a further reduction of the Balian-Werthamer (BW)-state susceptibility, which is shown for 27 bar, where $F_0^a = -0.755$. Note that the theoretical picture reflected in Figure 10, and also in Figures 6, 7, and 9, is in quantitative agreement with experimental observations.

In summary, superfluidity is a quantum-mechanical phenomenon seen on a macroscopic scale. It occurs below the degeneracy temperature $T^* \propto n^{2/3}/m$ of both Bose and Fermi many-particle systems (like liquid $^4$He and $^3$He) and is a property of a macroscopic number of particles, the condensate. The role of (weak or strong) interactions is manifested in the structure of the relevant elementary excitations, which always exist in addition to the condensate at finite temperatures and above certain critical velocities. These excitations form a gas, referred to as the normal fluid, since it gives rise to temperature-dependent thermodynamic and response functions and contributes to the entropy and the flow dissipation. Superfluidity is now well understood using various aspects of the concept of the macroscopic wave function. On the microscopic level, the mechanisms of BEC and BCS–Leggett pair formation have been successfully invoked to understand the fascinating properties of Bose and Fermi superfluids.

## Introduction: Minimal $D=4$ Supergravity

The essential idea of supersymmetry is an extension of the relativistic structure group of spacetime, which in ordinary four-dimensional physics in the absence of gravity is the Poincaré group ISO(3, 1). In a minimal supersymmetric theory in flat $D=4$ spacetime, the minimal supersymmetry algebra (the "graded Poincaré algebra") adds spinorial generators $Q_\alpha$ to the Lorentz generators $M_{mn}$ and the translational generators (momenta) $P_m$, where $m=0,1,2,3$. The core relation is the "anticommutator" of two $Q_\alpha$:

$$\{Q_\alpha, \bar{Q}_\beta\} = -2\gamma^m_{\alpha\beta}P_m \qquad [1]$$

where $\bar{Q}=Q^\dagger\gamma^0$ and the $\gamma^m$ are the Dirac gamma matrices. In the minimal $D=4$ supersymmetry algebra, the spinor generator $Q_\alpha$ is taken to be Majorana: $Q=C(\bar{Q})^{\mathrm{T}}$, where $C$ is the charge-conjugation matrix and $A^{\mathrm{T}}$ denotes the transpose of the matrix $A$. The full supersymmetry algebra adjoins to the anticommutation relation [1] the usual commutation relations among the Lorentz generators and the commutators of the Lorentz generators with the momenta and the spinors $Q_\alpha$; the latter express respectively the vectorial and spinorial characters of $P_m$ and $Q_\alpha$:

$$\mathrm{i}[M_{mn}, M_{pq}] = \eta_{np}M_{mq} - \eta_{mp}M_{nq} \qquad [2]$$

$$\mathrm{i}[M_{mn}, P_q] = \eta_{nq}P_m - \eta_{mq}P_n \qquad [3]$$

$$\mathrm{i}[M_{mn}, Q_\alpha] = \tfrac{1}{2}(\gamma_{mn}Q)_\alpha \qquad [4]$$

where $\gamma_{mn}=(1/2)(\gamma_m\gamma_n-\gamma_n\gamma_m)$ and $\eta_{mn}=\mathrm{diag}(-1,1,1,1)$ is the Minkowski metric. The final relation in the supersymmetry algebra expresses the flatness of Minkowski space:

$$[P_m, P_n] = 0 \qquad [5]$$

This algebra has been considered as an extension of the symmetry algebra of particle physics since the work of Gol'fand and Likhtman in 1971, and especially since the linearly realized supersymmetric model of Wess and Zumino in 1974. That model contains a pair of $D=4$ scalar fields and a $D=4$ Majorana spinor, so the numbers of bosonic and fermionic degrees of freedom are equal; this is a fundamental characteristic of supersymmetric theories.

The work of Wess and Zumino led to an explosion of interest in supersymmetry, especially once it was realized that renormalizable supersymmetric models display a cancellation of some of the divergences that have plagued relativistic quantum field theory since its inception in the 1930s. In particular, in renormalizable flat-space field theory models, divergences quadratic in a high-momentum cutoff vanish as a result of cancellations between virtual bosonic and fermionic particles. This is a very attractive feature for control of the "hierarchy problem" in particle physics, especially for the instability inherent in having vastly different scales within the same theory, for example, the TeV scale of ordinary electroweak physics and the $10^{16}$ GeV scale where unification with the strong interactions might come in.

When one includes gravity, the stability problems of particle physics become much more severe. Einstein's theory of general relativity is itself non-renormalizable, that is, its ultraviolet divergences are of different forms from the terms present in the original "classical" action and there is no acceptable finite set of correction terms that can be added to it to remove this defect. Moreover, when otherwise tolerably behaved matter field theories that are renormalizable in a flat-spacetime context are coupled to general relativity, the gravitational couplings pollute the matter theories with non-renormalizable divergences. This is a key aspect of the great difficulty that has been encountered in interpreting gravity as a quantum theory.

Supersymmetry, with its divergence-canceling powers, was thus a very attractive option in the struggle to formulate a quantum theory of gravity, and the creation of a supergravity theory was thus a very high priority task. This was achieved in 1976 by Freedman, Ferrara, and Van Nieuwenhuizen using the technique of iterative Noether coupling to build up this nonlinear theory order-by-order in powers of the fermionic fields. The fermionic partner of the massless spin-2 "graviton" field is a massless fermionic spin-3/2 field that has come to be called the "gravitino."

A second 1976 paper by Deser and Zumino soon followed, emphasizing how supergravity manages to circumvent the well-known problems of coupling spins higher than 1 to gravity. A key point in achieving this result is the role played by the local version of the supersymmetry algebra [1]–[5]. As one can see from the translations occurring on the right-hand side of [1], when one replaces translation symmetry by local general coordinate invariance in a gravitational context, the supersymmetry transformations must themselves become local as well. Local symmetries allow for transformation parameters

that are local in the spacetime coordinates $x^m$, and in interacting theories they require coupling of the corresponding “gauge field” to a conserved current. In the case of supergravity, the gravitino field $\psi_{m\alpha}$ plays this gauge-field role, and its coupling to the conserved current of supersymmetry is the key to allowing a consistent coupling between the spin-2 graviton and the spin-3/2 gravitino.

## The Minimal Supergravity Action

The action for minimal supergravity in $D=4$ dimensions can be written, using the vierbein formalism where the metric is expressed as a quadratic expression in a nonsymmetric $4\times 4$ vierbein matrix $e_m^a, g_{mn}=e_m^a e_n^b \eta_{ab}$, as

$$I=\frac{1}{2\kappa^2}\int \mathrm{d}^4x\,\det(e)R(e,\omega(e)+K(\psi)) - \frac{\mathrm{i}}{2}\int \mathrm{d}^4x\epsilon^{mnpq}\bar{\psi}_m\gamma_5\gamma_n D_p(e,\omega(e)+K(\psi))\psi_q \quad [6]$$

where $\kappa=\sqrt{8\pi G}$ is the gravitational coupling constant,

$$\omega_m^{ab}(e)=\tfrac{1}{2}e^{na}\left(e^b_{n,m}-e^b_{m,n}\right)-\tfrac{1}{2}e^{nb}\left(e^a_{n,m}-e^a_{m,n}\right) + \tfrac{1}{2}e^{na}e^{rb}(e_{nc,r}-e_{rc,n})e^c_m \quad [7]$$

is the usual vierbein formalism spin connection (in which $e^b_{n,m}=\partial_m e^b_n$ and $e^{ma}$ is the matrix inverse of $e_{ma}$), and

$$K_m^{ab}(\psi)=\frac{\mathrm{i}\kappa^2}{4}(\bar{\psi}_m\gamma^a\psi^b+\bar{\psi}^a\gamma_m\psi^b-\bar{\psi}_m\gamma^b\psi^a) \quad [8]$$

is the fermionic contorsion, an additional part of the covariant derivative $D_m(e+K(\psi))$ appearing in the action [6]. (Indices $m,n$ are taken to be “world” indices while indices $a,b$ are “tangent space” indices; one can convert from one type to another using the vierbein $e_m^a$ and its inverse, e.g., $\psi_{a\alpha}= e_a^m\psi_{m\alpha}$.)

Keeping the terms in the action grouped as above using the nonstandard covariant derivative $e_m^{ab}+K_m^{ab}$ is what has been called “1.5 order formalism”: this greatly simplifies the writing and analysis of the supergravity action [6]. In the action [6], one has the Ricci scalar $R(e,\omega(e)+K(\psi))$ written in terms of this generalized torsional spin connection. One may of course expand out all the $\omega_m^{ab}+K_m^{ab}$ combinations and write the nonlinear fermionic terms separately. Doing this produces a quartic term

$$L_4=\frac{\kappa^2}{32}[\bar{\psi}^b\gamma^a\psi^c(\bar{\psi}_b\gamma_a\psi_c+2\bar{\psi}_a\gamma_b\psi_c) - 4(\bar{\psi}^a\gamma^b\psi^c)(\bar{\psi}_a\gamma_b\psi_c)]$$

showing the highly nonlinear nature of supergravity theory – when expanded out, the theory becomes much more cumbersome to study. The 1.5 order formalism trick is one of a large number of algebraic simplifications that had to be developed in order to master the technical aspects of supergravity. It also reveals a characteristic physical feature: this theory naturally involves a connection with torsion built from the fermionic fields.

In terms of the torsional covariant derivative $D_m\epsilon(x)=(\partial_m+(1/4)(\omega_m^{ab}(e)+K_m^{ab}(\psi))\gamma_{ab})\epsilon(x)$ of the infinitesimal supersymmetry parameter $\epsilon(x)$, the local supersymmetry transformations which leave the action [6] invariant (up to the integral of a total derivative) are

$$\delta e_m^a=\mathrm{i}\bar{\epsilon}\gamma_a\psi_m \quad [9]$$

$$\delta\psi_m=2\kappa^{-1}D_m\epsilon \quad [10]$$

The inhomogeneous part $2\kappa^{-1}\partial_m\epsilon$ in the gravitino transformation [10] demonstrates the gauge-field nature of the gravitino field. For a distribution of “supermatter” fields (e.g., Wess–Zumino model scalars and spinors), the integrated “charge” that one would get from a Gauss’s law surface integral at spatial infinity using the gravitino gauge field is the total supercharge $Q_\alpha$, which in turn plays the role of the supersymmetry generator in the original matter-sector supersymmetry algebra [1].

Both the gravitational field and the gravitino field are thus effectively gauge fields, albeit not of a standard Yang–Mills type. The local algebra is a deformation of the rigid supersymmetry algebra [1]–[5], generalizing the relation between general covariance and flat-space Poincaré symmetry. Some basic consequences of the flat-space algebra are preserved, however. An extremely important instance of this is energy positivity. As one can see by multiplying [1] by $\gamma^0$ and then contracting on the spinor index,

$$E=P^0=\frac{1}{2}\sum_\alpha\{Q_\alpha,Q_\alpha^\dagger\}$$

The right-hand side is manifestly non-negative provided the theory is quantized in a positive-metric Hilbert space. One can see this even more explicitly in a Majorana spinor basis, where $Q_\alpha^\dagger=Q_\alpha$. Accordingly, for flat-space supersymmetric theories, one obtains directly the result that energy is non-negative. This carries over to the local algebra of supergravity, where the total energy is obtained from a Gauss’s law integral over the sphere at spatial infinity.

In general relativity, an integrated energy can be defined with respect to an asymptotic timelike Killing vector at spatial infinity. Showing that this

energy is non-negative remained for decades a famously unsolved problem in gravitational physics; it was ultimately proven in Yau's positive-energy theorem. The algebraic structure of supergravity makes energy positivity much more transparent, however. Since pure general relativity can be obtained by setting the gravitino field to zero, this result is inherited by pure Einstein theory as a consequence of its being embeddable into supergravity. Energy positivity can thus be proved even at the classical level using ideas taken from supergravity, as was done by Witten and later streamlined by Nester, in an argument much simpler than Yau's proof. This argument writes the energy as an integral over a positive-semidefinite expression quadratic in a commuting spinor field which is analogous to the (anticommuting) spinor parameter of supergravity in the transformations [9] and [10].

## Auxiliary Fields and Superspace

Supergravity shares with flat-space supersymmetric theories a curious technical feature that gives a hint of a new underlying geometry. Standard counting of the gauge-invariant continuous degrees freedom of the graviton and the gravitino in momentum space yield the same result per momentum value: two bosonic degrees of freedom and two fermionic degrees of freedom. This accords with the general requirement in supersymmetric theories that the numbers of bosonic and fermionic degrees of freedom match. This count follows from the Einstein and spin-3/2 equations of motion, or "on-shell." If one compares the count of nongauge degrees of freedom without using the equations of motion (i.e., "off-shell"), one obtains an imbalance, however: six nongauge graviton versus 12 nongauge fermion fields. This is directly related to another puzzling feature of the supergravity realization of local supersymmetry: the local supersymmetry algebra closes onto a finite set of transformations only when the equations of motion are imposed.

As in flat-space supersymmetry, the cure for this problem is to add nondynamical "auxiliary" fields to the action. In the supergravity case, the imbalance in the off-shell bose–fermi field count indicates that an additional six bosonic fields are needed. In the minimal set of auxiliary fields, these organize into a vector $b_m$ and a scalar-pseudoscalar pair $M$, $N$; the additional terms in the action [6] are simply

$$\int d^4x \det(e)\left(-\tfrac{1}{3}M^2 - \tfrac{1}{3}N^2 + \tfrac{1}{3}b_m b^m\right)$$

while the local supersymmetry transformations are changed to include the auxiliary fields, e.g., the gravitino transformation becomes

$$\delta\psi_m = 2\kappa^{-1}D_m(\omega, K)\epsilon + \gamma_5\left(b_m - \tfrac{1}{3}\gamma_m\gamma^n b_n\right)\epsilon - \tfrac{1}{3}\gamma_m(M + \gamma_5 N)\epsilon)$$

while the auxiliary fields transform into expressions that vanish on-shell. Since the field equations for the auxiliary fields are algebraic in character and since for source-free supergravity they have the simple solution $b_m = M = N = 0$, one can directly regain the on-shell formalism by algebraically eliminating the auxiliary fields.

The inclusion of auxiliary fields is not an empty trick, however. The local supersymmetry transformations including the auxiliary fields form a closed set without the use of equations of motion ("off-shell closure"). This standardizes the form of the supersymmetry transformations so that they remain the same even when supermatter is coupled to supergravity instead of needing a case-by-case Noether construction as in the case without the auxiliary fields. In this way, a standard set of coupling rules can be drawn up, known as the "tensor calculus." This tensor calculus is of great importance as it allows for the construction of general models of supergravity coupled to supermatter (Wess–Zumino multiplets and super Yang–Mills multiplets consisting of spin-1 gauge fields and spin-1/2 "gaugino" fields). These general couplings form the basis for essentially all supersymmetric phenomenology, and in particular for the formulation of the Minimal Supersymmetric Standard Model. Since supersymmetry is not directly observed in low-energy physics, it must be spontaneously broken, like many other gauge symmetries. As it happens, the physically realistic mechanisms of supersymmetry breaking all originate from supergravity couplings derived using the tensor calculus.

Given the regular set of tensor calculus rules for coupling supergravity to supermatter, one is led to suspect that a geometrical structure lies in the background. This is indeed the case; the corresponding construction is known as "superspace."

The basic idea of superspace is a generalization of the coset space construction of Minkowski space as the coset space given by the Poincaré group divided by the Lorentz group: $\mathcal{M}_4(x^m) = \mathrm{ISO}(3,1)/\mathrm{SO}(3,1)$. For supersymmetric theories, one analogously constructs $\mathrm{Superspace}(x^m, \theta^\alpha) = \mathrm{Graded\ Poincaré}/\mathrm{SO}(3,1)$. The basic ideas of superspace were introduced by Akulov and Volkov in 1972, while the idea of expanding in "functions" on this space, thus yielding "superfield," was introduced by Salam and Strathdee

in 1974. This led to a formulation of the Wess–Zumino model in terms of a chiral superfield $\phi(x, \theta)$, which is subjected to a covariant superspace constraint.

In order to manage the formalism of superspace more efficiently, it is convenient to use a two-component spinor formalism corresponding to the Weyl basis for the Dirac gamma matrices, in which the Majorana spinor coordinate $\theta$ is represented as

$$\theta = \begin{pmatrix} \theta_\alpha \\ \bar{\theta}^{\dot{\alpha}} \end{pmatrix}$$

where two-component indices $\alpha, \dot{\alpha} = 1, 2$ are raised and lowered with the covariant two-index antisymmetric tensors $\epsilon^{\alpha\beta}, \epsilon^{\dot{\alpha}\dot{\beta}}$, which both take the numerical value $\mathrm{i}\sigma_2$. The flat-space fermionic covariant derivatives are then

$$\begin{aligned} D_\alpha &= \frac{\partial}{\partial\theta^\alpha} + \mathrm{i}\sigma^m_{\alpha\dot{\beta}}\bar{\theta}^{\dot{\beta}}\partial_m \\ \bar{D}_{\dot{\alpha}} &= -\frac{\partial}{\partial\bar{\theta}^{\dot{\alpha}}} + \mathrm{i}\bar{\theta}^{\beta}\sigma^m_{\beta\dot{\alpha}}\partial_m \end{aligned} \qquad [11]$$

where the $\sigma^m_{\alpha\dot{\beta}} = (\mathbb{1}, \sigma_i)$ for $m = (0, i)$ (where $\sigma_i$ are the Pauli matrices) are the Van der Waerden matrices which establish the mapping between vector indices and (chiral, antichiral) spinor index pairs. The Wess–Zumino multiplet is then described by a complex chiral superfield satisfying the constraint $\bar{D}_{\dot{\alpha}}\phi = 0$. Unlike the situation in Minkowski space, where the only Lorentz-covariant solution to a constraint that sets to zero the $\partial/\partial x^m$ derivatives is a constant, superspace has a reducible set of coordinates $(x^m, \theta^\alpha, \bar{\theta}^{\dot{\alpha}})$ and, as a result, requiring $\phi$ to be annihilated by $\bar{D}_{\dot{\alpha}}$ does not require the whole superfield to be a constant.

Since the fermionic coordinates of superspace $\theta^\alpha, \bar{\theta}^{\dot{\alpha}}$ are anticommuting (i.e., they are elements of a Grassman algebra), and since $\alpha, \dot{\alpha} = 1, 2$ have an index range of two, powers of them higher than the second order necessarily vanish. As a result, superfields like $\phi$ can be expanded into sets of component fields, each of which is an ordinary field in Minkowski space. In this way, a chiral superfield expands into $(A(x), B(x), \chi_\alpha(x), \bar{\chi}_{\dot{\alpha}}(x), F(x), G(x))$, where the fields $A$, $B$, $\chi$, and $\bar{\chi}$ are the physical fields of the Wess–Zumino model, while $F$ and $G$ are dimension-2 auxiliary fields. In this way, the auxiliary fields of supersymmetry naturally fit into a superspace formalism as higher components in a superfield expansion. It is in this sense that they point toward the superspace formulations of supersymmetric theories.

For supergravity, there are a number of different approaches to realizing the theory in superspace, and these correspond naturally to the various possible choices of auxiliary-field sets. With the minimal set, the supergravity multiplet is described by a superfield carrying a vector index $H_m(x, \theta, \bar{\theta})$; this superfield is called the prepotential of supergravity. Note the fact that since the divisor group in the coset-space construction of superspace is the Lorentz group, superfields may carry indices corresponding to any Lorentz representation. The component-field expansion of the $H_m$ superfield yields the physical $e^a_m, \psi_{m\alpha}, \bar{\psi}_{m\dot{\alpha}}$ and auxiliary fields $(b_m, M, N)$ together with a number of other components of dimension lower than those of the physical fields. This is not, however, all that surprising: even the physical fields $e^a_m, \psi_{m\alpha}, \bar{\psi}_{m\dot{\alpha}}$ contain components that are not directly related to the physical modes because we are dealing with a gauge theory. What occurs in superspace is a redundant expression of the supergravity multiplet with the presence of various component gauge fields.

The full expression of local supersymmetry in superspace can be given in a number of different formalisms. Suffice it here to indicate the transformation of the linearized theory expanded in small fluctuations about empty flat superspace. Converting the vector index of $H_m$ into a (chiral, antichiral) spinor index pair via $H_{\alpha,\dot{\beta}} = \sigma^m_{\alpha\dot{\beta}}H_m$, the linearized local symmetry transformation of the supergravity multiplet is

$$\delta H_{\alpha\dot{\beta}} = D_\alpha\bar{L}_{\dot{\beta}} - \bar{D}_{\dot{\beta}}L_\alpha \qquad [12]$$

where the transformation parameter superfield $L_\alpha$ carrying a spinor index is antichiral: $D_\alpha\bar{L}_{\dot{\beta}} = 0$ (while the conjugate parameter superfield $\bar{L}_\alpha$ is chiral). Expanding in component fields and comparing with the expansion of $H_m$, one sees that the chiral spinor superfield contains precisely the components needed to provide the standard gauge symmetries of $e^a_m$ and $\psi_{m\alpha}, \psi_{m\dot{\alpha}}$ and also to transform the other gauge components of $H_m$ as well. One can then make various gauge choices according to taste in a given context.

One frequently encountered superspace gauge choice sets to zero all the fields in $H_m$ except for the physical and auxiliary fields $(e^a_m, \psi_{m\alpha}, \bar{\psi}_{m\dot{\alpha}}, b_m, M, N)$. This is called a Wess–Zumino gauge following the analogy to a similar construction for super Maxwell theory (containing spins 1 and 1/2). Wess–Zumino gauge choices are not, however, supersymmetrically covariant. This shows up when one works out the supersymmetry algebra in such a gauge: the presence of auxiliary fields gives closure, as required, without use of the equations of motion, but the anticommutator of two supersymmetry

transformations when acting on a gauge field such as the Maxwell field or the vierbein gives a combination of the anticipated translation with an admixture of a gauge transformation with a field-dependent parameter.

The prepotential superfield of minimal supergravity can itself be fit into larger formalisms in superspace that are analogous to standard differential geometry, with supervielbeins, superspin connections and so forth. An unavoidable feature of these more seemingly geometric constructions, however, is their high degree of redundancy: superspace vielbeins and spin connections carrying Lorentz indices have many component fields in addition to those found in the prepotential. This redundancy is then cut down in turn by imposing superspace constraints on the geometrical superfields, for example, on the components of the torsion tensor in superspace.

## Extended Supergravities and Supergravities in Higher Dimensions

The possible graded extensions of the Poincaré algebra allow for more than one spinorial generator. Thus, one can have $N$ supersymmetry generators $Q^i_\alpha, \bar{Q}_{\dot\beta j}, i, j = 1, \ldots N$, with basic anticommutators (in Lorentz two-component notation)

$$\{Q^i_\alpha, \bar{Q}_{\dot\beta i}\} = 2\delta^i_j \sigma^m_{\alpha\dot\beta} P_m \qquad [13]$$

$$\{Q^i_\alpha, Q^j_\beta\} = 2\epsilon_{\alpha\beta} a^{\ell ij} Z_\ell \qquad [14]$$

$$\{\bar{Q}_{\dot\alpha i}, \bar{Q}_{\dot\beta j}\} = 2\epsilon_{\dot\alpha\dot\beta} \bar{a}^\ell_{ij} Z_\ell \qquad [15]$$

The right-hand sides of [14] and [15] allow for the possibility of nonvanishing commutators between supersymmetry generators of the same chirality. As one can see from the overall symmetry in pairs of indices $(\alpha i, \beta j)$, the coefficients $a^{\ell ij}$ must be antisymmetric in the $i, j$ indices, so such nonvanishing same-chirality anticommutators cannot occur for $N = 1$. The corresponding abelian generators $Z_\ell$ are called central charges since they must commute with all the other $(Q^i_\alpha, \bar{Q}_{\dot\beta],j}, P_m)$ elements of the algebra.

The $i, j$ indices may be endowed with a symmetry meaning as well, although this is not obligatory in every model. When the central charges are absent, $Z_\ell = 0$, one has U($N$) (or SU($N$)) as the maximal such external automorphism; the choice of index placement on $Q^i_\alpha$ and $\bar{Q}_{\dot\beta j}$ anticipates this. If such a symmetry is realized in a given model, the fact that the $Q^i_\alpha, \bar{Q}_{\dot\beta j}$ carry representations both for that symmetry and for the spacetime Poincaré symmetry demonstrates how supersymmetry evades the no-go theorem barring unified spacetime and internal symmetries. This theorem (the Coleman–Mandula theorem) can be evaded, since at the time it was written, graded Lie symmetry algebras were not yet considered. For nonzero central charges, the external automorphism algebra becomes a subalgebra of U($N$) determined by the requirement that invariant antisymmetric tensors $a^{\ell ij}$ exist.

The representations of the algebra [13]–[14] span an increasing range of spins as the number $N$ of $D = 4$ supersymmetries increases. For massive representations without central charges, the spins of the smallest supersymmetry representation extend from states of spin 0 (scalars) up to spin $N/2$; with central charges, the spin range can be shortened down to a minimum range of $N/4$. For massless representations, the range of helicities in a PCT (parity–change–time reversal) symmetric multiplet is from $-N/4$ to $N/4$. This spin range has an important implication for the maximal extension of supersymmetry that can be realized in an interacting supersymmetric field theory, because no interacting theories with a finite set of spins exist for spins $>2$. Accordingly, the maximal extension of supersymmetry is $N = 8$ for massless theories, and in order to have massive states with spins that do not exceed spin 2 in an $N = 8$ theory, the central charges have to be active for maximal multiplet shortening.

The $N = 8$ supergravity theory, found by Cremmer and Julia in 1978, is thus the largest possible supergravity in $D = 4$ dimensions. It contains the following "spin" range (allowing for a certain imprecision of expression: for massless fields one should really speak only of helicities)

$N = 8$ supergravity spins

| Spin | 2 | $\frac{3}{2}$ | 1 | $\frac{1}{2}$ | 0 |
|---|---|---|---|---|---|
| Multiplicity | 1 | 8 | 28 | 56 | 70 |

In order to realize the automorphism SU(8) symmetry, one has to consider the field strengths for the 28 spin-1 fields, separated into complex self-dual and anti-self-dual parts in their antisymmetric Lorentz indices. These complex field strengths can then be endowed with a complex 28-dimensional representation of SU(8). The 70 scalars, on the other hand, fit precisely into the four-index antisymmetric self-dual representation of SU(8), $\phi^{i_1 i_2 i_3 i_4} = 1/(4!)\epsilon^{i_1 i_2 i_3 i_4 j_1 j_2 j_3 j_4} \bar{\phi}_{j_1 j_2 j_3 j_4}$. It is the use of the eight-index epsilon tensor here that restricts the automorphism group to SU(8) instead of U(8).

The SU(8) automorphism symmetry of $N = 8$ supergravity theory is linearly realized. It plays an important role in another symmetry of this theory which is highly nonlinear. This theory has a

remarkable nonlinear $E_7$ symmetry. In fact, the 70 scalars form a nonlinear sigma model with the fields taking their values in the coset space $E_7/\mathrm{SU}(8)$ (of dimension $133 - 63 = 70$), where the SU(8) divisor is the linearly realized automorphism group discussed above.

The extended supergravities point to another aspect of supergravity theory: the existence of higher-dimensional supergravities, from which the extended theories in $D = 4$ spacetime can be derived by Kaluza–Klein dimensional reduction. If one considers a $D'$ dimensional massless theory in a spacetime where $d$ dimensions form a compact $d$-torus, then the theory can be viewed as a $D = D' - d$ dimensional theory in which the discrete Fourier modes arising from the periodicity requirements on the $d$-torus give rise to towers of equally spaced massive Kaluza–Klein states, plus a massless sector in $D' - d$ dimensions corresponding to the modes with no dependence on the $d$-torus coordinates.

Importantly, $N = 8$ supergravity in four-dimensional spacetime can be obtained in this way from a supergravity theory that exists in 11 spacetime dimensions. Upon dimensional reduction on a 7-torus to four dimensions, one obtains $N = 8, D = 4$ supergravity at the massless level, plus an infinite tower of massive $N = 8$ supermultiplets with central charges so that their spin range extends only up to spin 2. This $D = 11$ supergravity was in fact found before the $N = 8$ theory by Cremmer, Julia, and Scherk, with the details of the more complicated $N = 8, D = 4$ theory being worked out via the techniques of Kaluza–Klein dimensional reduction. The fields of the $D = 11$ theory include an exotic field type not encountered in $D = 4$ theories: the bosonic fields of the theory comprise the graviton $e_M^A$ plus a three-index antisymmetric tensor gauge field $C_{MNP}$. Counting the number of propagating modes of these fields for a given momentum value gives $44 + 84 = 128$ bosonic degrees of freedom. This precisely balances the 128 fermionic degrees of freedom coming from the $D = 11$ gravitino $\psi_{M\alpha}$.

## Supergravity Effective Theories, Strings and Branes

The hope for a cancellation of the ultraviolet divergences in a supersymmetric theory of gravity turned out to be ephemeral, although there is in fact a postponement of the divergence onset until a higher order in quantum field loops. There is agreement that the nonmaximal supergravities diverge at the three-loop order. For the $N = 8, D = 4$ theory, the situation remains unclear, but divergences are nonetheless expected to occur at some finite loop order.

This persistence of nonrenormalizability in $D = 4$ supergravity theories is no longer seen as a disaster, however, because these theories are now seen as effective theories for the massless modes arising from a deeper microscopic quantum theory. In addition, the theories that are most directly connected to this underlying quantum theory are, surprisingly, the maximal supergravities in spacetime dimensions 10 and 11. $D = 11$ supergravity can be dimensionally reduced on a 1-torus (i.e., a circle) to $D = 10$ where the massless sector yields type IIA supergravity theory. This theory is the effective theory for a consistent quantum theory of type IIA superstrings in $D = 10$. Theories of relativistic strings (i.e., one-dimensional extended objects) have strikingly different properties from theories of point particles. In particular, the spread-out nature of the interactions leads to a damping out of the quantum field theory divergences, while the underlying supersymmetry causes a cancellation of other infinities that could have arisen owing to the two-dimensional nature of the string world sheets. This gives, for the first time, a perturbatively well-defined quantum theory including gravity.

In addition to the type IIA theory, there are four other consistent superstring theories in $D = 10$, and these are in turn related to various $D = 10$ supergravity effective theories for the massless modes: type IIB, $E_8 \times E_8$ heterotic, SO(32) heterotic, and SO(32) type I. Remarkably, the maximal $D = 11$ supergravity enters into this picture as well, as a consequence of a pattern of duality symmetries that have been found among the superstring theories.

The dualities of string theory are directly related to the nonlinear symmetries of the dimensionally reduced supergravities in $D = 4$. The string quantum corrections do not respect the $E_7$ symmetry of the classical $N = 8$ theory, but they do respect a discrete subgroup of this symmetry in which the $E_7$ group elements are required to take integer values: $E_7(\mathbb{Z})$.

This quantum-level restriction to a discrete subgroup can be seen from another phenomenon characteristic of superstring theories: the existence of "electric" and "magnetic" brane solutions. The antisymmetric-tensor (or "form") fields of the higher-dimensional supergravities naturally give rise to solitonic solutions in which $p + 1$ dimensions form a flat Poincaré invariant subspace. This can be interpreted as the world volume of an infinite $p$-brane extended object. In the $D = 11$ supergravity theory, the branes that emerge in this way are a 2-brane and a 5-brane. The three-dimensional world volume of the 2-brane naturally couples to the

3-form field $C_{MNP}$, just as an ordinary Maxwell vector field couples to the one-dimensional world line of a point particle (or 0-brane). The 2-brane is thus naturally electrically charged with respect to the 3-form field; its charge can be obtained, in a direct generalization of the Maxwell case, from a Gauss' law integral of the field strength $H_{[4]} = dC_{[3]}$ over a 7-sphere at spatial infinity in the eight directions transverse to the brane worldvolume. The 5-brane, on the other hand, has a magnetic type charge; it is the 7-form dual to $H_{[4]}$ that is integrated to give its charge. In addition to these static infinite $p$-branes, the theory contains dynamical finite-extent branes as well, although for these one generally does not have explicit solutions.

As one reduces a higher-dimensional supergravity to lower and lower dimensions, there is a proliferation of solitonic brane solutions of varying dimensionality, and of both electric and magnetic charge types. In a quantum theory context, these electrically and magnetically charged branes pair up in ways that must satisfy a generalization of the Dirac quantization condition for $D = 4$ electric and magnetic point particles. This ends up requiring all the supergravity solitonic brane charges to lie on a charge lattice. It is the requirement that this discrete brane-charge lattice be respected that restricts the classical supergravity nonlinear symmetry groups to discrete duality subgroups.

The dualities relate brane solutions within a given theory and also between different string theories. They include transformations that invert the radii of compactifying tori, giving a large–small compactification scale duality. They also include transformations that invert the string coupling constant, thus interchanging strong and weak coupling. The type IIB theory, for example, is self-dual under strong–weak coupling duality. In the case of the type IIA theory, however, something remarkable happens. The strong coupling limit of this theory turns out to be related by duality, not to another string theory, but to the maximal $D = 11$ supergravity. The role of the Kaluza–Klein massive modes for the 11 to 10 reduction is played by an infinite tower of extremal charged black holes.

Thus, even $D = 11$ supergravity theory has a role to play in the effective theory of the underlying quantum dynamics. This underlying theory has been dubbed "M-theory." It is still only partially understood, but many of its most important properties are presaged by the remarkable nonlinear structure of the classical supergravities.

## Introduction

A supermanifold is a generalization of a classical manifold to include coordinates that are in some sense anticommuting. Much of the motivation for the study of supermanifolds comes from supersymmetric physics, where it is useful to have a formalism which treats fermions and bosons in the same way. The underlying reason for the effectiveness of supermanifolds is that anticommuting coordinates allow the fermionic canonical anticommutation relations to be handled in a way analogous to the bosonic canonical commutation relations. Supersymmetric methods have proved immensely effective in fundamental physics; they also play a considerable role in geometrical index theory in mathematics. In this article we describe supermanifolds from two points of view – geometric and algebraic – and consider some of the standard features of manifold calculus, including integration since this is an area where the distinctive features of this generalized geometry are particularly apparent.

Thus, even $D = 11$ supergravity theory has a role to play in the effective theory of the underlying quantum dynamics. This underlying theory has been dubbed "M-theory." It is still only partially understood, but many of its most important properties are presaged by the remarkable nonlinear structure of the classical supergravities.

**F A Rogers**, King's College London, London, UK

## Introduction

A supermanifold is a generalization of a classical manifold to include coordinates that are in some sense anticommuting. Much of the motivation for the study of supermanifolds comes from supersymmetric physics, where it is useful to have a formalism which treats fermions and bosons in the same way. The underlying reason for the effectiveness of supermanifolds is that anticommuting coordinates allow the fermionic canonical anticommutation relations to be handled in a way analogous to the bosonic canonical commutation relations. Supersymmetric methods have proved immensely effective in fundamental physics; they also play a considerable role in geometrical index theory in mathematics. In this article we describe supermanifolds from two points of view – geometric and algebraic – and consider some of the standard features of manifold calculus, including integration since this is an area where the distinctive features of this generalized geometry are particularly apparent. One situation where supermanifolds are used in physics is in the superspace formulation of supergravity, where the physical fields are found in the component fields in the Taylor expansion of functions on the supermanifold in anticommuting variables. More fundamentally, the symmetry groups of supersymmetric theories have commuting and anticommuting generators, and are examples of super Lie groups, which are supermanifolds with a compatible group structure.

## Some Algebraic Preliminaries

The coordinates of a supermanifold have particular algebraic features which are best understood by introducing some of the basic concepts of superalgebra. (The word super here does not imply superiority, simply the extension of some classical concept to have odd as well as even, anticommuting as well as commuting, elements.) A "super vector space" is a vector space $V$ together with a direct sum decomposition

$$V = V_0 \oplus V_1 \qquad [1]$$

The subspaces $V_0$ and $V_1$ are referred to, respectively, as the even and odd parts of $V$. A general element $v$ of $V$ thus has the unique decomposition $v = v_0 + v_1$ with $v_0$ in $V_0$ and $v_1$ in $V_1$. We will normally consider homogeneous elements, that is, elements $v$ which are either even or odd, with parity denoted by $|v|$, so that $|v| = i$ if $v$ is in $V_i, i = 0, 1$. (Arithmetic of parity indices $i = 0, 1$ is always modulo 2.) A superalgebra is a super vector space whose elements can be multiplied together in such a way that the product of an even element with an even element and that of an odd element with an odd element are both even, while the product of an odd element with an even element is odd; more formally:

**Definition 1**

(i) A "superalgebra" is a super vector space $A = A_0 \oplus A_1$ which is also an algebra which satisfies $A_i A_j \subset A_{i+j}$.
(ii) The superalgebra is "supercommutative" if, for all homogeneous $a, b$ in $A, ab = (-1)^{(|a||b|)} ba$.

If the algebra is supercommutative then odd elements anticommute, and the square of an odd element is zero. The basic supercommutative superalgebra used is the real Grassmann algebra with generators $\mathbf{1}, \beta_1, \beta_2, \ldots$ and relations

$$\mathbf{1}\beta_i = \beta_i \mathbf{1} = \beta_i, \quad \beta_i \beta_j = -\beta_j \beta_i \qquad [2]$$

A typical element of this algebra is then

$$a = a_\emptyset \mathbf{1} + \sum_i a_i \beta_i + \sum_{i<j} a_{ij} \beta_i \beta_j \cdots \qquad [3]$$

This algebra, which is denoted $\mathbb{R}_S$, is a superalgebra with $\mathbb{R}_S := \mathbb{R}_{S,0} \oplus \mathbb{R}_{S,1}$, where $\mathbb{R}_{S,0}$ consists of linear combinations of products of even numbers of the anticommuting generators, while $\mathbb{R}_{S,1}$ is built similarly from odd products.

The Grassmann algebra $\mathbb{R}_S$ is used to build the $(m, n)$-dimensional superspace $\mathbb{R}_S^{m,n}$ in the following way:

**Definition 2.** An $(m, n)$-dimensional superspace is the space

$$\mathbb{R}_S^{m,n} = \underbrace{\mathbb{R}_{S0} \times \cdots \times \mathbb{R}_{S0}}_{m \text{ copies}} \times \underbrace{\mathbb{R}_{S1} \times \cdots \times \mathbb{R}_{S1}}_{n \text{ copies}} \qquad [4]$$

A typical element of $\mathbb{R}_S^{m,n}$ is written as $(x^1, \ldots, x^m; \xi^1, \ldots, \xi^n)$, where the convention is used that lower case Latin letters represent even objects and lower case Greek letters represent odd objects, while small capitals are used for objects of mixed or unspecified parity.

As will be described in more detail below, in the geometric approach supermanifolds are spaces locally modeled on $\mathbb{R}_S^{m,n}$. In order to define a supermanifold, we will need to define a topology on this space, and to have some notion of differentiation. Consider first multilinear functions of purely anticommuting variables. If there are $n$ such variables, $\xi^1, \ldots, \xi^n$, then a multilinear function $\textsc{f}$ can be expressed in the form

$$\textsc{f}(\xi^1, \ldots, \xi^n) = \textsc{f}_\emptyset + \sum_{i=1}^{n} \textsc{f}_i \xi^i + \sum_{1=i<j}^{n} \textsc{f}_{ij} \xi^i \xi^j + \cdots + \textsc{f}_{1\ldots n} \xi^1 \ldots \xi^n \qquad [5]$$

where the coefficients $\textsc{f}_\emptyset, \textsc{f}_i$ and so on are real numbers. Such functions will be known (anticipating the terminology for functions of both odd and even variables) as supersmooth. (A useful notation will be to write

$$\textsc{f}(\xi^1, \ldots, \xi^n) = \sum_\mu \textsc{f}_\mu \xi^\mu \qquad [6]$$

with $\mu$ a multi-index $\mu = \mu_1 \cdots \mu_k$ and $\xi^\mu = \xi^{\mu_1} \cdots \xi^{\mu_k} \mathbf{1}$. The set of multi-indices is restricted to those where $1 \le \mu_1 < \cdots < \mu_k \le n$.) More general supersmooth functions, with the coefficients $\textsc{f}_\emptyset, \ldots$ taking values in $\mathbb{C}, \mathbb{R}_S$, or some other algebra are also possible.

Differentiation of supersmooth functions of anticommuting variables is defined by linearity together with the rule

$$\frac{\partial(\xi^{\mu_1}\xi^{\mu_2}\ldots\xi^{\mu_r})}{\partial \xi^j} = \begin{cases} (-1)^{k-1} \xi^{\mu_1} \ldots \widehat{\xi^{\mu_k}} \ldots \xi^{\mu_r} & \text{if } j = \mu_k \\ 0 & \text{otherwise} \end{cases} \qquad [7]$$

where the caret $\widehat{}$ indicates an omitted factor.

In order to extend the notion of supersmoothness to functions on the more general superspace $\mathbb{R}_S^{m,n}$, we should strictly take note of the fact that an even Grassmann variable is not simply a real or complex variable, as explained in the appendix. Assuming this done, a supersmooth function on the general superspace $\mathbb{R}_S^{m,n}$ can then be defined as a function of the form

$$F(x^1, \ldots, x^m, \xi^1, \ldots, \xi^n) = \sum_\mu \textsc{f}_\mu(x^1, \ldots, x^m) \xi^\mu \qquad [8]$$

with each coefficient function $\textsc{f}_\mu$ a smooth function on $\mathbb{R}^m$.

The final preparatory idea needed is the topology on the superspace $\mathbb{R}_S^{m,n}$. It turns out that a coarse, non-Hausdorff topology leads to most of the supermanifolds used in physics. In order to define this topology, we introduce a mapping

$$\epsilon : \mathbb{R}_S \to \mathbb{R}$$

defined by

$$\epsilon\left(a_\emptyset \mathbf{1} + \sum_i a_i \beta_i + \sum_{i<j} a_{ij} \beta_i \beta_j \cdots\right) = a_\emptyset \qquad [9]$$

and the related mapping

$$\epsilon : \mathbb{R}_S^{m,n} \to \mathbb{R}^m$$

defined by

$$\epsilon((x^1,\ldots,x^m;\,\xi^1,\ldots,\xi^n)) = (\epsilon(x^1),\ldots,\epsilon(x^m)) \qquad [10]$$

These maps project out all the nilpotent Grassmann generators, leaving simply the real part. The topology involves the inverse of these projection maps: a subset $U$ of $\mathbb{R}_S^{m,n}$ is said to be open if and only if there exists an open set $V$ in $\mathbb{R}^m$ such that $U = \epsilon^{-1}(V)$. Thus, an open set is unlimited in the nilpotent directions.

In the sequel, where we consider integration, the superdeterminant of the matrix $M$ of an endomorphism of a super vector space $V$ will be useful. If $V$ is an $(m,n)$-dimensional super vector space (so that $V_0$ has dimension $m$ and $V_1$ dimension $n$), then $M$ will have the block diagonal form

$$\begin{pmatrix} M_{00} & M_{01} \\ M_{10} & M_{11} \end{pmatrix}$$

where the entries of $M_{00}$ and $M_{11}$ are even, whereas those of $M_{10}$ and $M_{10}$ are odd. If $N = M^{-1}$ has block form

$$\begin{pmatrix} N_{00} & N_{01} \\ N_{10} & N_{11} \end{pmatrix}$$

then the superdeterminant of $M$ is defined by

$$\mathrm{S}\,\det M = \det M_{00} \det N_{11}$$

It can be shown that the superdeterminant obeys the product rule, unlike the obvious generalization of the determinant to the super case.

## The Geometric Approach to Supermanifolds

A manifold is a space locally modeled on the topological space $\mathbb{R}^m$, where $m$ is the dimension of the manifold. Thus, each point in a manifold has a neighborhood which is essentially a neighborhood in $\mathbb{R}^m$. The most geometrically intuitive approach to supermanifolds is to generalize this directly by modeling a space locally on an extension of $\mathbb{R}^m$ to include anticommuting variables; the most straightforward space with the required algebraic property is the superspace $\mathbb{R}_S^{m,n}$ built from a Grassmann algebra, leading to a supermanifold of dimension $(m,n)$. (The dimension of a supermanifold is a pair of integers, indicating the numbers of even and odd coordinates of each point.)

The formal definition of a supermanifold will now be given in a manner very closely analogous to that of a classical manifold.

**Definition 3.** Let $M$ be a set.

(i) An $(m,n)$ open chart on $M$ is a pair $(U,\phi)$ such that $U$ is a subset of $M$ and $\phi$ is an injective map of $U$ into $\mathbb{R}_S^{m,n}$, with the image $\phi(U)$ an open set in $\mathbb{R}_S^{m,n}$.

(ii) An $(m,n)$ atlas on $M$ is a collection $\{(U_\alpha,\phi_\alpha)\}$ of $(m,n)$ charts on $M$ such that the $U_\alpha$ cover $M$ and, whenever $U_\alpha \cap U_\beta$ is not empty, the change of coordinate function $\phi_\alpha \circ \phi_\beta^{-1}$ is supersmooth.

An $(m,n)$-dimensional supermanifold is a set $M$ together with a maximal $(m,n)$ atlas on $M$.

The space $M$ is given a topology by defining $U \subset M$ to be open if and only if, for each $\alpha$ such that $U \cap U_\alpha$ is not empty, the set $\phi_\alpha(U \cap U_\alpha)$ is an open subset of $\mathbb{R}_S^{m,n}$.

Examples of supermanifolds include $\mathbb{R}_S^{m,n}$ itself, and also supermanifolds constructed from the data of a vector bundle over a classical manifold in a manner which will now be described. If $N$ is a classical $m$-dimensional real manifold and $E$ is an $n$-dimensional vector bundle over $N$, then an $(m,n)$-dimensional supermanifold can be constructed in the following way: suppose that $\{(V_\alpha,\psi_\alpha)\}$ is an atlas of charts on $N$, so that each $V_\alpha$ is an open subset of $N$ and each $\psi_\alpha$ is an injective map of $V_\alpha$ onto an open subset of $\mathbb{R}^m$, with $\psi_\alpha \circ \psi_\beta^{-1}$ smooth. Suppose further that the $V_\alpha$ are also local trivialization neighborhoods of the bundle $E$ with transition functions $g_{\alpha\beta}: V_\alpha \cap V_\beta \to \mathrm{GL}(n)$. Then we build the supermanifold $M$ by patching together the sets $\epsilon^{-1}(\psi_\alpha(V_\alpha) \times \mathbb{R}_S^{0,n})$ in a consistent way. This leads to a supermanifold with coordinate change functions

$$\phi_\alpha \circ \phi_\beta^{-1}\left(x_\beta^1,\ldots x_\beta^m,\xi_\beta^1,\ldots,\xi_\beta^n\right) = \left(x_\alpha^1,\ldots x_\alpha^m,\xi_\alpha^1,\ldots,\xi_\alpha^n\right)$$

where

$$\begin{aligned}\left(x_\alpha^1,\ldots x_\alpha^m\right) &= \psi_\alpha \circ \psi_\beta^{-1}\left(x_\beta^1,\ldots x_\beta^m\right) \\ \xi_\alpha^j &= \sum_{k=1}^n g_{\alpha\beta jk}\left(x_\beta^1,\ldots,x_\beta^m\right)\xi_\beta^k\end{aligned} \qquad [11]$$

(Here again we refer to the appendix for the way in which functions of even Grassmann variables, as opposed simply to real numbers, are handled.) Particular examples of this construction are the tangent bundle over $N$ and bundles of spinors over $N$. It was actually shown by Batchelor that all real, supersmooth supermanifolds are of this form.

A similar definition may be made of a complex supermanifold using a complex Grassmann algebra, with the coordinate transition functions required to be superanalytic. In this case, supermanifolds which

are not related to vector bundles in the manner described above are possible, basically because partitions of unity do not exist in the analytic setting. An example is the twisted supertorus, which is built over the standard torus and has transition functions $(z, \zeta) \to (z + 1, \zeta)$ and $(z, \zeta) \to (z + a + \alpha\zeta, \zeta + \alpha)$, extending the standard torus with transition functions $z \to z + 1$, $z \to z + a$. (Here $a, \alpha$ are, respectively, even and odd constants.) This supermanifold is an example of a super Riemann surface; such surfaces play an important role in the quantization of the spinning string.

As with classical manifolds, a natural class of functions can be defined on a supermanifold: a function $f$ on an open subset $U$ of the supermanifold $M$ is said to be supersmooth if, for each $\alpha$ such that $U \cap U_\alpha$ is nonempty, the function $f \circ \phi_\alpha^{-1}$ is supersmooth on $\phi_\alpha(U \cap U_\alpha)$. In local coordinates supersmooth functions are such that $f(x^1, \ldots, x^m, \xi^1, \ldots, \xi^n) = \sum_\mu f_{\alpha\mu}(x^1, \ldots, x^m)\xi^\mu$ with each $f_{\alpha\mu}$ a smooth function.

## The Algebraic Approach to Supermanifolds

In the algebraic approach to supermanifolds, it is the algebra of functions, rather than the manifold itself, which is extended to include anticommuting elements. In this approach an $(m, n)$-dimensional supermanifold is defined to be a pair $(N, A)$, where $N$ is an $m$-dimensional classical manifold and $A$ is a sheaf of superalgebras over $N$ with various properties, described below. The statement that $A$ is a sheaf of algebras over $N$ means that corresponding to each open subset $U$ of $N$ there is an algebra $A(U)$; also, if $V \subset U$, there is a "restriction map" $\rho_{U,V}$ mapping $A(U)$ into $A(V)$, and the various restriction maps obey certain consistency conditions. A particular example of such a sheaf (with trivial odd part) is the sheaf $A_\emptyset$ of real-valued functions on $N$, with $A_\emptyset(U) = C^\infty(U)$, the set of real-valued smooth functions on $U$ and $\rho_{U,V}$ mapping a function in $C^\infty(U)$ to its restriction in $C^\infty(V)$. The defining property of the sheaf corresponding to an $(m, n)$-dimensional supermanifold is that there is a cover $\{U_\alpha\}$ of $N$ for which the algebras $A(U_\alpha)$ have the form $A(U_\alpha) \cong C^\infty(U_\alpha) \otimes \Lambda(\mathbb{R}^n)$, so that a typical element $f$ of $A(U_\alpha)$ may be expressed as $f = \sum_\mu f_\mu \xi^\mu$, where $f_\mu \in C^\infty(U_\alpha)$ and $\xi^1, \ldots, \xi^n$ are generators of $\Lambda(\mathbb{R}^n)$. The notation here is chosen to emphasize the close correspondence with the algebra of smooth functions described at the end of the previous section. This makes it clear that, despite an apparent difference, the two approaches lead to essentially equivalent supermanifolds.

The advantage of the algebraic approach is its mathematical elegance and economy – there is no need to introduce the auxiliary Grassmann algebra $\mathbb{R}_S$ in which coordinate functions take values – but from the point of view of physicists, the geometric point of view has two advantages: first, it is closer to the standard manifold picture and thus easier to grasp, and, second, it allows a wider class of supermanifolds, because Grassmann constants are allowed; for instance, the twisted supertorus described above cannot be included in the algebraic approach without either introducing an auxiliary algebra or moving to the more difficult concept of a family of supermanifolds.

While there have been various attempts to develop infinite-dimensional supermanifolds, most of the constructions have been developed for very specific purposes, such as path integration and functional integration methods for theories with fermions. Even the question of defining a basic infinite-dimensional superalgebra with the necessary analytic properties, such as a Hilbert–Banach superalgebra, requires sophisticated procedures, so that the development of a theory of infinite-dimensional supermanifolds becomes extremely technical.

## Calculus on Supermanifolds

Much of the calculus of functions on supermanifolds proceeds in simple analogy to that of classical manifolds, with addition sign factors occurring whenever two odd quantities are transposed. For instance, a vector field on $M$ may be described as a superderivation of the algebra of supersmooth functions on $M$, that is, a linear mapping of this space obeying the super Leibniz rule $X fg = Xf\, g + (-1)^{(|X||f|)} f\, Xg$. Standard examples of vector fields (defined locally) are coordinate derivatives $\partial/\partial x^i$ and $\partial/\partial \xi^j$, defined by $(\partial/\partial x^i)f = \partial_i(f \circ \phi)$ and $(\partial/\partial \xi^j)f = \partial_{j+m}(f \circ \phi)$ with $\phi$ the coordinate function corresponding to the coordinates $(x^1, \ldots, x^m; \xi^1, \ldots, \xi^n)$. Equipped with this concept of vector field, much of differential calculus on manifolds can be directly generalized to supermanifolds in a relatively straightforward way. However, in the case of integration the situation is quite different. The standard approach to integration of anticommuting variables is the Berezin integral, which is a formal, algebraic integral that is not an antiderivative and has no measure-theoretic features. There are various reasons why such an integral is used: for instance, even the simple function $\xi$ of a single anticommuting variable has no antiderivative, while the topology on $\mathbb{R}_S^{m,n}$ does not allow open sets which discriminate in

odd directions. Additionally, when changing variables on $\mathbb{R}_S^{m,n}$ it is the superdeterminant of the Jacobian matrix which must be used. In the purely odd sector, differentials thus transform the "wrong" way.

The Berezin integral of a function $f$ of $n$ anti-commuting variables is defined by

$$\int \mathrm{d}^n\xi \left( \sum_\mu f_\mu \xi^\mu \right) = f_{1\dots n} \qquad [12]$$

In other words, Berezin integration simply picks out the coefficient of the highest-order term, thus resembling differentiation more than integration in the classical sense. Nonetheless, the Berezin integral has very useful properties, in particular allowing direct analoges of Fourier transformations and integral kernel. Given that it is the algebra of functions, and the operators acting on these algebras, which is the key element in supergeometry, these are vital properties of the integral.

The transformation rule under change of variable is the inverse of that which one expects. For instance, in the case of a single variable, if one makes the transformation $\xi \to \phi = a\xi + \beta$ with $a$ and $\beta$ constants, a direct calculation shows that the integral is invariant provided that one sets $\mathrm{d}\xi = a\,\mathrm{d}\phi$.

Integration on $\mathbb{R}_S^{m,n}$ is essentially defined by combining classical integration for the even variables with Berezin integration for odd variables, giving

$$\int_{\epsilon^{-1}(V)} \mathrm{d}^m x\, \mathrm{d}^n\xi \left( \sum_\mu f_\mu(x^1, \dots, x^m)\xi^\mu \right) = \int_V \mathrm{d}^m x \big( f_{1\dots n}(x^1, \dots, x^m) \big) \qquad [13]$$

This also defines integration on supermanifolds, provided that we can find a rule for the change of variable. This, as indicated above, may be done by using the superdeterminant of the Jacobian matrix. Suppose that $(y, \phi)$ are a new set of coordinates on our supermanifold. Then an invariant definition of integral is obtained if we set

$$\mathrm{d}^m y\, \mathrm{d}^n\xi = \mathrm{Sdet} \begin{pmatrix} \dfrac{\partial y}{\partial x} & \dfrac{\partial y}{\partial \xi} \\ \dfrac{\partial \phi}{\partial x} & \dfrac{\partial \phi}{\partial \xi} \end{pmatrix} \mathrm{d}^m x\, \mathrm{d}^n \xi \qquad [14]$$

## Appendix

We now describe the device which allows functions of even Grassmann variables to be handled simply as functions of conventional variables. The necessary class of functions is captured by defining supersmooth functions on $\mathbb{R}_S^{m,0}$ as extensions by Taylor expansion from smooth functions on $\mathbb{R}^m$.

**Definition 4.** The function $F : \mathbb{R}_S^{m,0} \to \mathbb{R}_S$ is said to be supersmooth if there exists a smooth function $\tilde{F} : \mathbb{R}^m \to \mathbb{R}$, such that

$$\begin{aligned} F(x^1, \dots, x^m) &= \tilde{F}(\epsilon(x)) + \sum_{i=1}^m (x^i - \epsilon(x^i)\mathbf{1}) \frac{\partial \tilde{F}}{\partial x^i}(\epsilon(x)) \\ &\quad + \frac{1}{2} \sum_{i,j=1}^m (x^i - \epsilon(x^i)\mathbf{1}) \\ &\quad \times (x^j - \epsilon(x^j)\mathbf{1}) \frac{\partial^2 \tilde{F}}{\partial x^i \partial x^j}(\epsilon(x)) \dots \end{aligned} \qquad [15]$$

(Although this Taylor series will in general be infinite, it gives well-defined coefficients for each $\beta_\mu$ in the expansion [3], so that the value of $F$ is a well-defined element of $\mathbb{R}_S$.) A number of different classes of function can be obtained, by varying the space in which the function $\tilde{F}$ takes its value.

## Introduction

String theory postulates that all elementary particles in nature correspond to different vibration states of an underlying relativistic string. In the quantum theory both the frequencies and the amplitudes of vibration are quantized, so that the quantum states of a string are discrete. They can be characterized by their mass, spin, and various gauge charges. One of these states has zero mass and spin equal to $2\hbar$, and can be identified with the messenger of gravitational interactions, the graviton. Thus, string theory is a candidate for a unified theory of all fundamental interactions, including quantum gravity.

In this article, we discuss the theory of superstrings as consistent theories of quantum gravity. The aim is to provide a quick (mostly lexicographic and bibliographic) entry to some of the salient features of the subject for a nonspecialist audience. Our treatment is thus neither complete nor comprehensive – there exist for this several excellent expert books, in particular by Green, *et al.* (1987) and by Polchinski (1998). An introductory textbook by Zwiebach (2004) is also highly recommended for beginners. Several other complementary reviews on various aspects of superstring theories are available on the internet (see the "Further reading" section); some more will be given as we proceed.

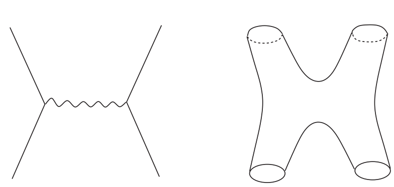

**Figure 1** A four-particle and a four-string interaction.

## The Five Superstring Theories

Theories of relativistic extended objects are tightly constrained by anomalies, that is, quantum violations of classical symmetries. These arise because the classical trajectory of an extended $p$-dimensional object (or "$p$-brane") is described by the embedding $X^\mu(\zeta^a)$, where $\zeta^{a=0,\dots,p}$ parametrize the brane world volume, and $X^{\mu=0,\dots,D-1}$ are coordinates of the target space. The quantum mechanics of a single $p$-brane is therefore a $(p+1)$-dimensional quantum field theory, and as such suffers *a priori* from ultraviolet divergences and anomalies. The case $p=1$ is special in that these problems can be exactly handled. The story for higher values of $p$ is much more complicated, as will become apparent later on.

The theory of ordinary loops in space is called closed bosonic string theory. The classical trajectory of a bosonic string extremizes the Nambu–Goto action (proportional to the invariant area of the world sheet)

$$S_{\mathrm{NG}} = -\frac{1}{2\pi\alpha'} \int \mathrm{d}^2\zeta \sqrt{-\det(G_{\mu\nu}\partial_a X^\mu \partial_b X^\nu)} \qquad [1]$$

where $G_{\mu\nu}(X)$ is the target-space metric, and $\alpha'$ is the Regge slope (which is inversely proportional to the string tension and has dimensions of length squared). In flat spacetime, and for a conformal choice of world-sheet parameters $\zeta^\pm = \zeta^0 \pm \zeta^1$, the equations of motion read:

$$\partial_+\partial_- X^\mu = 0 \quad \text{and} \quad \eta_{\mu\nu}\partial_\pm X^\mu \partial_\pm X^\nu = 0 \qquad [2]$$

with $\eta_{\mu\nu}$ the Minkowski metric. The $X^\mu$ are thus free two-dimensional fields, subject to quadratic phase-space constraints known as the Virasoro conditions. These can be solved consistently at the quantum level in the critical dimension $D=26$. Otherwise, the symmetries of eqns [2] are anomalous: either Lorentz invariance is broken, or there is a conformal anomaly leading to unitarity problems. (For $D<26$, unitary noncritical string theories in highly curved rather than in the originally flat background can be constructed.)

Even for $D=26$, bosonic string theory is, however, sick because its lowest-lying state is a tachyon,

The finiteness of string perturbation theory has been, strictly speaking, only established up to two loops – for a recent review see D'Hoker and Phong (2002). However, even though the technical problem is open and hard, the qualitative case for all-order finiteness is convincing. It can be illustrated with the torus diagram which makes a one-loop contribution to string amplitudes. The thin torus of **Figure 2** could be traced either by a short, light string propagating (virtually) for a long time, or by a long, heavy string propagating for a short period of time. In conventional field theory, these two virtual trajectories would have made distinct contributions to the amplitude, one in the infrared and the second in the ultraviolet region. In string theory, on the other hand, they are related by a modular transformation (that exchanges $\zeta^0$ with $\zeta^1$) and must not, therefore, be counted twice. A similar kind of argument shows that all potential divergences of string theory are infrared – they are therefore kinematical (i.e., occur for special values of the external momenta), or else they signal an instability of the vacuum and should cancel if one expands around a stable ground state.

The low-energy limit of the heterotic and type I string theories is $N=1$ supergravity plus super Yang–Mills. In addition to the $N=1$ graviton multiplet, the massless spectrum now also includes gauge bosons and their associated gauginos. The two-derivative effective action in the heterotic case reads:

$$S_{\text{het}} = \frac{1}{2\kappa^2}\int \mathrm{d}^{10}x\sqrt{-G}\,\mathrm{e}^{-2\Phi} \times \left[R + 4\partial_\mu\Phi\partial^\mu\Phi + \frac{\kappa^2}{g^2_{\text{YM}}}\mathrm{tr}(F_{\mu\nu}F^{\mu\nu}) - \frac{1}{2}\left|\mathrm{d}B_2 - \frac{\kappa^2}{g^2_{\text{YM}}}\omega_3^{\text{gauge}}\right|^2\right] + \text{fermions} \qquad [7]$$

where $\omega_3^{\text{gauge}} = \mathrm{tr}(AdA + (2/3)A^3)$ is the Chern–Simons gauge 3-form. Again, supersymmetry fixes completely the above action – the only freedom is in the choice of the gauge group and of the Yang–Mills coupling $g_{\text{YM}}$. Thus, up to redefinitions of the fields, the type I theory has necessarily the same low-energy limit.

The $D=10$ supergravity plus super Yang–Mills has a hexagon diagram that gives rise to gauge and gravitational anomalies, similar to the triangle anomaly in $D=4$. It turns out that for the two special groups $E_8 \times E_8$ and SO(32), the structure of these anomalies is such that they can be canceled by a combination of local counter-terms. One of them is of the form $\int B_2 \wedge X_8(F,R)$, where $X_8$ is an 8-form quartic in the curvature and/or Yang–Mills field strength. The other is already present in the lower line of expression [7], with the replacement $\omega_3^{\text{gauge}} \rightarrow \omega_3^{\text{gauge}} - \omega_3^{\text{Lorentz}}$, where the second Chern–Simons form is built out of the spin connection. Note that these modifications of the effective action involve terms with more than two derivatives, and are not required by supersymmetry at the classical level. The discovery by Green and Schwarz that string theory produces precisely these terms (from integrating out the massive string modes) was called the "first superstring revolution."

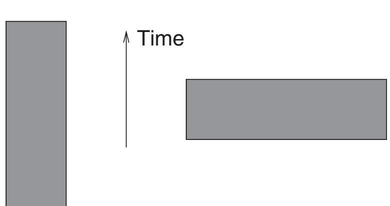

**Figure 2** The same torus diagram viewed in two different channels.

## D-Branes

A large window into the nonperturbative structure of string theory has been opened by the discovery of D(irichlet)-branes, and of strong/weak-coupling duality symmetries. A D$p$ brane is a solitonic $p$-dimensional excitation, defined indirectly by the property that open string endpoints can attach to its world volume (see **Figure 3**). Stable D$p$ branes exist in the type IIA and type IIB theories for $p$ even, respectively, odd, and in the type I theory for $p=1$ and 5. They are charged under the R–R $(p+1)$-form potential or, for $p > 4$, under its magnetic dual. Strictly speaking, only for $0 \leq p \leq 6$ do D-branes resemble regular solitons the word stands for "solitary waves"). The D7 branes are more like

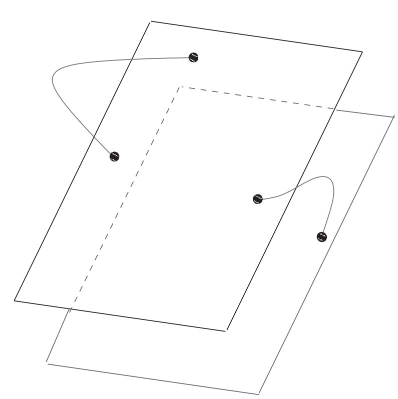

**Figure 3** D-branes and open strings.

cosmic strings, the D8 branes are domain walls, while the D9 branes are spacetime filling. Indeed, type I string theory can be thought as arising from type IIB through the introduction of an orientifold 9-plane (required for tadpole cancelation) and of 32 D9 branes.

The low-energy dynamics of a D$p$ brane is described by a supersymmetric abelian gauge theory, reduced from ten down to $p+1$ dimensions. The gauge field multiplet includes $9-p$ real scalars, plus gauginos in the spinor representation of the R-symmetry group SO$(9-p)$. These are precisely the massless states of an open string with endpoints moving freely on a hyperplane. The real scalar fields are Goldstone modes of the broken translation invariance, that is, they are the transverse coordinate fields $\vec{Y}(\xi^a)$ of the D-brane. The bosonic part of the low-energy effective action is the sum of a Dirac–Born–Infeld (DBI) and a Chern–Simons (CS) like term:

$$I_p = -T_p \int d^{p+1}\xi \, e^{-\Phi} \sqrt{-\det(\hat{G}_{ab} + \mathcal{F}_{ab})} - \rho_p \int \sum_n \hat{C}_n \wedge e^{\mathcal{F}} \qquad [8]$$

where $\mathcal{F}_{ab} = \hat{B}_{ab} + 2\pi\alpha' F_{ab}$, hats denote pullbacks on the brane of bulk tensor fields (e.g., $\hat{G}_{ab} = G_{\mu\nu}\partial_a Y^\mu \partial_b Y^\nu$), $F_{ab}$ is the field strength of the world-volume gauge field, and in the CS term one is instructed to keep the $(p+1)$-form of the expression under the integration sign. The constants $T_p$ and $\rho_p$ are the tension and charge density of the D-brane. As was the case for the effective supergravities, the above action receives curvature corrections that are higher order in the $\alpha'$ expansion. Note however that a class of higher-order terms have been already resummed in expression [8]. These involve arbitrary powers of $F_{ab}$, and are closely related more precisely $T$-dual, see later) to relativistic effects which can be important even in the weak-acceleration limit. When refereing to the D9 branes of the type I superstring, the action [8] includes the GS terms required to cancel the gauge anomaly.

The tension and charge density of a D$p$ brane can be extracted from its coupling to the (closed-string) graviton and R–R $(p+1)$-form, with the result:

$$T_p^2 = \rho_p^2 = \frac{\pi}{\kappa^2}(4\pi^2\alpha')^{3-p} \qquad [9]$$

The equality of tension and charge follows from unbroken supersymmetry, and is also known as a Bogomol'nyi–Prasad–Sommerfeld (BPS) condition. It implies that two or more identical D-branes exert no net static force on each other, because their R–R repulsion cancels exactly their gravitational attraction. A nontrivial check of the result [9] comes from the Dirac quantization condition (generalized to extended objects by Nepomechie and Teitelboim). Indeed, a D$p$ brane and a D$(6-p)$-brane are dual excitations, like electric and magnetic charges in four dimensions, so their couplings must obey

$$2\kappa^2 \rho_p \rho_{6-p} = 2\pi k \quad \text{where } k \in Z \qquad [10]$$

This ensures that the Dirac singularity of the long-range R–R fields of the branes does not lead to an observable Bohm–Aharonov phase. The couplings [9] obey this condition with $k=1$, so that D-branes carry the smallest allowed R–R charges in the theory.

A simple but important observation is that open strings living on a collection of $n$ identical D-branes have matrix-valued wave functions $\psi_{ij}$, where $i, j = 1, \ldots, n$ label the possible endpoints of the string. The low-energy dynamics of the branes is thus described by a nonabelian gauge theory, with group U$(n)$ if the open strings are oriented, and SO$(n)$ or Sp$(n)$ if they are not. We have already encountered such Chan–Paton factors in our discussion of the type I superstring. More generally, this simple property of D-branes has led to many insights on the geometric interpretation and engineering of gauge theories, which are reviewed in the articles Brane Construction of Gauge Theories and Gauge Theories from Strings. It has also placed on a firmer footing the idea of a brane world, according to which the fields and interactions of the standard model would be confined to a set of D-branes, while gravitons are free to propagate in the bulk (for reviews, *see* Brane Worlds and reference Lust (2004)). It has, finally, inspired the gauge/string theory or AdS/CFT correspondence (*see* Ads/CFT Correspondence and Aharony *et al.* (2000)) on which we will comment later.

## Dualities and M Theory

One other key role of D-branes has been to provide evidence for the various nonperturbative duality conjectures. Dual descriptions of the same physics arise also in conventional field theory. A prime example is the Montonen–Olive duality of four-dimensional, $N=4$ supersymmetric Yang–Mills, which is the low-energy theory describing the dynamics of a collection of D3 branes. The action

for the gauge field and six associated scalars $\Phi^I$ (all in the adjoint representations of the gauge group $G$) is

$$S_{N=4} = -\frac{1}{4g^2}\int d^4x\,\mathrm{tr} \times \left(F_{\mu\nu}F^{\mu\nu} + 2\sum_I D_\mu\Phi^I D^\mu\Phi^I + \sum_{I<J} 2[\Phi^I,\Phi^J]^2\right) - \frac{\theta}{32\pi^2}\int d^4x\,\mathrm{tr}\left(F_{\mu\nu}{}^*F^{\mu\nu}\right) + \text{fermionic terms} \qquad [11]$$

Consider for simplicity the case $G = SU(2)$. The scalar potential has flat directions along which the six $\Phi^I$ commute. By an SO(6) R-symmetry rotation, we can set all but one of them to zero, and let $<\mathrm{tr}(\Phi^1\Phi^1)> = v^2$ in the vacuum. In this "Coulomb phase" of the theory, a U(1) gauge multiplet stays massless, while the charged states become massive by the Higgs effect. The theory admits furthermore smooth magnetic-monopole and dyon solutions, and there is an elegant formula for their mass:

$$M = v|n_{el} + \tau n_{mg}|, \quad \text{where } \tau = \frac{\theta}{2\pi} + \frac{4\pi i}{g^2} \qquad [12]$$

and $n_{el}(n_{mg})$ denotes the quantized electric (magnetic) charge. This is a BPS formula that receives no quantum corrections. It exhibits the $SL(2,Z)$ covariance of the theory,

$$\tau \to \frac{a\tau + b}{c\tau + d}$$

and

$$(n_{el}, n_{mg}) \to (n_{el}, n_{mg})\begin{pmatrix} a & b \\ c & d \end{pmatrix}^{-1} \qquad [13]$$

Here $a, b, c, d$ are integers subject to the condition $ad - bc = 1$. Of special importance is the transformation $\tau \to -1/\tau$, which exchanges electric and magnetic charges and (at least for $\theta = 0$) the strong- with the weak-coupling regimes. For more details see the review by Harvey (1996).

The extension of these ideas to string theory can be illustrated with the strong/weak- coupling duality between the type I theory, and the $\mathrm{Spin}(32)/Z_2$ heterotic string. Both have the same massless spectrum and low-energy action, whose form is dictated entirely by supersymmetry. The only difference lies in the relations between the string and supergravity parameters. Eliminating the latter, one finds

$$\lambda_{het} = \frac{1}{2\lambda_I} \qquad \text{and} \qquad \alpha'_{het} = \sqrt{2}\lambda_I\alpha'_I \qquad [14]$$

It is thus tempting to conjecture that the strongly coupled type I theory has a dual description as a weakly coupled heterotic string. These are, indeed, the only known ultraviolet completions of the theory [7]. Furthermore, for $\lambda_I \gg 1$, the D1 brane of the type I theory becomes light, and could be plausibly identified with the heterotic string. This conjecture has been tested successfully by comparing various supersymmetry-protected quantities (such as the tensions of BPS excitations and special higher-derivative terms in the effective action), which can be calculated exactly either semiclassically, or at a given order in the perturbative expansion. Testing the duality for nonprotected quantities is a hard and important problem, which looks currently out of reach.

The other three string theories have also well-motivated dual descriptions at strong coupling $\lambda$. The type IIB theory is believed to have an $SL(2,Z)$ symmetry, similar to that of the $N = 4$ super Yang–Mills. (Note that $\lambda$ is a dynamical parameter, that changes with the vacuum expectation value of the dilaton $<\phi>$. Thus, dualities are discrete gauge symmetries of string theory.) The type IIA theory has a more surprising strong-coupling limit: it grows one extra dimension (of radius $R_{11} = 1/\lambda\sqrt{\alpha'}$), and can be approximated at low energy by the maximal 11-dimensional supergravity of Cremmer, Julia, and Scherk. The latter is a very economical theory – its massless bosonic fields are only the graviton and a 3-form potential $A_3$. The bosonic part of the action reads

$$S_{11D} = \frac{1}{2\kappa_{11}^2}\int d^{11}x\sqrt{-G}\left(R - \tfrac{1}{2}|F_4|^2\right) - \frac{1}{12\kappa_{11}^2}\int A_3 \wedge F_4 \wedge F_4 \qquad [15]$$

The electric and magnetic charges of the 3-form are a (fundamental?) membrane and a solitonic 5-brane. Standard Kaluza–Klein reduction on a circle maps $S_{11D}$ to the IIA supergravity action [6], where $G_{\mu\nu}$, $\phi$, and $C_1$ descend from the 11-dimensional graviton, and $B_2$ and $C_3$ from the 3-form $A_3$. Furthermore, all BPS excitations of the type IIA string theory have a counterpart in 11 dimensions, as summarized in **Table 1**. Finally, if one compactifies the eleventh dimension on an interval (rather than a circle), one finds the conjectured strong-coupling limit of the $E_8 \times E_8$ heterotic string.

The web of duality relations can be extended by compactifying further to $D \leq 9$ dimensions. Readers interested in more details should consult Polchinski (1998) or one of the many existing reviews of the subject (Townsend (1996), see also "Further Reading" section). In nine dimensions, in particular, the two type II theories, as well as the two heterotic superstrings, are pairwise $T$-dual. $T$-duality is a perturbative symmetry (thus firmly established, not

**Table 1** BPS excitations of type IIA string theory, and their counterparts in $\mathcal{M}$ theory compactified on a circle of radius $R_{11}$

only conjectured) which exchanges momentum and winding modes. Putting together all the links one arrives at the fully connected web of Figure 4. This makes the point that all five consistent superstrings, and also 11-dimensional supergravity, are limits of a unique underlying structure called M theory. (For lack of a better definition, "M" is sometimes also used to denote the $D = 11$ supergravity plus supermembranes, as in Figure 4.) A background-independent definition of M theory has remained elusive. Attempts to define it as a matrix model of D0 branes, or by quantizing a fundamental membrane, proved interesting but incomplete. A difficulty stems from the fact that in a generic background, or in $D = 11$ Minkowski spacetime, there is only a dimensionful parameter fixing the scale at which the theory becomes strongly coupled.

## Other Developments and Outlook

We have not discussed in this brief review some important developments covered in other contributions to the encyclopedia. For the reader's convenience, and for completeness, we enumerate (some of) them giving the appropriate cross-references:

*Compactification*. To make contact with the standard model of particle physics, one has to compactify string theory on a six-dimensional manifold. There is an embarassment of riches, but no completely realistic vacuum and, more significantly, no guiding dynamical principle to help us decide (*see* Compactification of Superstring Theory). The controlled (and phenomenologically required) breaking of spacetime supersymmetry is also a problem.

*Conformal field theory and quantum geometry*. The algebraic tools of 2D conformal field theory, both bulk and boundary (*see* Two-Dimensional Conformal Field Theory and Vertex Operator Algebras), play an important role in string theory. They allow, in certain cases, a resummation of $\alpha'$ effects, thereby probing the regime where classical geometric notions do not apply.

*Microscopic models of black holes*. Charged extremal black holes can be modeled in string theory by BPS configurations of D-branes. This has led to the first microscopic derivation of the Bekenstein–Hawking entropy formula, a result expected from any consistent theory of quantum gravity. As with the tests of duality, the extension of these results to neutral black holes is a difficult open problem – *see* Branes and Black Hole Statistical Mechanics.

*AdS/CFT and holography*. A new type of (holographic) duality is the one that relates supersymmetric gauge theories in four dimensions to string theory in asymptotically anti-de Sitter spacetimes. The sharpest and best-tested version of this duality relates $N = 4$ super Yang–Mills to string theory in $AdS_5 \times S_5$. Solving the $\sigma$-model in this latter background is one of the keys to further progress in the subject (*see* AdS/CFT Correspondence).

*String phenomenology*. Finding an experimental confirmation of string theory is clearly one of the most pressing outstanding questions. There exist several interesting possibilities for this – cosmic strings, large extra dimensions, modifications of gravity, primordial cosmology (*see* String Theory: Phenomenology for a

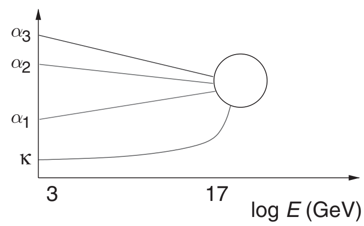

**Figure 5** The unification of couplings.

review). Here we point out the one supporting piece of experimental evidence: the unification of the gauge couplings of the (supersymmetric, minimal) standard model at a scale close to, but below the Planck scale, as illustrated in Figure 5. This is a generic "prediction" of string theory, especially in its heterotic version.

# Supersymmetric Particle Models

**S Pokorski**, Warsaw University, Warsaw, Poland

## Introduction

Supersymmetric quantum field theories (*see* Supergravity) are characterized by the existence of one ($N = 1$ supersymmetry) or several ($N > 1$ extended supersymmetry) conserved Noether-like charges $Q_A$ $A = 1, \ldots, N$, which establish symmetry links between particle states of different spin. Supersymmetry ensures equal numbers of bosonic and fermionic particle states. If it is exact, bosons and fermions related by supersymmetry transformations have equal masses. Moreover, supersymmetry imposes stringent relations between interactions which involve particles of different spin. This gives rise to a special ultraviolet behavior of supersymmetric theories. Their ultraviolet divergences are much softer than in nonsupersymmetric theories. In particular, $N = 4$ supersymmetric quantum field theories are finite and for any $N$ they are free from quadratic divergences plaguing ordinary theories with elementary scalars. $N > 4$ supersymmetric theories necessarily involve particles of spin higher than 1 and are not renormalizable. Supersymmetry promoted to a local symmetry includes gravity.

Only $N = 1$ supersymmetric theories allow for chiral fermions which are the fundamental objects in elementary particle interactions (*see* Standard Model of Particle Physics). This is because parity and

charge conjugation symmetries are violated in weak interactions. Therefore, $N > 1$ theories may not be of immediate phenomenological relevance. However, they may be useful for constructing supersymmetric theories in more than four dimensions (more than three spatial dimensions). Chiral (effective) theory in four dimensions can be then obtained after compactification of extra dimensions. For instance, $N=2$ theory in five dimensions $(x_\mu, y)$ compactified on a circle with reflection symmetry $y \to -y$ (orbifold compactification) gives chiral $N=1$ theory in four dimensions.

Absence of quadratic divergences in supersymmetric theories is the main argument supporting the belief that fundamental interactions of elementary particles at energies not higher that $\mathcal{O}(1\,\text{TeV})$ should be described by an (approximately) $N=1$ supersymmetric extension of the standard model (SM). Indeed, supersymmetric models elegantly solve the so-called hierarchy problem of the SM. At present, supersymmetry remains a theoretical hypothesis. No experimental evidence for it has been found yet (for experimental lower bounds on the masses of supersymmetric particles see Eidelman *et al.* (2004)). Supersymmetric models will be tested experimentally at the Large Linear Collider at CERN (Geneva), after the completion of its construction in 2007. Supergravity theories may be physically relevant as an intermediate step in constructing phenomenologically viable models from superstring theories.

The essence of the hierarchy problem of the standard model (SM) – the successful $\mathrm{SU}(3)_c \times \mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ gauge theory of interactions of quarks and leptons at energies up to about 100 GeV – is the following. By itself, the SM does not explain the value of the Fermi scale $v$ of the electroweak $\mathrm{SU}(2)_L \times \mathrm{U}(1)_Y$ symmetry breaking ($v \sim G_{\mathrm{F}}^{-1/2}$ where $G_{\mathrm{F}}$ is the Fermi constant determined by the life time of the muon). Indeed, in the SM, the electroweak symmetry breaking is realized by an elementary Higgs field $H$ (an SU(2) doublet) with a potential

$$V = m^2 H^\dagger H + \frac{\lambda}{2}(H^\dagger H)^2 \qquad [1]$$

where $m$ and $\lambda$ are free parameters of the SM. When $m^2 < 0$ is chosen, the minimum of the potential occurs when

$$\langle H^\dagger H\rangle = -\frac{m^2}{\lambda} \equiv \frac{v^2}{2} \qquad [2]$$

that is, the Higgs doublet acquires $\mathrm{SU}(2) \times \mathrm{U}(1)_Y$ breaking vacuum expectation value $v$ which is just the Fermi scale. The masses of the intermediate vector bosons $W^\pm$ and $Z^0$ are proportional to $v$ and depend also on the gauge couplings. Within the SM understood as a theory with the momentum cut-off $\Lambda_{\mathrm{SM}}$, quantum corrections to the mass parameter $m^2$ in eqn [1] are quadratically divergent:

$$\delta m^2 = \frac{3}{64\pi^2}\left(3g_2^2 + g_1^2 + \lambda - 8y_t^2\right)\Lambda_{\mathrm{SM}}^2 + \cdots \qquad [3]$$

Here, $g_1, g_2$, and $y_t$ are the gauge couplings of the groups $\mathrm{U}(1)_Y, \mathrm{SU}(2)_L$, and the top-quark Yukawa coupling, respectively. This means that if, above the energy scale $\Lambda_{\mathrm{SM}}$, the SM is replaced by some more fundamental theory, in which there are particles of masses $M \gtrsim \Lambda_{\mathrm{SM}}$, the quantum corrections to $m^2$ are quadratically dependent on the new mass scale $M$. For $M \gg v$, this is very unnatural even if the original parameter $m^2$ remains a free parameter of this underlying theory and particularly difficult to accept if in the underlying theory $m^2$ is fixed by some more fundamental considerations. If the SM was the correct theory up to, for example, the mass scale suggested by the see-saw mechanism for the neutrino masses, $\Lambda_{\mathrm{SM}} \sim 10^{15}$ GeV

$$|\delta m^2| \sim 10^{28}\,\mathrm{GeV}^2 \sim 10^{24} v^2!$$

Clearly, this excludes the possibility of understanding the magnitude of the Fermi scale $v$ in any sensible way. Thus, for naturalness of the Higgs mechanism in the SM there should exist a new mass scale $M \gtrsim v$, say only one order of magnitude higher than $v$ and the theory describing the physics above that scale should be free of quadratic divergences. (Approximate) supersymmetry is at present the most elegant and theoretically most complete solution to the hierarchy problem of the SM.

## Supersymmetric Extensions of the SM

In supersymmetry, the gauge fields $A_\mu^a$ are promoted to vector superfields $\hat{V}^a = (A_\mu^a, \lambda^a, D^a)$, one for each gauge symmetry group generator, where $\lambda^a$'s are Weyl fermions (called gauginos) and $D^a$'s are nondynamical auxiliary fields. A renormalizable supersymmetric gauge theory is completely defined (see, e.g., Sohnius (1985) and Wess and Bagger (1992)) by specifying the gauge group, the set of chiral supermultiplets $\hat{\Phi}_i = (\phi_i, \psi_i, F_i)$ representing matter fields, and the superpotential – a holomorphic polynomial function of at most third order in the chiral superfields which determines Yukawa couplings of the fermions $\psi_i$ and scalars $\phi_i$. Auxiliary fields $D^a$ and $F_i$ can be eliminated via their (algebraic) equations of motion.

The so-called minimal supersymmetric SM (MSSM) encodes the main features of any supersymmetric extension of the SM. Its gauge group is

$SU(3) \times SU(2) \times U(1)$ – the same as in the SM – and the chiral superfields are associated to each of the SM quark and lepton fields. Thus, quarks and leptons get scalar spin zero superpartners, the squarks and sleptons, carrying the same quantum numbers as their corresponding fermions and the vector superfields provide spin 1/2 superpartners for the gauge fields – the gluinos, the winos, and the bino. The SM Higgs doublet with weak hypercharge $Y = 1/2$ becomes a scalar component of a chiral superfield $\hat{H}_u$ which contains in addition one doublet of Weyl fermions – the Higgsinos. The chiral anomaly cancelation condition requires that there be also a second Higgs chiral superfield $\hat{H}_d$ with $Y = -1/2$. Such a superfield is also required for giving masses to all flavors of quarks; because of the holomorphicity of the superpotential the same Higgs doublet cannot couple simultaneously to all quarks.

With the MSSM superfield content, the most general renormalizable superpotential consistent with the gauge symmetry has the form

$$W = Y_u \hat{U}^c \hat{Q} \hat{H}_u + Y_d \hat{D}^c \hat{Q} \hat{H}_d + Y_l \hat{E}^c \hat{L} \hat{H}_d + \mu \hat{H}_d \hat{H}_u + \lambda_1 \hat{D}^c \hat{Q} \hat{L} + \lambda_2 \hat{E}^c \hat{L} \hat{L} + \lambda_3 \hat{U}^c \hat{D}^c \hat{D}^c + \lambda_4 \hat{L} \hat{H}_u \quad [4]$$

(flavor indices are suppressed) where the superfield $\hat{Q}$ contains the SU(2) quark doublet $Q$ and its scalar superpartner $\tilde{Q}$ and similarly for the lepton doublet $\hat{L}$, quark singlets $\hat{U}, \hat{D}$, and lepton singlet $\hat{E}$ superfields. The three first terms in [4] give the SM-like Yukawa couplings of quarks and leptons to the Higgs fields together with Yukawa couplings of the corresponding superpartners. The fourth term has no SM analogy; it gives supersymmetric masses to the Higgs scalar and Higgsinos. The interactions in the second line do not conserve baryon and lepton numbers, respectively $B$ and $L$, and should be forbidden (or strongly suppressed) by some additional symmetry of the theory as they would lead to rapid proton decay. A discrete symmetry, called $R$-parity $R = (-1)^{2S+3(B-L)}$, where $S$ is the spin of the field, is an interesting possibility. $R$-parity acts differently on the different components of the superfields: it is even for all SM particles and odd for their superpartners. Its conservation implies that superpartners must appear in pairs in any interaction vertex. Thus, with $R$-parity imposed, the lightest supersymmetric particle is stable and it is an excellent candidate for the dark matter in the universe.

Supersymmetry cannot be an exact symmetry of nature because there do not exist elementary fermions and bosons degenerate in mass. The superpotential [4] does not break supersymmetry spontaneously but even if it did the elementary fermions and bosons would on average have equal masses (they would satisfy some mass sum rule) which is also contradicted by the experimental data. Therefore, in the MSSM, supersymmetry has to be broken explicitly but in such a way that the soft ultraviolet behavior remains intact. Remarkably, the supersymmetry breaking terms which can be added to the MSSM Lagrangian without reintroducing quadratic divergences make heavy just those fields which are opposite statistics superpartners of the SM gauge bosons and fermions. These so-called soft terms are:

$$\begin{aligned}\mathcal{L}_{\text{soft}} = &-\tfrac{1}{2}\tilde{G}\tilde{G}^a\tilde{G}^a - \tfrac{1}{2}\tilde{W}\tilde{W}^a\tilde{W}^a - \tfrac{1}{2}\tilde{B}\tilde{B}\tilde{B} \\ &- m_Q^2|\tilde{Q}|^2 - m_U^2|\tilde{U}^c|^2 - m_D^2|\tilde{D}^c|^2 \\ &- m_L^2|\tilde{L}|^2 - m_E^2|\tilde{E}^c|^2 - m_{H_u}^2|H^u|^2 \\ &- m_{H_d}^2|H^d|^2 - m_3^2(H^u H^d + \text{c.c.}) \\ &+ A_U \tilde{U}^c \tilde{Q} H_u + A_D \tilde{D}^c \tilde{Q} H_d + A_E \tilde{E}^c \tilde{L} H_d \qquad [5]\end{aligned}$$

and yield gaugino (gluino $\tilde{G}$, wino $\tilde{W}$, and bino $\tilde{B}$) and scalar mass terms as well as explicit trilinear couplings between scalars (scalar mass terms and $A$-terms are $3 \times 3$ matrices in the flavor space). As a result, supersymmetry is broken in the mass spectra but not in the dimensionless couplings.

The origin of the soft supersymmetry breaking remains an open issue. Terms [5] are most probably remnants of the spontaneous supersymmetry breaking in the so-called "hidden" sector – a hypothetical set of fields that do not interact directly with the MSSM fields. For example, in the popular scenario, they interact with the MSSM fields only gravitationally and spontaneous supersymmetry breaking in the hidden sector is communicated to the MSSM sector by gravitational interactions giving rise to terms [5]. Several other mechanisms of supersymmetry breaking transmission have also been proposed (gauge mediation, anomaly mediation, etc.).

The mass parameters and $A$-terms in [5] are free parameters of the low-energy supersymmetric theory and, combined with the interactions like $Q\tilde{Q}\tilde{G}$ originating from supersymmetric kinetic terms, may be a new, troublesome, source of flavor changing neutral currents and of $CP$ violation.

## Higgs Sector of the MSSM

The MSSM Higgs potential reads

$$V = m_1^2|H_d|^2 + m_2^2|H_u|^2 + m_3^2(H_u H_d + \text{c.c.}) + \frac{g_1^2 + g_2^2}{8}\left(|H_d|^2 - |H_u|^2\right)^2 \qquad [6]$$

Its quartic part is uniquely determined by the structure of the supersymmetric gauge theory. The parameters $m_1^2$, $m_2^2$, and $m_3^2$ are determined by

the soft supersymmetry breaking Higgs boson masses [5] and the $\mu$ parameter in [4]. The potential [6] is bounded from below for $m_1^2 + m_2^2 > 2m_3^4$, and for $m_1^2 m_2^2 - m_3^2 < 0$ it has the electroweak symmetry breaking minimum at $v_u = \langle H_u^0 \rangle \neq 0, v_u = \langle H_d^0 \rangle \neq 0$. The ratio $v_u/v_d \equiv \tan\beta$ is then phenomenologically a very important parameter.

Quantum corrections to the mass parameters in [6] are controlled by the mass scale $M_{\rm soft}$ of the supersymmetry breaking terms [5]; at the one-loop level instead of [3], one finds

$$\delta m_{1,2}^2 \sim \frac{1}{16\pi^2}\left(3g_2^2 + g_1^2 - 12y_{\rm b,t}^2\right) M_{\rm soft}^2 \ln\frac{\Lambda_{\rm NEW}^2}{M_{\rm soft}^2} \qquad [7]$$

where $y_{\rm b}$ and $y_{\rm t}$ are the bottom- and top-quark Yukawa couplings, respectively and $\Lambda_{\rm NEW}$ is the scale at which the soft supersymmetry breaking terms are generated by the putative supersymmetry breaking transmission mechanism. In gravity mediation scenarios, $\Lambda_{\rm NEW} \sim M_{\rm Pl}$. In gauge mediation scenarios, $\Lambda_{\rm NEW}$ is low but it is a new scale, introduced by hand.

In the softly broken supersymmetric models, the hierarchy problem is solved for $M_{\rm soft} \lesssim \mathcal{O}(10)v$. Moreover, eqn [7] shows that via quantum corrections the large top-quark Yukawa coupling $y_{\rm t}$ drives the mass parameter $m_2^2$ to a negative value, inducing the electroweak symmetry breaking. This means that in supersymmetric models the electroweak scale is calculable in terms of the known coupling constants and the (unknown) scales $M_{\rm soft}$ and cutoff scale $\Lambda_{\rm NEW}$ to the MSSM. If $M_{\rm soft} \lesssim \mathcal{O}(10)v$, the correct electroweak scale is obtained for $\Lambda_{\rm NEW} \sim M_{\rm GUT}$. This nicely fits with unification of the gauge couplings.

In supersymmetric models, the quartic couplings in the Higgs potential are restricted. This typically leads to a strong upper bound on the mass of the lightest Higgs particle. In the minimal model with the potential [6], at the tree level

$$M_{\rm Higgs} < M_Z \approx 91\,{\rm GeV} \qquad [8]$$

This bound is substantially modified by quantum corrections. They depend quadratically on the top-quark mass and logarithmically on the stop mass scale $M_{\tilde{t}} \sim M_{\rm soft}$:

$$M_{\rm Higgs}^2 < \lambda v^2 \qquad [9]$$

where $\lambda$ is given by

$$\lambda = \tfrac{1}{8}\left(g_2^2 + g_1^2\right)\cos^2 2\beta + \Delta\lambda$$

$$\text{with } \Delta\lambda = \frac{3g_2^2}{8\pi^2}\frac{m_t^4}{v^2 M_W^2}\ln\frac{M_{\tilde{t}}^2}{m_t^2} \qquad [10]$$

For $M_{\tilde{t}} < 1\,{\rm TeV}, M_{\rm Higgs} < 130\,{\rm GeV}$.

The minimal-model bound on the Higgs mass can be relaxed in models with extended Higgs sector. For instance, if an additional gauge group singlet chiral superfield couples to the Higgs doublets, the Higgs self-coupling $\lambda$ in [9] receives additional contributions. Explicit calculations show that in such and other models, with $M_{\rm soft} \lesssim 1\,{\rm TeV}$, the bound on the Higgs mass cannot be raised above $\sim$150 GeV if one wants to preserve perturbative gauge coupling unification.

## Supersymmetric Grand Unified Theories

There are two striking aspects of the matter spectrum in the SM. One is the chiral anomalies cancelation (Weinberg 1996–2000, Pokorski 2000), which is necessary for a unitary (and renormalizable) theory, and occurs thanks to certain conspiracy between quarks and leptons suggesting a deeper link between them. The second one is that the spectrum fits into simple representations of the SU(5) and SO(10) groups (Ross 1985). Indeed, each generation of the SM matter fills $\mathbf{5}^* + \mathbf{10} + \mathbf{1}$ (if the right-handed neutrino is included into the spectrum) representations of SU(5) and for SO(10), $\mathbf{16} = \mathbf{5}^* + \mathbf{10} + \mathbf{1}$. The assignment of fermions to the SU(5) or SO(10) representations fixes the normalization of the $U(1)_Y$ generator. Both facts suggest unification of strong and electroweak elementary forces in a grand unified theory with some bigger gauge symmetry group. Such unification implies that all the SM gauge forces become of equal strength at some unification scale. Their strength is measured by the running gauge couplings $\alpha_i = g_i^2/4\pi$, $i = 1, 2, 3$, of the three group factors $SU(3)_c \times SU(2)_L \times U(1)_Y$. The energy scale dependence of $\alpha_i$ is governed by the renormalization group equations. In the first nontrivial approximation, they read:

$$\frac{1}{\alpha_i(Q)} = \frac{1}{\alpha_i(M_Z)} - \frac{b_0^{(i)}}{2\pi}\ln\left(\frac{Q}{M_Z}\right) \qquad [11]$$

Here, $1/\alpha_i(M_Z) = (58.98 \pm 0.04, 29.57 \pm 0.03, 8.40 \pm 0.14)$ are the experimental values of the gauge couplings at the Fermi scale and $b_0^{(i)}$ are the coefficients which depend on the matter content of the theory. They are

$$b_0 = \left(\tfrac{1}{10} + \tfrac{4}{3}N_g, -\tfrac{43}{6} + \tfrac{4}{3}N_g, -11 + \tfrac{4}{3}N_g\right)$$

in the SM and

$$b_0 = \left(\tfrac{3}{5} + 2N_g, -5 + 2N_g, -9 + 2N_g\right)$$

in the MSSM, where $N_g$ is the number of fermion generations. In the SM, the running gauge couplings

approach each other at high scale of order $10^{13}$ GeV but never unify.

In the MSSM, with sparticle spectrum characterized by $M_{\text{soft}} \approx 1$ TeV and for the initial Fermi scale values given above, the three gauge couplings unify with high precision at the scale $M_{\text{GUT}} \sim 10^{16}$ GeV. Therefore, the MSSM can be embedded into supersymmetric grand unified theories with no hierarchy problem for the Fermi scale (it is stable with respect to radiative corrections generated by particles with masses $\sim M_{\text{GUT}}$) and no conflict with the measured values of the gauge couplings.

In the SM, the baryon number is (perturbatively) conserved since there are no renormalizable couplings violating this symmetry. Experimental search for proton decay, for example, $p \to e^+\pi^0$, $p \to K^+\nu$, is one of the most fundamental tests for particle physics. The present limit on the proton life time is $\tau_p > 10^{33}$ yr. In grand unified theories, baryon number conservation is violated by interactions mediated by the heavy gauge bosons corresponding to the enlarged gauge symmetry (e.g., SU(5)), spontaneously broken at $M_{\text{GUT}}$ to the SM gauge symmetry. Such interactions manifest themselves at low energy as additional, nonrenormalizable interactions added to the SM Lagrangian. Proton decay is then induced by the set of dimension-6 operators of the form

$$\mathrm{O}_i^{(6)} = \frac{c_i^{(6)}}{M_{(6)}^2} qqql \qquad [12]$$

where $q, l$ denote quarks and leptons, respectively. For $c_i^{(6)} \sim \alpha_{\text{GUT}} \approx 1/25$, the experimental limit on $\tau_p$ requires $M_{(6)} \gtrsim 10^{15}$ GeV, consistently with $M_{\text{GUT}} = 10^{16}$ GeV in supersymmetric GUTs. However, in supersymmetric GUTs, there is still another, genuinely supersymmetric, source of contributions to the proton decay amplitudes. These are the dimension-5 operators

$$\mathrm{O}_i^{(5)} = \frac{c_i^{(5)}}{M_{(5)}^2} qq\tilde{q}\tilde{l} \qquad [13]$$

where $\tilde{q}, \tilde{l}$ denote squarks and sleptons, respectively. Such operators originate from the exchange of the color triplet scalars present in the Higgs boson GUT multiplets, with $M_{(5)} \sim M_{\text{GUT}} \sim 10^{16}$ GeV, and $c^{(5)} \gtrsim 10^{-7}$ is given by the Yukawa couplings. Inserted into diagrams with gaugino exchanges they give rise to dimension-6 operators of the form [12]. One then gets $c^{(6)} = \alpha_{\text{GUT}} c^{(5)}$, $M_{(6)}^2 = M_{(5)} M_{\text{SUSY}}$. Given various uncertainties, for example, in the unknown squark, gaugino, and heavy Higgs boson mass spectrum, such contributions in supersymmetric GUT models predict the proton life time to be consistent with but close to the present experimental limits.

## Summary

Supersymmetry is distinct in several very important points from all other proposed solutions to the hierarchy problem. First of all, it provides a general theoretical framework which allows one to address many physical questions. Supersymmetric models, like the MSSM or its simple extensions, satisfy a very important criterion of "perturbative calculability." In particular, they are easily consistent with the precision electroweak data. The SM is their low-energy approximation in the sense of the Appelquist–Carazzone decoupling, so most of the successful structure of the SM is built into supersymmetric models. The quadratically divergent quantum corrections to the Higgs mass parameter (the origin of the hierarchy problem in the SM) are absent in any order of perturbation theory. Therefore, the cutoff to a supersymmetric theory can be as high as the Planck scale, and "small" scale of the electroweak breaking is still natural. Supersymmetry is not only consistent with grand unification of elementary forces but, in fact, makes it very successful. And, finally, supersymmetry is needed for string theory.

However, there are also some problems to be solved: the hierarchy problem of the electroweak scale is solved but the origin of the soft supersymmetry breaking scale $M_{\text{soft}}$ remains an open question: spontaneous supersymmetry breaking and its transmission to the visible sector is a difficult problem and a fully satisfactory mechanism which would yield $M_{\text{soft}}$ hierarchically smaller than the Planck (string) scale has not yet been found. On the phenomenological side, there are new potential sources of flavor-changing neutral current transitions and of CP violation, and baryon and lepton numbers are not automatically conserved by the renormalizable couplings. But even those problems can at least be discussed in a concrete quantitative way.

# Supersymmetric Quantum Mechanics

**J-W van Holten**, NIKHEF, Amsterdam, The Netherlands

## Introduction

Supersymmetric quantum mechanics is a specific extension of quantum mechanics with fermionic degrees of freedom. In quantum field theory and many-body theory, a fermionic degree of freedom is one which is subject to Pauli's principle: any nondegenerate quantum state associated with a fermionic degree of freedom can be occupied at most once at any time. Similarly, in quantum mechanics, one associates a fermionic degree of freedom with an observable, the eigenvalue spectrum of which is restricted to the discrete set (0, 1).

The simplest example of a purely fermionic quantum system is the fermionic oscillator. It is represented by conjugate operators $(f, f^\dagger)$ such that

$$f^2 = 0, \quad f^{\dagger 2} = 0, \quad ff^\dagger + f^\dagger f = 1 \qquad [1]$$

with a Hamiltonian $H$ given by the bilinear expression

$$H_f = \varepsilon_f + \hbar\omega f^\dagger f \qquad [2]$$

The state space of this system is spanned by two independent state vectors $|0\rangle$ and $|1\rangle$, such that

$$\begin{aligned} f|0\rangle &= 0, \qquad f^\dagger|0\rangle = |1\rangle \\ f|1\rangle &= |0\rangle, \qquad f^\dagger|1\rangle = 0 \end{aligned} \qquad [3]$$

By construction, the states $|n_f\rangle$ are eigenstates of fermion number,

$$N_f = f^\dagger f, \qquad N_f^2 = N_f \qquad [4]$$

with eigenvalue $n_f = (0, 1)$; this implements the Pauli principle. The states have energy eigenvalues

$$E_{n_f} = \varepsilon_f + n_f\hbar\omega, \quad n_f = (0, 1) \qquad [5]$$

differing in energy by $\Delta E = \hbar\omega$. Physically, the system can be identified with a single fixed magnetic dipole in an external magnetic field, the only polarization states of the dipole being spin up or spin down.

In the Schrödinger representation of quantum mechanics (wave mechanics), fermionic degrees of freedom are represented by anticommuting Grassmann variables. These have no immediate classical analog, but can be used to construct quasiclassical observables like spin.

A supersymmetric quantum system is a system possessing both fermionic and bosonic degrees of freedom, characterized by a degeneracy between states with even and odd fermion number. In the Schrödinger representation, this is manifest in a symmetry transforming bosonic (Grassmann-even) into fermionic (Grassmann-odd) variables. The generators of the supersymmetry transformations square to the Hamiltonian of the system.

## The Supersymmetric Oscillator

An elementary example of a supersymmetric quantum system is the supersymmetric oscillator. It is a physical system combining a standard bosonic quantum oscillator with a fermionic oscillator of the same frequency. The ordinary harmonic oscillator is described by the pair of lowering and raising operators $(b, b^\dagger)$, with commutator

$$bb^\dagger - b^\dagger b = 1 \qquad [6]$$

and the Hamiltonian

$$H_b = \varepsilon_b + \hbar\omega b^\dagger b \qquad [7]$$

In this case, the eigenvalue spectrum of the occupation number

$$N_b = b^\dagger b \qquad [8]$$

consists of all non-negative integers $n_b = 0, 1, 2, \ldots$, with corresponding energy eigenvalues. To construct the supersymmetric oscillator, the harmonic oscillator is combined with a fermionic oscillator [2] of the same frequency:

$$H_s = \varepsilon_0 + \hbar\omega\left(b^\dagger b + f^\dagger f\right) \qquad [9]$$

where $\varepsilon_0 = \varepsilon_b + \varepsilon_f$. The ground state of this system is the state annihilated by both $b$ and $f$:

$$b|0,0\rangle = f|0,0\rangle = 0 \qquad [10]$$

The full set of energy eigenstates of the system is constructed by taking

$$|n_b, n_f\rangle = \frac{1}{\sqrt{n_b!}} b^{\dagger n_b} f^{\dagger n_f} |0,0\rangle$$
$$n_b = (0,1,2,\ldots), \qquad n_f = (0,1) \qquad [11]$$

with the energy eigenvalue spectrum

$$E(n_b, n_f) = \varepsilon_0 + n\hbar\omega, \quad n = n_b + n_f \qquad [12]$$

Clearly, there is a degeneracy in energy between the states $|n_b+1,0\rangle$ and $|n_b,1\rangle$, which have the same total occupation number $n$, but differ in the bosonic and fermionic occupation number by one unit. This is illustrated in Figure 1. Such pairs of states which are degenerate in energy can be transformed into each other by the operators

$$Q = \sqrt{2\hbar\omega}\, b^\dagger f, \qquad Q^\dagger = \sqrt{2\hbar\omega}\, f^\dagger b \qquad [13]$$

The explicit transformations are

$$|n_b+1,0\rangle = \frac{1}{\sqrt{2(n_b+1)\hbar\omega}} Q|n_b,1\rangle$$
$$|n_b,1\rangle = \frac{1}{\sqrt{2(n_b+1)\hbar\omega}} Q^\dagger|n_b+1,0\rangle \qquad [14]$$

The operations [14] are called supersymmetry transformations, and the operators $Q$ and $Q^\dagger$ are called supercharges.

As the zero point of energy is arbitrary in systems without gravitational interactions, it is customary to take $\varepsilon_0 = 0$, that is, $\varepsilon_f = -\varepsilon_b$; with the normalization [13], the Hamiltonian $H$ is then the symmetrized absolute square of the supercharges:

$$QQ^\dagger + Q^\dagger Q = 2H \qquad [15]$$

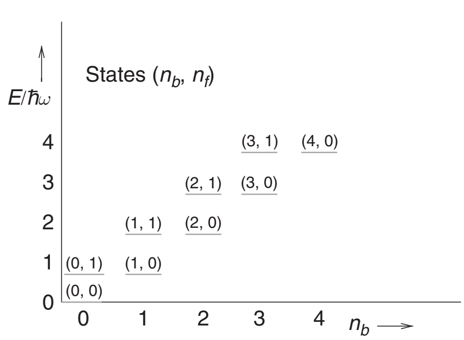

**Figure 1** Spectrum of states of the supersymmetric oscillator.

whilst

$$Q^2 = Q^{\dagger 2} = 0 \qquad [16]$$

The above relations suffice to guarantee that the supercharges $(Q, Q^\dagger)$ are conserved:

$$[Q,H] = [Q^\dagger, H] = 0 \qquad [17]$$

a result re-expressing the degeneracy between states with the same $n$ but different $n_b$ and $n_f$. The real form of the supercharges is

$$Q_1 = \frac{1}{2}(Q + Q^\dagger), \qquad Q_2 = \frac{1}{2\mathrm{i}}(Q - Q^\dagger) \qquad [18]$$

In this representation

$$H = Q_1^2 + Q_2^2 \qquad [19]$$

An important observation is that the ground state is the only state annihilated by both supersymmetry operators:

$$Q|0,0\rangle = 0, \qquad Q^\dagger|0,0\rangle = 0 \qquad [20]$$

Indeed, it is the only state with zero energy eigenvalue, and only such a state can be an invariant supersinglet; all other states have positive energy and they necessarily occur in supersymmetry pairs.

## Anticommuting Variables

Fermionic degrees of freedom can be described in a pseudoclassical formulation by anticommuting variables $\xi$ taking values in an infinite-dimensional Grassmann algebra:

$$\xi\xi' + \xi'\xi = 0 \qquad [21]$$

With an anticommuting variable $\xi$, we can associate a derivative operator $\partial/\partial\xi$, which is an element of another Grassmann algebra such that

$$\left\{\frac{\partial}{\partial\xi}, \xi\right\} = \frac{\partial}{\partial\xi}\xi + \xi\frac{\partial}{\partial\xi} = 1, \quad \frac{\partial^2}{\partial\xi^2} = 0 \qquad [22]$$

This extends the original Grassmann algebra to a Clifford algebra. Integration with respect to an anticommuting variable is defined in the same way:

$$\int \mathrm{d}\xi \cdot \xi = 1, \quad \int \mathrm{d}\xi \cdot 1 = 0 \qquad [23]$$

that is, integration is the same as differentiation for anticommuting variables. With these definitions, we can represent the fermionic raising and lowering operators in terms of anticommuting variables as

$$f^\dagger \to \xi, \qquad f \to \frac{\partial}{\partial\xi} \qquad [24]$$

and the states by

$$|0\rangle \rightarrow 1, \qquad |1\rangle \rightarrow \xi \qquad [25]$$

Then an arbitrary state takes the form of a linear superposition

$$|\Psi\rangle = \psi_0|0\rangle + \psi_1|1\rangle \;\rightarrow\; \Psi(\xi) = \psi_0 + \psi_1\xi \qquad [26]$$

and the standard positive-semidefinite inner product on the state space is represented on the wave functions by the double integral

$$\langle\Phi|\Psi\rangle = \int \mathrm{d}\xi\,\mathrm{d}\bar{\xi}\,\mathrm{e}^{\bar{\xi}\xi}\,\Phi^*(\bar{\xi})\Psi(\xi) = \phi_0^*\psi_0 + \phi_1^*\psi_1 \quad [27]$$

By construction, $f^\dagger = \xi$ and $f = \partial/\partial\xi$ are conjugates with respect to this inner product:

$$\int \mathrm{d}\xi\,\mathrm{d}\bar{\xi}\,\mathrm{e}^{\bar{\xi}\xi}\Phi^*(\bar{\xi})\xi\Psi(\xi) = \int \mathrm{d}\bar{\xi}\,\mathrm{e}^{\bar{\xi}\xi}\left(\frac{\partial\Phi}{\partial\xi}\right)^*(\bar{\xi})\Psi(\xi) \quad [28]$$

The real (self-conjugate) forms of the fermion operators are, therefore, defined by

$$\sigma_1 = \left(\xi + \frac{\partial}{\partial\xi}\right), \qquad \sigma_2 = \mathrm{i}\left(\xi - \frac{\partial}{\partial\xi}\right) \qquad [29]$$

which satisfy the Pauli–Dirac anticommutation relations

$$\sigma_i\sigma_j + \sigma_j\sigma_i = 2\delta_{ij} \qquad [30]$$

By taking the product, we obtain

$$\sigma_3 = -\mathrm{i}\sigma_1\sigma_2 = 1 - 2\xi\frac{\partial}{\partial\xi} = 1 - 2N_f$$
$$\Leftrightarrow\; N_f = \frac{1}{2}(1 - \sigma_3) \qquad [31]$$

Thus, we may think of the wave functions as two-component spinors, the components being labeled either by the eigenvalues of the spin operator $\sigma_3$, or equivalently by the fermion number $N_f$, which is a projection operator on the states with negative spin.

The action of the Hamiltonian on a wave function $\Psi(\xi)$ is represented by the integral

$$[H\Psi](\xi) = \int \mathrm{d}\xi'\,\mathrm{d}\bar{\xi}\,\mathrm{e}^{\bar{\xi}(\xi'-\xi)}H(\xi,\bar{\xi})\Psi(\xi') \qquad [32]$$

where $H(\xi,\bar{\xi})$ is the ordered symbol of the Hamiltonian:

$$H(\xi,\bar{\xi}) = \varepsilon_f + \hbar\omega\xi\bar{\xi} \qquad [33]$$

This expression is to be considered as the classical Hamiltonian of the system. In particular, the exponent of the action

$$S = \int_1^2 \mathrm{d}t\big(\mathrm{i}\hbar\bar{\xi}\dot{\xi} - H(\xi,\bar{\xi})\big)$$
$$= \hbar\int_1^2 \mathrm{d}t\big(\mathrm{i}\bar{\xi}\dot{\xi} + \omega\bar{\xi}\xi\big) + \varepsilon_f(t_2 - t_1) \qquad [34]$$

provides the integrand for the path-integral representation of the evolution operator in the quantum theory. The proof is not given here; the reader is referred to the literature. In passing, note that as the anticommuting variables $(\xi,\bar{\xi})$ are taken to be dimentionless, one actually should identify the momentum conjugate to $\xi$ with $\pi = -\mathrm{i}\hbar\bar{\xi}$; in the quantum theory, this is replaced by the operator $-\mathrm{i}\hbar\partial/\partial\xi$.

## Classical Supersymmetry

The classical action for the supersymmetric oscillator with bosonic amplitude $x$ and fermionic amplitude $\xi$ is

$$S = \int_1^2 \mathrm{d}t\left(\frac{1}{2}\dot{x}^2 - \frac{\omega}{2}x^2 + \mathrm{i}\bar{\xi}\dot{\xi} + \omega\bar{\xi}\xi\right) \qquad [35]$$

As inferred from the quantum theory, it is a combination of a linear harmonic oscillator and a fermionic oscillator of the same frequency. A factor $\sqrt{\hbar}$ is also absorbed in $\xi$ and $\bar{\xi}$; equivalently, we can use natural units in which $\hbar = 1$. In the following, we use this convention.

The action [35] is invariant under infinitesimal symmetry transformations

$$\delta x = -\mathrm{i}\big(\bar{\epsilon}\xi + \epsilon\bar{\xi}\big)$$
$$\delta\xi = (\dot{x} + \mathrm{i}\omega x)\epsilon, \qquad \delta\bar{\xi} = (\dot{x} - \mathrm{i}\omega x)\bar{\epsilon} \qquad [36]$$

with $(\bar{\epsilon},\epsilon)$ Grassmann-odd parameters. The Noether theorem then implies that there are conserved fermionic charges

$$Q = (p - \mathrm{i}\omega x)\xi, \qquad \bar{Q} = (p + \mathrm{i}\omega x)\bar{\xi} \qquad [37]$$

with the momentum defined by $p = \dot{x}$. The other conserved quantity is the energy, represented by the Hamiltonian

$$H = \frac{1}{2}\left(p^2 + \omega^2x^2\right) + \omega\xi\bar{\xi} \qquad [38]$$

The canonical phase-space formulation is obtained by defining brackets of two functions $(A, B)$ on the phase space $(x, p\,; \xi, \bar{\xi})$ by

$$\{A,B\} = \frac{\partial A}{\partial x}\frac{\partial B}{\partial p} - \frac{\partial A}{\partial p}\frac{\partial B}{\partial x}$$
$$+\,\mathrm{i}(-1)^A\left(\frac{\partial A}{\partial\xi}\frac{\partial B}{\partial\bar{\xi}} + \frac{\partial A}{\partial\bar{\xi}}\frac{\partial B}{\partial\xi}\right) \qquad [39]$$

where $(-1)^A$ is the Grassmann parity of $A$. In terms of these brackets, the time evolution and supersymmetry transformations take the form

$$\dot{A} = -\{H, A\}, \qquad \delta A = \mathrm{i}\big\{\bar{\epsilon}Q + \epsilon\bar{Q}, A\big\} \qquad [40]$$

Moreover, the charges $Q$ and $\bar{Q}$ satisfy the bracket algebra

$$\{Q, \bar{Q}\} = -2\mathrm{i}H, \qquad \{Q, H\} = \{\bar{Q}, H\} = 0 \quad [41]$$

Thus, the action [35] is the classical counterpart of the quantum theory [9]–[17] in the correspondence limit $\mathrm{i}\{A, B\} \to [A, B]_{\pm} = AB \pm BA$. For these theories, supersymmetry is rooted in the classical transformations [36].

## Supersymmetric Quantum Mechanics

The construction for the supersymmetric oscillator can be generalized to other dynamical systems in two ways. First, the nature of the interactions as represented by the potential can be modified. Second, the number of degrees of freedom can be varied. This section presents a generalization of the supersymmetric oscillator to anharmonic interactions, obtained by modification of the supercharges [37] with a general function $\Phi(x)$ as follows:

$$Q = (p - \mathrm{i}\Phi(x))\xi, \qquad \bar{Q} = (p + \mathrm{i}\Phi(x))\bar{\xi} \quad [42]$$

The brackets [39] imply the supersymmetry algebra [41] with the Hamiltonian

$$\begin{aligned} H &= \frac{\mathrm{i}}{2}\{Q, \bar{Q}\} \\ &= \frac{1}{2}p^2 + \frac{1}{2}\Phi^2(x) + \frac{1}{2}\Phi'(x)(\xi\bar{\xi} - \bar{\xi}\xi) \end{aligned} \quad [43]$$

In quantum mechanics, the supercharges become operators $Q$ and $Q^\dagger$ upon reinterpretation of $(x, p)$ as canonically conjugate operators, and the replacement $\xi \to f^\dagger$ and $\bar{\xi} \to f$; this procedure involves no ordering ambiguity. The Hamiltonian operator defined by the anticommutator of $Q$ and $Q^\dagger$ then takes the operator form associated with [43]. With the identification

$$A = \frac{1}{\sqrt{2}}(p - \mathrm{i}\Phi), \qquad A^\dagger = \frac{1}{\sqrt{2}}(p + \mathrm{i}\Phi) \quad [44]$$

and making use of the (anti)commutation relations

$$AA^\dagger - A^\dagger A = \Phi'(x), \qquad ff^\dagger + f^\dagger f = 1 \quad [45]$$

this Hamilton operator can be written in normal-ordered form as

$$H = \tfrac{1}{2}(QQ^\dagger + Q^\dagger Q) = A^\dagger A + \Phi'(x)f^\dagger f \quad [46]$$

It is positive-semidefinite by construction. All results for the supersymmetric oscillator are reproduced upon taking $\Phi(x) = \omega x$.

As the Hamiltonian commutes with the fermion number operator $N_f$, we can label all stationary states $|E, n_f\rangle$ by the energy $E$ and the fermion number $n_f = (0, 1)$. Moreover, all states of positive energy are degenerate with respect to fermion number, as they form pairs related by supersymmetry:

$$Q|E, 0\rangle = \sqrt{2E}\,|E, 1\rangle, \quad \bar{Q}|E, 1\rangle = \sqrt{2E}\,|E, 0\rangle \quad [47]$$

Only ground states with $E_0 = 0$ can occur as singlets under supersymmetry. The existence of such a ground state with fermion number $n_f$ amounts to the existence of a state $|0, n_f\rangle$ satisfying

$$A^\dagger f|0, n_f\rangle = Af^\dagger|0, n_f\rangle = 0 \quad [48]$$

The corresponding wave functions are of the form

$$\begin{aligned} |0, 0\rangle &\to \Psi_0(x, \xi) = \psi_-(x) \\ |0, 1\rangle &\to \Psi_1(x, \xi) = \psi_+(x)\xi \end{aligned} \quad [49]$$

where $\psi_\pm(x)$ are solutions of the equations

$$A\psi_- = 0, \qquad A^\dagger\psi_+ = 0 \quad [50]$$

These functions are formally given by the expressions

$$\psi_\pm(x) = C_\pm \mathrm{e}^{\pm\int_0^x \Phi(y)\,\mathrm{d}y} \quad [51]$$

For a zero-energy ground state to exist, one of these functions must be normalizable. For example, if $\Phi(x)$ is a polynomial of positive odd degree $2k - 1$, then, depending on the sign of the coefficient of $x^{2k-1}$, one of the exponents is bounded, approaching zero for $x \to \pm\infty$, and as a result becomes square integrable.

If no normalizable wave functions of the form [51] exist, the ground state cannot have zero energy ($E_0 > 0$) and all states necessarily belong to superdoublets.

## Spinning-Particle Mechanics

Minimal supersymmetric classical or quantum mechanics requires equal number of bosonic and fermionic coordinates in configuration space $(x_i, \xi_i)$, rather than equal number of bosonic and fermionic degrees of freedom in phase space. Specifically, minimal free supersymmetric particle mechanics in $n$ dimensions is described by the classical Lagrangian

$$L = \frac{1}{2}\dot{x}_i^2 + \frac{i}{2}\xi_i\dot{\xi}_i, \quad i = 1, \ldots, n \quad [52]$$

It is invariant modulo a total time derivative under infinitesimal supersymmetry transformations

$$\delta x_i = -\mathrm{i}\epsilon\xi_i, \qquad \delta\xi_i = \dot{x}_i\epsilon \quad [53]$$

The canonical phase-space formulation is phrased in terms of the free-particle momentum and Hamiltonian

$$p_i = \dot{x}_i, \qquad H = \tfrac{1}{2}p_i^2 \tag{54}$$

and the brackets

$$\{A, B\} = \frac{\partial A}{\partial x_i}\frac{\partial B}{\partial p_i} - \frac{\partial A}{\partial p_i}\frac{\partial B}{\partial x_i} + \mathrm{i}(-1)^A \frac{\partial A}{\partial \xi_i}\frac{\partial B}{\partial \xi_i} \tag{55}$$

The supersymmetry transformations are generated by the supercharge

$$Q = p_i \xi_i, \qquad \delta A = \mathrm{i}\epsilon\{Q, A\} \tag{56}$$

with the supersymmetry algebra

$$\mathrm{i}\{Q, Q\} = 2H, \qquad \{Q, H\} = 0 \tag{57}$$

An important quantity in these models is the bilinear (Grassmann-even) antisymmetric tensor

$$\sigma_{ij} = \mathrm{i}\xi_i\xi_j \tag{58}$$

For a free particle, it is a set of constants of motion forming a representation of so($n$), the Lie algebra of $n$-dimensional rotations:

$$\left\{\sigma_{ij}, \sigma_{kl}\right\} = \delta_{jk}\sigma_{il} - \delta_{jl}\sigma_{ik} - \delta_{ik}\sigma_{jl} + \delta_{il}\sigma_{jk} \tag{59}$$

Therefore, the physical interpretation of $\sigma_{ij}$ is that it represents the particle spin. For this reason, supersymmetric particle mechanics is often called spinning-particle mechanics.

Quantum mechanics of the spinning particle has the same algebraic structure, with $(x_i, p_i)$ the standard canonically conjugate operators, and the fermionic coordinates $\xi_i$ represented by the generators of a Clifford algebra; the irreducble representation in terms of Pauli–Dirac matrices of dimension $2^{[n/2]} \times 2^{[n/2]}$ is

$$\xi_i \to \frac{1}{\sqrt{2}}\gamma_i, \quad \gamma_i\gamma_j + \gamma_j\gamma_i = 2\delta_{ij} \tag{60}$$

It follows that the wave functions have $2^{[n/2]}$ components, describing different polarization states. Furthermore, in minimal supersymmetric quantum mechanics, the supersymmetry operator is represented by the Dirac operator:

$$Q \to \frac{1}{\sqrt{2}}\gamma \cdot p, \quad (\gamma \cdot p)^2 = p_i^2 = 2H \tag{61}$$

Hence, the stationary states of the system solve the Dirac equation

$$\gamma \cdot p\Psi = \sqrt{2E}\Psi \tag{62}$$

The models can, without difficulty, be extended to include interactions with external fields. As an example, we consider the coupling to a magnetic field described by a vector potential $A_i(x)$. An extension of the free-particle action [52], invariant under the same supersymmetry transformations [53], is

$$S = \int \mathrm{d}t\left(\frac{1}{2}\dot{x}_i^2 + \frac{\mathrm{i}}{2}\xi_i\dot{\xi}_i + qA_i(x)\dot{x}_i - \frac{\mathrm{i}q}{2}F_{ij}(x)\xi_i\xi_j\right) \tag{63}$$

where $F_{ij} = \nabla_i A_j - \nabla_j A_i$ is the field strength. The canonical momentum in this model is

$$p_i = \dot{x}_i + qA_i(x) \tag{64}$$

with the result that the canonical expressions for the Hamiltonian and supercharge become

$$H = \tfrac{1}{2}(p_i - qA_i(x))^2, \qquad Q = (p_i - qA_i(x))\xi_i \tag{65}$$

In the quantum theory, these constants of motion become the covariant Laplacian and Dirac operator in an external vector potential $A_i(x)$. Observe that supersymmetry requires the spin to couple to the magnetic field with gyromagnetic ratio $g = 2$. Explicitly, the equation of motion for $\xi$ can be transformed into an equation for the spin precession:

$$\dot{\xi}_i = qF_{ij}\xi_j \;\Rightarrow\; \dot{\sigma}_{ij} = q(F_{ik}\sigma_{kj} - \sigma_{ik}F_{kj}) \tag{66}$$

In three dimensions, this is equivalent to an equation in terms of axial vectors:

$$F_{ij} = \varepsilon_{ijk}B_k,\ \sigma_{ij} = \varepsilon_{ijk}s_k \;\Rightarrow\; \dot{\mathbf{s}} = -q\boldsymbol{B} \times \mathbf{s} \tag{67}$$

showing that the precession rate of $\mathbf{s}$ is given by twice the Larmor frequency.

## Extended Supersymmetry

It is possible to construct theories with more supersymmetries by associating with every bosonic coordinate several fermionic coordinates. An example is the supersymmetric oscillator and its generalizations considered earlier, which has equal number of bosonic and fermionic degrees of freedom in phase space, rather than equal number of bosonic and fermionic coordinates in configuration space. The classical phase space, spanned by variables $(x_i, p_i; \xi_i, \bar{\xi}_i)$ with $i = 1, \ldots, n$, then has double the number of fermionic variables compared to the minimal supersymmetric particle models. Such models can be constructed for systems with an $n$-dimensional bosonic configuration space. Their supercharges take the form

$$Q = (p_i - \mathrm{i}\Phi_i(\boldsymbol{x}))\xi_i, \quad \bar{Q} = (p_i + \mathrm{i}\Phi_i(\boldsymbol{x}))\bar{\xi}_i \\ \boldsymbol{x} = (x_1, \ldots, x_n) \tag{68}$$

whilst the Hamiltonian becomes

$$H = \tfrac{1}{2}p_i^2 + \tfrac{1}{2}\Phi_i^2(\boldsymbol{x}) + \tfrac{1}{4}(\nabla_j\Phi_i + \nabla_i\Phi_j)(\xi_i\bar{\xi}_j - \bar{\xi}_i\xi_j) \quad [69]$$

The supercharges are conserved if the curl of $\Phi_i(\boldsymbol{x})$ vanishes: $\nabla_i\Phi_j - \nabla_j\Phi_i = 0$. It follows that at least locally there exists a single function $W(\boldsymbol{x})$ such that

$$\Phi_i(\boldsymbol{x}) = \nabla_i W(\boldsymbol{x}) \quad [70]$$

$W(\boldsymbol{x})$ is called the superpotential. Defining the operators

$$A_i = p_i - \mathrm{i}\Phi_i(\boldsymbol{x}), \qquad A_i^\dagger = p_i + \mathrm{i}\Phi_i(\boldsymbol{x})$$
$$A_i A_j^\dagger - A_j^\dagger A_i = \nabla_i\Phi_j + \nabla_j\Phi_i \quad [71]$$

the supersymmetric quantum theory is defined by

$$Q = A_i f_i^\dagger, \qquad Q^\dagger = A_i^\dagger f_i$$
$$H = \tfrac{1}{2}(QQ^\dagger + Q^\dagger Q) \quad [72]$$

The Hamiltonian is the direct operator translation of the classical expression [69]; its normal-ordered form is

$$H = A_i^\dagger A_i + \tfrac{1}{2}(\nabla_i\Phi_j + \nabla_j\Phi_i) f_i^\dagger f_j \quad [73]$$

The total fermion number operator

$$N_f = f_i^\dagger f_i \quad [74]$$

(summed over $i$) satisfying the commutation relations

$$\left[N_f, f_j^\dagger\right]_- = f_j^\dagger, \qquad [N_f, f_j]_- = -f_j \quad [75]$$

commutes with the Hamiltonian. Hence, the stationary states can be labeled by the energy $E$ and the total fermion number $n_f = (0, \ldots, n)$. The energy spectrum being positive semidefinite, all positive-energy states occur in pairs of fermion number $(n_f, n_f + 1)$; zero-energy states exist only if the equations

$$A_i f_i^\dagger\,|0, n_f\rangle = A_i^\dagger f_i\,|0\,, n_f\rangle = 0 \quad [76]$$

admit a normalizable solution. In this context, the vanishing of the curl of $\Phi_i(\mathbf{x})$ is important, as it is a necessary condition for the formal solutions

$$\psi_\pm(\boldsymbol{x}) = C_\pm \exp\left(\pm\int_0^{\mathbf{x}} \Phi(\boldsymbol{y})\cdot \mathrm{d}\boldsymbol{y}\right) = C'_\pm\,\mathrm{e}^{\pm W(\mathbf{x})} \quad [77]$$

to be single-valued. If one of them is normalizable, there exists a zero-energy ground state with $n_f = 0$ or $n_f = n$, represented by a wave function:

$$|0,0\rangle \rightarrow \Psi_0(\boldsymbol{x},\boldsymbol{\xi}) = \psi_-(\boldsymbol{x})$$
$$|0,r\rangle \rightarrow \Psi_r(\boldsymbol{x},\boldsymbol{\xi}) = \psi_+(\boldsymbol{x})\xi_1\ldots\xi_n \quad [78]$$

Alternatively, we can represent the wave functions as spinors of dimension $2^n$, on which the fermion operators $f_i^\dagger$ and $f_i$ act as a $2^n$-dimensional matrix representation of the Clifford algebra with generators $\gamma_a, a = 1, \ldots, 2n$, defined by

$$\gamma_i = f_i + f_i^\dagger, \qquad \gamma_{i+r} = \mathrm{i}\left(f_i - f_i^\dagger\right) \quad [79]$$

These operators indeed satisfy the anticommutation rule

$$\gamma_a\gamma_b + \gamma_b\gamma_a = 2\delta_{ab} \quad [80]$$

Thus, the wave functions have $2^n$ components, as compared to the $2^{[n/2]}$ polarization states of the minimal models.

## The Witten Index

We have noted that for supersymmetric quantum systems, like the harmonic and anharmonic supersymmetric oscillator, states exist in pairs of different fermion number, degenerate in energy, except for possibly one or more zero-energy states which are superinvariant in the sense that

$$Q|0,n\rangle = \bar{Q}|0,n\rangle = 0 \;\Leftrightarrow\; H|0,n\rangle = 0 \quad [81]$$

In the Schrödinger representation, these states are characterized as zero modes of the Dirac operator:

$$\gamma\cdot D\,\Psi = 0 \quad [82]$$

where $D_i$ is an ordinary or field-dependent (e.g., covariant) derivative. Clearly, the existence of such states can, in some cases, be guaranteed if there is no state which can pair up with a given state to form a superdoublet. Witten developed a topological characterization of this condition, encoded in an index defined by

$$I = \mathrm{tr}(-1)^{N_f} = n_b(E=0) - n_f(E=0) \quad [83]$$

where $N_f$ is the fermion number operator, and $n_{b,f}(E=0)$ are the number of bosonic and fermionic zero-energy states. The trace is taken over the complete space of states, but as all nonzero energy states occur in pairs of a bosonic and a fermionic state, their contributions to the trace cancel, having opposite sign. Therefore, the trace is actually only over the zero-energy states, and counts the number of bosonic states with positive sign, and the number of fermionic states with negative sign. If the index vanishes, $I = 0$, then any zero-energy states necessarily exist in equal number of bosonic and fermionic states; under perturbations of the potential, these states can form pairs and change their energy to a positive value. However, if the index does not vanish, $I \neq 0$, then there are states which have no

partner of complementary fermion number; these states can never get a nonzero energy under changes in the parameters of the potential, as long as the changes respect supersymmetry. Such systems, therefore, necessarily possess exact zero-energy states which are invariant under all supersymmetries.

Deformations of the potential respecting supersymmetry are those obtained by changing the parameters in the superpotential. The usefulness of this concept is, therefore, that the index for models with complicated superpotentials can be computed by comparing them with models with simple superpotentials having similar topological properties.

Counting the number of states is not always a simple procedure, in particular when the spectrum includes continuum states. Therefore, in practice one often needs a regularization procedure, by taking the trace over the full state space of the exponentially damped quantity

$$I(\beta) = \mathrm{tr}(-1)^{N_f} \mathrm{e}^{-\beta H} \qquad [84]$$

and taking the limit $\beta \to 0$. The quantity [84] can be computed in terms of a path integral with periodic boundary conditions for the fermionic degrees of freedom.

Finally, as the wave function representation of supersymmetric quantum mechanics [82] links the Witten index to the space of zero modes of a Dirac operator, in particular cases it can be used to describe topological aspects of sigma models and gauge theories, and related mathematical quantities such as the Atiyah–Singer index.

More details and references to the original literature can be found in the reviews listed in the Further Reading section.

# Supersymmetry Methods in Random Matrix Theory

**M R Zirnbauer**, Universität Köln, Köln, Germany

## Introduction

A prominent theme of modern condensed matter physics is electronic transport – in particular, the electrical conductivity – of disordered metallic systems at very low temperatures. From the Landau theory of weakly interacting Fermi liquids, one expects the essential aspects of the situation to be captured by the single-electron approximation. Mathematical models that have been proposed and studied in this context include random Schrödinger operators and band random matrices.

If the physical system has infinite size, two distinct possibilities exist: the quantum single-electron motion may either be bounded or unbounded. In the former case, the disordered electron system is an insulator, in the latter case, a metal with finite conductivity (if the electron motion is not critical but diffusive). Metallic behavior is expected for weakly disordered systems in three dimensions; insulating behavior sets in when the disorder strength is increased or the space dimension reduced.

The main theoretical tool used in the physics literature on the subject is the "supersymmetry method" pioneered by Wegner and Efetov (1979–83). Over the past 20 years, physicists have applied the method in many instances, and a rather complete picture of weakly disordered metals has emerged. Several excellent reviews of these developments are available in print.

From the perspective of mathematics, however, the method has not always been described correctly, and what is sorely lacking at present is an exposition of how to implement the method rigorously. (Unfortunately, the correct exposition by Schäfer and Wegner (1980) was largely ignored or forgotten by later authors.) In this article, an attempt is made to help remedy the situation, by giving a careful review of the Wegner–Efetov supersymmetry method for the case of Hermitian band random matrices.

## Gaussian Ensembles

Let $V$ be a unitary vector space of finite dimension. A Hermitian random matrix model on $V$ is defined

by some probability distribution on Herm($V$), the Hermitian linear operators on $V$. We may fix some orthonormal basis of $V$ and represent the elements $H$ of Herm($V$) by Hermitian square matrices.

Quite generally, probability distributions are characterized by their Fourier transform or characteristic function. In the present case this is

$$\Omega(K) = \left\langle \mathrm{e}^{\mathrm{itr} HK} \right\rangle$$

where the Fourier variable $K$ is some other linear operator on $V$, and $\langle \dots \rangle$ denotes the expectation value with respect to the probability distribution for $H$. Later, it will be important that, if $\Omega(K)$ is an analytic function of $K$, the matrix entries of $K$ need not be from $\mathbb{R}$ or $\mathbb{C}$ but can be taken from the even part of some exterior algebra.

The probability distributions to be considered in this article are Gaussian with zero mean, $\langle H \rangle = 0$. Their Fourier transform is also Gaussian:

$$\Omega(K) = \mathrm{e}^{-(1/2)J(K,K)}$$

with $J$ some quadratic form. We now describe $J$ for a large family of hierarchical models that includes the case of band random matrices.

Let $V$ be given a decomposition by orthogonal vector spaces:

$$V = V_1 \oplus V_2 \oplus \cdots \oplus V_{|\Lambda|}$$

We should imagine that every vector space $V_i$ corresponds to one site $i$ of some lattice $\Lambda$, and the total number of sites is $|\Lambda|$. For simplicity, we take all dimensions to be equal: $\dim V_1 = \cdots = \dim V_{|\Lambda|} = N$. Thus, the dimension of $V$ is $N|\Lambda|$. The integer $N$ is called the number of orbitals per site.

If $\Pi_i$ is the orthogonal projector on the linear subspace $V_i \subset V$, we take the bilinear form $J$ to be

$$J(K, K') = \sum_{i,j=1}^{|\Lambda|} J_{ij} \, \mathrm{tr}(\Pi_i K \, \Pi_j K')$$

where the coefficients $J_{ij}$ are real, symmetric, and positive. This choice of $J$ implies invariance under the group $\mathscr{U}$ of unitary transformations in each subspace:

$$\mathscr{U} = \mathrm{U}(V_1) \times \mathrm{U}(V_2) \times \cdots \times \mathrm{U}(V_{|\Lambda|})$$

Clearly, $\Omega(K) = \Omega(UKU^{-1})$ or, equivalently, the probability distribution for $H$ is invariant under conjugation $H \mapsto UHU^{-1}$, for $U \in \mathscr{U}$.

If $\{e_i^a\}_{a=1,\dots,N}$ is an orthonormal basis of $V_i$, we define linear operators $E_{ij}^{ab} : V_j \to V_i$ by $E_{ij}^{ab} e_j^b = e_i^a$. By evaluating $J(E_{ij}^{ab}, E_{j'i'}^{b'a'}) = J_{ij}\delta_{ii'}\delta_{jj'}\delta^{aa'}\delta^{bb'}$, one sees that the matrix entries of $H$ all are statistically independent.

By varying the lattice $\Lambda$, the number of orbitals $N$, and the variances $J_{ij}$, one obtains a large class of Hermitian random matrix models, two prominent subclasses of which are the following:

1. For $|\Lambda| = 1$, one gets the Gaussian Unitary Ensemble (GUE). Its symmetry group is $\mathscr{U} = \mathrm{U}(N)$, the largest one possible in dimension $N = \dim V$.
2. If $|i - j|$ denotes a distance function for $\Lambda$, and $f$ a rapidly decreasing positive function on $\mathbb{R}_+$ of width $W$, the choice $J_{ij} = f(|i - j|)$ with $N = 1$ gives an ensemble of band random matrices with bandwidth $W$ and symmetry group $\mathscr{U} = \mathrm{U}(1)^{|\Lambda|}$.

Beyond being real, symmetric, and positive, the variances $J_{ij}$ are required to have two extra properties in order for all of the following treatment to go through:

- They must be positive as a quadratic form. This is to guarantee the existence of an inverse, which we denote by $w_{ij} = (J^{-1})_{ij}$.
- The off-diagonal matrix entries of the inverse must be nonpositive: $w_{ij} \leq 0$ for $i \neq j$.

## Basic Tools

### Green's Functions

A major goal of random matrix theory is to understand the statistical behavior of the spectrum and the eigenstates of a random Hamiltonian $H$. Spectral and eigenstate information can be extracted from the Green's function, that is, from matrix elements of the operator $(z - H)^{-1}$ with complex parameter $z \in \mathbb{C} \backslash \mathbb{R}$. For the models at hand, the good objects to consider are averages of $\mathscr{U}$-invariant observables such as

$$G_i^{(1)}(z) = \left\langle \mathrm{tr}\, \Pi_i (z - H)^{-1} \right\rangle \quad [1]$$

$$G_{ij}^{(2)}(z_1, z_2) = \left\langle \mathrm{tr}\, \Pi_i (z_1 - H)^{-1} \Pi_j (z_2 - H)^{-1} \right\rangle \quad [2]$$

The discontinuity of $G_i^{(1)}(z)$ across the real $z$-axis yields the local density of states. In the limit of infinite volume ($|\Lambda| \to \infty$), the function $G_{ij}^{(2)}(z_1, z_2)$ for $z_1 = E + \mathrm{i}\varepsilon$, $z_2 = E - \mathrm{i}\varepsilon$, real energy $E$, and $\varepsilon > 0$ going to zero, gives information on transport, for example, the electrical conductivity by the Kubo–Greenwood formula.

Mathematically speaking, if $G_{ij}^{(2)}(E + \mathrm{i}\varepsilon, E - \mathrm{i}\varepsilon)$ is bounded (for infinite volume) in $\varepsilon$ and decreases algebraically with distance $|i - j|$ at $\varepsilon = 0+$, the

spectrum is absolutely continuous and the eigenstates are extended at energy $E$. On the other hand, a pure point spectrum and localized eigenstates are signaled by the behavior $G^{(2)}_{ij} \sim \varepsilon^{-1} e^{-\lambda |i-j|}$ with positive Lyapunov exponent $\lambda$.

#### Green's Functions from Determinants

For any pair of linear operators $A$, $B$ on a finite-dimensional vector space $V$, the following formula from basic linear algebra holds if $A$ has an inverse:

$$\frac{\mathrm{d}}{\mathrm{d}t} \det(A + tB)\Big|_{t=0} = \det(A)\,\mathrm{tr}(A^{-1}B)$$

Using it with $A = z - H$ and $z \in \mathbb{C}\backslash\mathbb{R}$, all Green's functions can be expressed in terms of determinants; for example,

$$G^{(2)}_{ij}(w,z) = \sum_{a,b=1}^{N} \frac{\partial^2}{\partial s \partial t} \left\langle \frac{\det(w-H)\det(z-H+tE^{ab}_{ij})}{\det(w-H-sE^{ba}_{ji})\det(z-H)} \right\rangle \Bigg|_{s=t=0}$$

It is clear that, given a formula of this kind, what one wants is a method to handle ensemble averages of ratios of determinants. This is what is reviewed in the sequel.

#### Determinants as Gaussian Integrals

Let the Hermitian scalar product of the unitary vector space $V$ be written as $\varphi_1, \varphi_2 \mapsto (\bar{\varphi}_1, \varphi_2)$, and denote the adjoint or Hermitian conjugate of a linear operator $A$ on $V$ by $A^*$. If $\mathfrak{Re}\, A := (1/2)(A + A^*) > 0$, the standard Lebesgue integral of the Gaussian function $\varphi \mapsto e^{-(\bar{\varphi}, A\varphi)}$ makes sense and gives

$$\int e^{-(\bar{\varphi}, A\varphi)} = \det A^{-1} \qquad [3]$$

where it is understood that we are integrating with the Lebesgue measure on (the normed vector space) $V$ normalized by $\int e^{-(\bar{\varphi},\varphi)} = 1$. The same integral with anticommuting $\psi$ instead of the (commuting) $\varphi \in V$ gives

$$\int e^{-(\bar{\psi}, A\psi)} = \det A \qquad [4]$$

This basic formula from the field theory of fermionic particles is a consequence of the integration over anticommuting variables actually being *differentiation*:

$$\int \mathrm{d}\bar{\psi}_1\, \mathrm{d}\psi_1 f(\bar{\psi}_1, \psi_1, \ldots) := \frac{\partial^2}{\partial \bar{\psi}_1\, \partial \psi_1} f(\bar{\psi}_1, \psi_1, \ldots)$$

## Fermionic Variant

The supersymmetry method of random matrix theory is a theme with many variations. The first variation to be described is the "fermionic" one. To optimize the notation, we now write $\mathrm{d}\mu_{N,J}(H)$ for the density of the Gaussian probability distribution of $H$:

$$\langle F(H) \rangle = \int F(H)\, \mathrm{d}\mu_{N,J}(H)$$

All determinants and traces appearing below will be taken over vector spaces that are clear from the context.

Let $z_1, \ldots, z_n$ be any set of $n$ complex numbers, put $z := \mathrm{diag}(z_1, \ldots, z_n)$ for later purposes, and consider

$$\Omega^{\mathrm{ferm}}_{n,N}(z, J) = \int \prod_{\alpha=1}^{n} \det(z_\alpha - H)\, \mathrm{d}\mu_{N,J}(H) \qquad [5]$$

The supersymmetry method expresses this average of a product of determinants in an alternative way, by integrating over a "dual" measure as follows.

Introducing an auxiliary unitary vector space $\mathbb{C}^n$, one associates with every site $i$ of the lattice $\Lambda$ an object $Q_i \in \mathrm{Herm}(\mathbb{C}^n)$, the space of Hermitian $n \times n$ matrices. If $\mathrm{d}Q_i$ for $i = 1, \ldots, |\Lambda|$ are Lebesgue measures on $\mathrm{Herm}(\mathbb{C}^n)$, one puts $DQ = \mathrm{const.} \times \prod_i \mathrm{d}Q_i$ and

$$\mathrm{d}\nu_{n,J}(Q) := e^{-(1/2)\Sigma_{i,j}(J^{-1})_{ij}\,\mathrm{tr}\, Q_i Q_j} DQ \qquad [6]$$

The multiplicative constant in $DQ$ is fixed by requiring the density to be normalized: $\int \mathrm{d}\nu_{n,J}(Q) = 1$. By completing the square, this Gaussian probability measure has the characteristic function

$$\int e^{\mathrm{i}\Sigma_j \mathrm{tr} Q_j K_j}\, \mathrm{d}\nu_{n,J}(Q) = e^{-(1/2)\Sigma_{ij} J_{ij}\,\mathrm{tr}\, K_i K_j}$$

where the Fourier variables $K_1, \ldots, K_{|\Lambda|}$ are $n \times n$ matrices with matrix entries taken from $\mathbb{C}$ or another commutative algebra.

The key relation of the fermionic variant of the supersymmetry method is that the expectation of the product of determinants [5] has another expression as

$$\Omega^{\mathrm{ferm}}_{n,N}(z, J) = \int \prod_{j=1}^{|\Lambda|} \det{}^N(z - \mathrm{i}Q_j)\, \mathrm{d}\nu_{n,J}(Q) \qquad [7]$$

($\mathrm{i} = \sqrt{-1}$). The strategy of the proof is quite simple: one writes the determinants in both expressions for $\Omega^{\mathrm{ferm}}_{n,N}$ as Gaussian integrals over $nN|\Lambda|$ complex fermionic variables $\psi_1, \ldots, \psi_n$ (each $\psi_\alpha$ is a vector in $V$ with anticommuting coefficients), using the basic

formula [4]. The integrals then encountered are essentially the Fourier transforms of the distributions $d\mu_{N,J}(H)$ resp., $d\nu_{n,J}(Q)$. The result is

$$\int e^{-\Sigma_\gamma z_\gamma(\bar\psi_\gamma,\psi_\gamma)}\, e^{-(1/2)\Sigma_{ij}J_{ij}\Sigma_{\alpha\beta}(\bar\psi_\alpha,\Pi_i\psi_\beta)(\bar\psi_\beta,\Pi_j\psi_\alpha)}$$

for both expressions of $\Omega^{\text{ferm}}_{n,N}$. In other words, although the probability distributions $d\mu_{N,J}(H)$ and $d\nu_{n,J}(Q)$ are distinct (they are defined on different spaces), their characteristic functions coincide when evaluated on the Fourier variables $K = \sum_\alpha \psi_\alpha(\bar\psi_\alpha, \bullet)$ for $H$ and $(K_i)_{\alpha\beta} = (\bar\psi_\alpha, \Pi_i\psi_\beta)$ for $Q_i$. This establishes the claimed equality of the expressions [5] and [7] for $\Omega^{\text{ferm}}_{n,N}(z,J)$.

What is the advantage of passing to the alternative expression by $d\nu_{n,J}(Q)$? The answer is that, while $H$ is made up of independent random variables, the new variables $Q_i$, called the Hubbard–Stratonovich field, are correlated: they interact through the "exchange" constants $w_{ij} = (J^{-1})_{ij}$. If that interaction creates enough collectivity, a kind of mean-field behavior results.

For the simple case of GUE ($|\Lambda| = 1, w_{11} = N/\lambda^2$) with $z_1 = \cdots = z_n = E$, one gets the relation

$$\langle \det^n(E-H)\rangle = \int \det^N(E-iQ)\, e^{-(N/2\lambda^2)\operatorname{tr} Q^2}\, dQ$$

the right-hand side of which is easily analyzed by the steepest descent method in the limit of large $N$.

For band random matrices in the so-called ergodic regime, the physical behavior turns out to be governed by the constant mode $Q_1 = \cdots = Q_{|\Lambda|}$ – a fact that can be used to establish GUE universality in that regime.

## Bosonic Variant

The bosonic variant of the present method, due to Wegner, computes averages of products of determinants placed in the denominator:

$$\Omega^{\text{bos}}_{n,N}(z,J) = \int \prod_{\alpha=1}^{n} \det^{-1}(z_\alpha - H)\, d\mu_{N,J}(H) \qquad [8]$$

where we now require $\mathfrak{Im} z_\alpha \neq 0$ for all $\alpha = 1,\ldots,n$. Complications relative to the fermionic case arise from the fact that the integrand in [8] has poles. If one replaces the anticommuting vectors $\psi_\alpha$ by commuting ones $\varphi_\alpha$, and then simply repeats the previous calculation in a naive manner, one arrives at

$$\Omega^{\text{bos}}_{n,N}(z,J) \overset{?}{=} \int \prod_{j=1}^{|\Lambda|} \det^{-N}(z - Q_j)\, d\nu_{n,J}(Q) \qquad [9]$$

where the integral is still over $Q_j \in \text{Herm}(\mathbb{C}^n)$. The calculation is correct, and relation [9] therefore holds true, provided that the parameters $z_1,\ldots,z_n$ all lie in the same half (upper or lower) of the complex plane. To obtain information on transport properties, however, one needs parameters in both the upper and lower halves; see the paragraph following [2]. The general case to be addressed below is $\mathfrak{Im} z_\alpha > 0$ for $\alpha = 1,\ldots,p$, and $\mathfrak{Im} z_\alpha < 0$ for $\alpha = p+1,\ldots,n$. Careful inspection of the steps leading to eqn [9] reveals a convergence problem for $0 < p < n$. In fact, [9] with $Q_j$ in $\text{Herm}(\mathbb{C}^n)$ turns out to be false in that range. Learning how to resolve this problem is the main step toward mathematical mastery of the method. Let us therefore give the details.

If $s_\alpha := \operatorname{sgn} \mathfrak{Im} z_\alpha$, the good (meaning convergent) Gaussian integral to consider is

$$\int e^{i\Sigma_\alpha s_\alpha(\bar\varphi_\alpha,(z_\alpha - H)\varphi_\alpha)} = \prod_{\alpha=1}^{n} \det^{-1}(-is_\alpha(z_\alpha - H))$$

To avoid carrying around trivial constants, we now assume $i^{(n-2p)N|\Lambda|} = 1$. Use of the characteristic function of the distribution for $H$ then gives

$$\Omega^{\text{bos}}_{n,N}(z,J) = \int e^{i\Sigma_\gamma s_\gamma z_\gamma(\bar\varphi_\gamma,\varphi_\gamma)} \times e^{-\frac{1}{2}\Sigma_{ij}J_{ij}\Sigma_{\alpha\beta}s_\alpha(\bar\varphi_\alpha,\Pi_i\varphi_\beta)s_\beta(\bar\varphi_\beta,\Pi_j\varphi_\alpha)} \qquad [10]$$

The difficulty of analyzing this expression stems from the "hyperbolic" nature (due to the indefiniteness of the signs $s_\alpha = \pm 1$) of the term quartic in the $\varphi_\alpha, \bar\varphi_\alpha$.

### Fyodorov's Method

The integrand for $\Omega^{\text{bos}}$ is naturally expressed in terms of $n \times n$ matrices $M_i$ with matrix elements $(M_i)_{\alpha\beta} = (\bar\varphi_\alpha, \Pi_i\varphi_\beta)$. These matrices lie in $\text{Herm}^+(\mathbb{C}^n)$, that is, they are non-negative as well as Hermitian. Fyodorov's idea was to introduce them as the new variables of integration. To do that step, recall the basic fact that, given two differentiable spaces $X$ and $Y$ and a smooth map $\psi: X \to Y$, a distribution $\mu$ on $X$ is pushed forward to a distribution $\psi(\mu)$ on $Y$ by $\psi(\mu)[f] := \mu[f \circ \psi]$, where $f$ is any test function on $Y$.

We apply this universal principle to the case at hand by identifying $X$ with $V^n$, and $Y$ with $(\text{Herm}^+(\mathbb{C}^n))^{|\Lambda|}$, and $\psi$ with the mapping that sends

$$(\varphi_1,\ldots,\varphi_n) \in X \quad \text{to} \quad (M_1,\ldots,M_{|\Lambda|}) \in Y$$

by $(M_i)_{\alpha\beta} = (\bar\varphi_\alpha, \Pi_i\varphi_\beta)$. On $X = V^n$ we are integrating with the product Lebesgue measure normalized by $\int e^{-\Sigma_\alpha(\bar\varphi_\alpha,\varphi_\alpha)} = 1$. We now want the push-forward of this flat measure (or distribution) by the mapping $\psi$. In general, the push-forward of a measure is not

guaranteed to have a density but may be singular (like a Dirac $\delta$-distribution). This is in fact what happens if $N < n$. The matrices $M_i$ then have less than the maximal rank, so they fail to be positive but possess zero eigenvalues, which implies that the flat measure on $X$ is pushed forward by $\psi$ into the boundary of $Y$. For $N \geq n$, on the other hand, the push-forward measure does have a density on $Y$; and that density is $\prod_{i=1}^{|\Lambda|}(\det M_i)^{N-n}\mathrm{d}M_i$, as is seen by transforming to the eigenvalue representation and comparing Jacobians. The $\mathrm{d}M_i$ are Lebesgue measures on $\mathrm{Herm}(\mathbb{C}^n)$, normalized by the condition

$$\int_{M_i>0} \mathrm{e}^{-\mathrm{tr}M_i}(\det M_i)^{N-n}\,\mathrm{d}M_i = \int \mathrm{e}^{-\Sigma_\alpha(\bar{\varphi}_\alpha,\Pi_i\varphi_\alpha)} = 1$$

Assembling the sign information for $\mathfrak{Im} z_\alpha$ in a diagonal matrix $s := \mathrm{diag}(s_1,\ldots,s_n)$, and pushing the integral over $X$ forward to an integral over $Y$ with measure $DM := \prod_i \mathrm{d}M_i$, we obtain Fyodorov's formula:

$$\Omega^{\mathrm{bos}}_{n,N}(z,J) = \int_Y \mathrm{e}^{-(1/2)\Sigma_{ij}J_{ij}\mathrm{tr}(sM_isM_j)} \times \mathrm{e}^{\Sigma_k \mathrm{tr}(\mathrm{i}szM_k+(N-n)\ln M_k)}DM \qquad [11]$$

This formula has a number of attractive features. One is ease of derivation, another is ready generalizability to the case of non-Gaussian distributions. The main disadvantage of the formula is that it does not apply to the case of band random matrices (because of the restriction $N \geq n$); nor does it combine nicely with the fermionic formula [7] to give a supersymmetric formalism, as one formula is built on $J_{ij}$ and the other on $w_{ij}$.

Note that [11] clearly displays the dependence on the signature of $\mathfrak{Im} z$: you cannot remove the $s_1,\ldots,s_n$ from the integrand without changing the domain of integration $Y = (\mathrm{Herm}^+(\mathbb{C}^n))^{|\Lambda|}$. This important feature is missing from the naive formula [9].

Setting $q = n - p$, let $\mathrm{U}(p,q)$ be the pseudounitary group of complex $n \times n$ matrices $T$ with inverse $T^{-1} = sT^*s$. Since $|\det T| = 1$ for $T \in \mathrm{U}(p,q)$, the integration domain $Y$ and density $DM = \prod_i \mathrm{d}M_i$ of Fyodorov's formula are invariant under $\mathrm{U}(p,q)$ transformations $M_i \mapsto TM_iT^*$, and so is actually the integrand in the limit where all parameters $z_1,\ldots,z_n$ become equal. Thus, the elements of $\mathrm{U}(p,q)$ are global symmetries in that limit. This observation holds the key to another method of transforming the expression [10].

### The Method of Schäfer and Wegner

To rescue the naive formula [9], what needs to be abandoned is the integration domain $\mathrm{Herm}(\mathbb{C}^n)$ for the matrices $Q_i$. The good domain to use was constructed by Schäfer and Wegner, but was largely forgotten in later physics work.

Writing $(M_k)_{\alpha\beta} = (\bar{\varphi}_\alpha, \Pi_k\varphi_\beta)$ as before, consider the function

$$F_M(Q) = \mathrm{e}^{(1/2)\Sigma_{ij}w_{ij}\mathrm{tr}(sQ_i+\mathrm{i}z)(sQ_j+\mathrm{i}z)-\Sigma_k \mathrm{tr}M_kQ_k} \qquad [12]$$

viewed as a holomorphic function of

$$Q = (Q_1,\ldots,Q_{|\Lambda|}) \in \mathrm{End}(\mathbb{C}^n)^{|\Lambda|}$$

If the Gaussian integral $\int F_M(Q)DQ$ with holomorphic density $DQ = \prod_i \mathrm{d}Q_i$ is formally carried out by completing the square, one gets the integrand of [10]. This is just what we want, as it would allow us to pass to a $Q$-matrix formulation akin to the one of the previous section. But how can that formal step be made rigorous? To that end, one needs to (1) construct a domain on which $|F_M(Q)|$ decreases rapidly so that the integral exists, and (2) justify completion of the square and shifting of variables.

To begin, take the absolute value of $F_M(Q)$. Putting $(1/2)(Q_j + Q_j^*) =: \mathfrak{Re}Q_j$ and $(1/2\mathrm{i})(Q_j - Q_j^*) =: \mathfrak{Im}Q_j$, we have $|F_M| = \mathrm{e}^{-(1/4)(f_1+f_2+f_3)}$ with

$$f_1(Q) = \sum_{ij} w_{ij}\mathrm{tr}(s\mathfrak{Im}Q_i + z)(s\mathfrak{Im}Q_j + z) + \mathrm{c.c.}$$

$$f_2(Q) = -2\sum_{ij} w_{ij}\mathrm{tr}(s\mathfrak{Re}Q_i)(s\mathfrak{Re}Q_j)$$

$$f_3(Q) = 4\sum_i \mathrm{tr}\left(M_i + s\mathfrak{Im}z\sum_j w_{ij}\right)\mathfrak{Re}Q_i$$

These expressions suggest making the following choice of integration domain for $Q_i (i = 1,\ldots,|\Lambda|)$. Pick some real constant $\lambda > 0$ and put

$$\mathfrak{Re}Q_i = \lambda T_iT_i^*, \qquad \mathfrak{Im}Q_i = P_i := \begin{pmatrix} P_i^+ & 0 \\ 0 & P_i^- \end{pmatrix}$$

with $T_i \in \mathrm{U}(p,q), P_i^+ \in \mathrm{Herm}(\mathbb{C}^p), P_i^- \in \mathrm{Herm}(\mathbb{C}^q)$. The set of matrices $Q_i$ so defined is referred to as the Schäfer–Wegner domain $X_\lambda^{p,q}$. The range of the field $Q = (Q_1,\ldots,Q_{|\Lambda|})$ is the direct product $\mathscr{X} := (X_\lambda^{p,q})^{|\Lambda|}$.

To show that this is a good choice of domain, we first of all show convergence of the integral $\int_{\mathscr{X}} F_M(Q)DQ$. The matrices $P_i$ commute with $s$, so

$$f_1(Q)|_{\mathscr{X}} = 2\mathfrak{Re}\sum_{ij} w_{ij}\mathrm{tr}(P_i + sz)(P_j + sz)$$

Since the coefficients $w_{ij}$ are positive as a quadratic form, this expression is convex (with a positive Hessian) in the Hermitian matrices $P_i$. Second, the function

$$f_2(Q)|_{\mathscr{X}} = -2\lambda^2\sum_{ij} w_{ij}\mathrm{tr}\left(T_iT_i^*\right)^{-1}T_jT_j^*$$

is bounded from below by the constant $-2\lambda^2 n\Sigma_i w_{ii}$. This holds true because $w_{ij}$ is negative for $i \neq j$, and because $T_i T_i^* > 0$ and the trace of a product of two positive Hermitian matrices is always positive. Third,

$$f_3(Q)|_{\mathscr{X}} = 4\lambda \sum_i \mathrm{tr}\left(M_i + s\Im\mathfrak{m} z \sum_j w_{ij}\right) T_i T_i^*$$

is positive, as $(\ldots)$ is positive Hermitian. As long as $s\Im\mathfrak{m} z > 0$, the function $f_3$ goes to infinity for all possible directions of taking the $T_i$ to infinity on $\mathrm{U}(p,q)$.

Thus, when the matrices $Q_i$ are taken to vary on the Schäfer–Wegner domain $X_\lambda^{p,q}$, the absolute value $|F_M| = \mathrm{e}^{-(1/4)(f_1+f_2+f_3)}$ decreases rapidly at infinity. This establishes the convergence of $\int_{\mathscr{X}} F_M(Q)DQ$.

Next, let us count dimensions. The mapping $T \mapsto TT^*$ for $T \in \mathrm{U}(p,q) =: G$ is invariant under right multiplication of $T$ by elements of the unitary subgroup $H := \mathrm{U}(p) \times \mathrm{U}(q)$ – it is called the "Cartan embedding" of $G/H$ into $G$. The real manifold $G/H$ has dimension $2pq$ and so does its image under the Cartan embedding. Augmenting this by the dimension of $\mathrm{Herm}(\mathbb{C}^p)$ and $\mathrm{Herm}(\mathbb{C}^q)$ (from $P_i$), one gets $\dim X_\lambda^{p,q} = 2pq + p^2 + q^2 = (p+q)^2 = n^2$, which is as it should be.

Finally, why can one shift variables and do the Gaussian integral over $Q$ (with translation-invariant $DQ$) by completing the square? This question is legitimate as the Schäfer–Wegner domain $X_\lambda^{p,q}$ lacks invariance under the required shift, which is $Q_i \mapsto Q_i - \mathrm{i}sz + \sum_j J_{ij} s M_j s$.

To complete the square in [12], introduce a parameter $t \in [0,1]$ and consider the family of shifts

$$Q_i \mapsto Q_i + t\left(-\mathrm{i}sz + \Sigma_j J_{ij} s M_j s\right)$$

For fixed $t$, this shift takes $\mathscr{X} = (X_\lambda^{p,q})^{|\Lambda|}$ into another domain, $\mathscr{X}(t)$. Inspection shows that the function [12] still decreases rapidly (uniformly in the $M_i$) on $\mathscr{X}(t)$, as long as $t < 1$. Without changing the integral, one can add pieces to $\mathscr{X}(t)$ (for $t < 1$) at infinity to arrange for the chain $\mathscr{X} - \mathscr{X}(t)$ to be a cycle. Because $\mathscr{X}(t)$ is homotopic to $\mathscr{X}(0) = \mathscr{X}$, this cycle is a boundary: there exists a manifold $\mathscr{Y}(t)$ of dimension $\dim \mathscr{X} + 1$ such that $\partial\mathscr{Y}(t) = \mathscr{X} - \mathscr{X}(t)$. Viewed as a holomorphic differential form of degree $(n^2|\Lambda|, 0)$ in the complex space $\mathrm{End}(\mathbb{C}^n)^{|\Lambda|}$, the integrand $\omega := F_M(Q)DQ$ is closed (i.e., $\mathrm{d}\omega = 0$). Therefore, by Stokes' theorem,

$$\int_{\mathscr{X}} \omega - \int_{\mathscr{X}(t)} \omega = \int_{\partial\mathscr{Y}(t)} \omega = \int_{\mathscr{Y}(t)} \mathrm{d}\omega = 0$$

which proves $\int_{\mathscr{X}(t)} F_M(Q)DQ = \int_{\mathscr{X}} F_M(Q)DQ$, independent of $t$. (This argument does not go through for the nonrigorous choice $sQ_i := T_i P_i T_i^{-1}$ usually made!)

In the limit $t \to 1$, one encounters the expression

$$\int_{\mathscr{X}(1)} F_M(Q)DQ = \int_{\mathscr{X}} \mathrm{d}\nu_{n,J}(\mathrm{i}sQ) \times \mathrm{e}^{-(1/2)\Sigma_{ij} J_{ij} \mathrm{tr}(sM_i sM_j) + \mathrm{i}\Sigma_k \mathrm{tr}(szM_k)}$$

with $\mathrm{d}\nu_{n,J}$ as in [6]. The normalization integral over $\mathscr{X}$ is defined by taking the Hermitian matrices $P_i$ to be the inner variables of integration. The outer integrals over the $T_i$ then demonstrably exist, and one can fix the (otherwise arbitrary) normalization of $DQ$ by setting $\int_{\mathscr{X}} \mathrm{d}\nu_{n,J}(\mathrm{i}sQ) = 1$. Making that choice, and comparing with [10], one has proved

$$\Omega_{n,N}^{\mathrm{bos}} = \int_{\varphi,\bar\varphi} \left( \int_{\mathscr{X}} F_{(M_i)_{\alpha\beta} = (\bar\varphi_\alpha, \Pi_i \varphi_\beta)}(Q)DQ \right)$$

The final step is to change the order of integration over the $Q$- and $\varphi$-variables, which is permitted since the $Q$-integral converges uniformly in $\varphi$. Doing the Gaussian $\varphi$-integral and shifting $Q_k \to Q_k - \mathrm{i}sz$, one arrives at the Schäfer–Wegner formula for $\Omega_{n,N}^{\mathrm{bos}}$:

$$\Omega_{n,N}^{\mathrm{bos}}(z, w^{-1}) = \int_{\mathscr{X}} \mathrm{e}^{(1/2)\Sigma_{ij} w_{ij} \mathrm{tr}(sQ_i sQ_j)} \times \mathrm{e}^{-N\Sigma_k \mathrm{tr}\ln(Q_k - \mathrm{i}sz)} DQ \qquad [13]$$

which is a rigorous version of the naive formula [9]. Compared to Fyodorov's formula, it has the disadvantage of not being manifestly invariant under global hyperbolic transformations $Q_i \mapsto TQ_iT^*$ (the integration domain $\mathscr{X}$ is not invariant). Its best feature is that it does apply to the case of band random matrices with one orbital per site ($N = 1$).

## Supersymmetric Variant

We are now in a position to tackle the problem of averaging ratios of determinants. For concreteness, we shall discuss the case where the number of determinants is two for both the numerator and the denominator, which is what is needed for the calculation of the function $G_{ij}^{(2)}(z_1, z_2)$ defined in eqn [2]. We will consider the case of relevance for the electrical conductivity: $z_1 = E + \mathrm{i}\epsilon, z_2 = E - \mathrm{i}\epsilon$, with $E \in \mathbb{R}$ and $\epsilon > 0$.

A $Q$-integral formula for $G_{ij}^{(2)}(z_1, z_2)$ can be derived by combining the fermionic method for

$$\left\langle \det(z_1 - H)\det\left(z_2 - H + t_2 E_{ij}^{ab}\right) \right\rangle$$

with the Schäfer–Wegner bosonic formalism for

$$\left\langle \det^{-1}\left(z_1 - H - t_1 E_{ji}^{ba}\right)\det^{-1}(z_2 - H)\right\rangle$$

and eventually differentiating with respect to $t_1, t_2$ at $t_1 = t_2 = 0$ and summing over $a, b$; see the subsection "Green's functions from determinants." All steps are formally the same as before, but with traces and determinants replaced by their supersymmetric analogs. Having given a great many technical details in the last two sections, we now just present the final formula along with the necessary definitions and some indication of what are the new elements involved in the proof.

Let each of $Q_{\mathrm{BB}}, Q_{\mathrm{FF}}, Q_{\mathrm{BF}}$, and $Q_{\mathrm{FB}}$ stand for a $2 \times 2$ matrix. If the first two matrices have commuting entries and the last two anticommuting ones, they combine to a $4 \times 4$ supermatrix:

$$Q = \begin{pmatrix} Q_{\mathrm{BB}} & Q_{\mathrm{BF}} \\ Q_{\mathrm{FB}} & Q_{\mathrm{FF}} \end{pmatrix}$$

Relevant operations on supermatrices are the supertrace,

$$\mathrm{Str}Q = \mathrm{tr}Q_{\mathrm{BB}} - \mathrm{tr}Q_{\mathrm{FF}}$$

and the superdeterminant,

$$\mathrm{Sdet}Q = \frac{\det(Q_{\mathrm{BB}})}{\det(Q_{\mathrm{FF}} - Q_{\mathrm{FB}}{Q_{\mathrm{BB}}}^{-1}Q_{\mathrm{BF}})}$$

These are related by the identity $\mathrm{Sdet} = \exp \circ \mathrm{Str} \circ \ln$ whenever the superdeterminant exists and is nonzero.

In the process of applying the method described earlier, a supermatrix $Q_i$ gets introduced at every site $i$ of the lattice $\Lambda$. The domain of integration for each of the matrix blocks $(Q_i)_{\mathrm{BB}} (i = 1, \ldots, |\Lambda|)$ is taken to be the Schäfer–Wegner domain $X_\lambda^{1,1}$ (with some choice of $\lambda > 0$); the integration domain for each of the $(Q_i)_{\mathrm{FF}}$ is the space of Hermitian $2 \times 2$ matrices, as before.

Let $E_{\mathrm{BB}}^{11}$ be the $4 \times 4$ (super)matrix with unit entry in the upper-left corner and zeros elsewhere; similarly, $E_{\mathrm{FF}}^{22}$ has unity in the lower-right corner and zeros elsewhere. Putting $s = \mathrm{diag}(1, -1, 1, 1)$ and $z = \mathrm{diag}(z_1, z_2, z_1, z_2)$, the supersymmetric $Q$-integral formula for the generating function of $G_{ij}^{(2)}$ – obtained by combining the Schäfer–Wegner bosonic method with the fermionic variant – is written as

$$\left\langle \frac{\det(z_1 - H)\det(z_2 - H + t_2 E_{ij}^{ab})}{\det(z_1 - H - t_1 E_{ji}^{ba})\det(z_2 - H)} \right\rangle$$
$$= \int DQ \mathrm{e}^{(1/2)\Sigma_{kl} w_{kl} \mathrm{Str}(sQ_k s Q_l)}$$
$$\times\, \mathrm{e}^{-\mathrm{Str}\ln\left(\Sigma_{r,c}(Q_r - \mathrm{i}sz)\otimes E_{rr}^{cc} + \mathrm{i}t_1 E_{\mathrm{BB}}^{11}\otimes E_{ji}^{ba} - \mathrm{i}t_2 E_{\mathrm{FF}}^{22}\otimes E_{ij}^{ab}\right)} \qquad [14]$$

where the second supertrace includes a sum over sites and orbitals, and on setting $t_1 = t_2 = 0$ becomes

$$\mathrm{e}^{-N\Sigma_r \mathrm{Str}\ln(Q_r - \mathrm{i}sz)} = \prod_r \mathrm{Sdet}^{-N}(Q_r - \mathrm{i}sz)$$

The superintegral "measure" $DQ = \prod_r DQ_r$ is the flat Berezin form, that is, the product of differentials for all the commuting matrix entries in $(Q_r)_{\mathrm{BB}}$ and $(Q_r)_{\mathrm{FF}}$, times the product of derivatives for all the anticommuting matrix entries in $(Q_r)_{\mathrm{BF}}$ and $(Q_r)_{\mathrm{FB}}$.

To prove the formula [14], two new tools are needed, a brief account of which is as follows.

### Gaussian Superintegrals

There exists a supersymmetric generalization of the Gaussian integration formulas given in the subsection "Determinants as Gaussian integrals": if $A, D(B, C)$ are linear operators or matrices with commuting (resp., anticommuting) entries, and $\mathfrak{Re}A > 0$, one has

$$\mathrm{Sdet}^{-1}\begin{pmatrix} A & B \\ C & D \end{pmatrix} = \int \mathrm{e}^{-(\bar\varphi, A\varphi) - (\bar\varphi, B\psi) - (\bar\psi, C\varphi) - (\bar\psi, D\psi)}$$

Verification of this formula is straightforward. Using it, one writes the last factor in [14] as a Gaussian superintegral over four vectors: $\varphi_1, \varphi_2, \psi_1$, and $\psi_2$. The integrand then becomes Gaussian in the matrices $Q_r$.

### Shifting Variables

The next step in the proof is to do the "Gaussian" integral over the supermatrices $Q_r$. By definition, in a superintegral, one first carries out the Fermi integral, and afterwards the ordinary integrations. The Gaussian integral over the anticommuting parts $(Q_r)_{\mathrm{BF}}$ and $(Q_r)_{\mathrm{FB}}$ is readily done by completing the square and shifting variables using the fact that fermionic integration is differentiation:

$$\int \mathrm{d}\xi f(\xi - \xi') = \frac{\partial}{\partial \xi} f(\xi - \xi') = \int \mathrm{d}\xi f(\xi)$$

Similarly, the Gaussian integral over the Hermitian matrices $(Q_r)_{\mathrm{FF}}$ is done by completing the square and shifting. The integral over $(Q_r)_{\mathrm{BB}}$, however, is not Gaussian, as the domain is not $\mathbb{R}^n$ but the Schäfer–Wegner domain. Here, more advanced calculus is required: these integrations are done by using a supersymmetric change-of-variables theorem due to Berezin to make the necessary shifts by nilpotents. (There is not enough space to describe this here, so please consult Berezin's (1987) book.) Without difficulty, one finds the result to agree with the left-hand side of eqn [14], thereby establishing that formula.

## Approximations

All manipulations so far have been exact and, in fact, rigorous (or can be made so with little extra effort). Now we turn to a sequence of approximations that have been used by physicists to develop a quantitative understanding of weakly disordered quantum dots, wires, films, etc. While physically satisfactory, not all of these approximations are under full mathematical control. We will briefly comment on their validity as we go along.

### Saddle-Point Manifold

We continue to consider $G^{(2)}_{kl}(E+\mathrm{i}\varepsilon, E-\mathrm{i}\varepsilon)$ and focus on $E=0$ (the center of the energy band) for simplicity. By varying the exponent on the right-hand side of [14] and setting the variation to zero one obtains, for $t_1 = t_2 = 0$,

$$\sum_j w_{ij} s Q_j s - N Q_i^{-1} = 0$$

which is called the saddle-point equation.

Let us now assume translational invariance, $w_{ij} = f(|i-j|)$. Then, if $\lambda = \sqrt{N/\Sigma_j w_{ij}}$, the saddle-point equation has $i$-independent solutions of the form

$$Q_i = \lambda \begin{pmatrix} q_{\mathrm{BB}} & 0 \\ 0 & q_{\mathrm{FF}} \end{pmatrix}$$

where for $q_{\mathrm{FF}}$ there are three possibilities: two isolated points $q_{\mathrm{FF}} = \pm\mathbf{1}$ (unit matrix) coexist with a manifold

$$q_{\mathrm{FF}} = \begin{pmatrix} \cos\theta_1 & \sin\theta_1\, \mathrm{e}^{\mathrm{i}\phi_1} \\ \sin\theta_1\, \mathrm{e}^{-\mathrm{i}\phi_1} & -\cos\theta_1 \end{pmatrix} \qquad [15]$$

which is two-dimensional; whereas the solution space for $q_{\mathrm{BB}}$ consists of a single connected 2-manifold:

$$q_{\mathrm{BB}} = \begin{pmatrix} \cosh\theta_0 & \sinh\theta_0\, \mathrm{e}^{\mathrm{i}\phi_0} \\ \sinh\theta_0\, \mathrm{e}^{-\mathrm{i}\phi_0} & \cosh\theta_0 \end{pmatrix} \qquad [16]$$

The solutions $q_{\mathrm{FF}} = \pm\mathbf{1}$ are usually discarded in the physics literature. (The argument is that they break supersymmetry and therefore get suppressed by fermionic zero modes. For the simpler case of the one-point function [1] and in three space dimensions, such suppression has recently been proved by Disertori, Pinson, and Spencer.) Other solutions for $q_{\mathrm{BB}}$ are ruled out by the requirement $\mathfrak{Re}\, Q_i > 0$ for the Schäfer–Wegner domain.

The set of matrices [16] and [15] – the "saddle-point manifold" – is diffeomorphic to the product of a 2-hyperboloid $\mathrm{H}^2$ with a 2-sphere $\mathrm{S}^2$. Moving along that manifold $M := \mathrm{H}^2 \times \mathrm{S}^2$ leaves the $Q$-field integrand [14] unchanged (for $z_1 = z_2 = t_1 = t_2 = 0$).

One can actually anticipate the existence of such a manifold from the symmetries at hand. These are most transparent in the starting point of the formalism as given by the characteristic function $\langle \mathrm{e}^{-\mathrm{i}K_H} \rangle$ with

$$K_H = (\bar\varphi_1, H\varphi_1) - (\bar\varphi_2, H\varphi_2) + (\bar\psi_1, H\psi_1) + (\bar\psi_2, H\psi_2)$$

The signs of this quadratic expression are what is encoded in the signature matrix $s = \mathrm{diag}(1, -1, 1, 1)$ (recall that the first two entries are forced by $\mathfrak{Im}\, z_1 > 0$ and $\mathfrak{Im}\, z_2 < 0$). The Hermitian form $K_H$ is invariant under the product of two Lie groups: $\mathrm{U}(1,1)$ acting on the $\varphi$'s, and $\mathrm{U}(2)$ acting on the $\psi$'s. This invariance gets transferred by the formalism to the $Q$-side; the saddle-point manifold $M$ is in fact an "orbit" of the group action of $G := \mathrm{U}(1,1) \times \mathrm{U}(2)$ on the $Q$-field. In the language of physics, the degrees of freedom of $M$ correspond to the Goldstone bosons of a broken symmetry.

$K_{\mathrm{H}}$ also has some supersymmetries, mixing $\varphi$'s with $\psi$'s. At the infinitesimal level, these combine with the generators of $G$ to give a Lie superalgebra of symmetries $\mathfrak{g} := \mathfrak{u}(1,1|2)$. One therefore expects some kind of saddle-point supermanifold, say $\mathcal{M}$, on the $Q$-side.

$\mathcal{M}$ can be constructed by extending the above solution $q_0 := \mathrm{diag}(q_{\mathrm{BB}}, q_{\mathrm{FF}})$ of the dimensionless saddle-point equation $sqs = q^{-1}$ to the full $4 \times 4$ supermatrix space. Putting $q = q_0 + q_1$ with

$$q_1 = \begin{pmatrix} 0 & q_{\mathrm{BF}} \\ q_{\mathrm{FB}} & 0 \end{pmatrix}$$

and linearizing in $q_1$, one gets

$$s q_1 s = -q_0^{-1} q_1 q_0^{-1} \qquad [17]$$

The solution space of this linear equation for $q_1$ has dimension 4 for all $q_0 \in M$. Based on it, one expects four Goldstone fermions to emerge along with the four Goldstone bosons of $M$.

For the simple case under consideration, one can introduce local coordinates and push the analysis to nonlinear order, but things get quickly out of hand (when done in this way) for more challenging, higher-rank cases. Fortunately, there exists an alternative, coordinate-independent approach, as the mathematical object to be constructed is completely determined by symmetry!

### Riemannian Symmetric Superspace

The linear equation [17] associates with every point $x \in M$ a four-dimensional vector space of solutions,

$V_x$. As the point $x$ moves on $M$ the vector spaces $V_x$ turn and twist; thus, they form what is called a vector bundle $V$ over $M$. (The bundle at hand turns out to be nontrivial, i.e., there exists no global choice of coordinates for it.)

A section of $V$ is a smooth mapping $\nu : M \to V$ such that $\nu(x) \in V_x$ for all $x \in M$. The sections of $V$ are to be multiplied in the exterior sense, as they represent anticommuting degrees of freedom; hence the proper object to consider is the exterior bundle, $\wedge V$.

It is a beautiful fact that there exists a unique action of the Lie superalgebra $\mathfrak{g}$ on the sections of $\wedge V$ by first-order differential operators, or derivations for short. (Be advised however that this canonical $\mathfrak{g}$-action is not well known in physics or mathematics.)

The manifold $M$ is a symmetric space, that is, a Riemannian manifold with $G$-invariant geometry. Its metric tensor, $g$, uniquely extends to a second-rank tensor field (still denoted by $g$) which maps pairs of derivations of $\wedge V$ to sections of $\wedge V$, and is invariant with respect to the $\mathfrak{g}$-action. This collection of objects – the symmetric space $M$, the exterior bundle $\wedge V$ over it, the action of the Lie superalgebra $\mathfrak{g}$ on the sections of $\wedge V$, and the $\mathfrak{g}$-invariant second-rank tensor $g$ – form what the author calls a "Riemannian symmetric superspace," $\mathcal{M}$.

#### Nonlinear Sigma Model

According to the Landau–Ginzburg–Wilson (LGW) paradigm of the theory of phase transitions, the large-scale physics of a statistical mechanical system near criticality is expected to be controlled by an effective field theory for the long-wavelength excitations of the order parameter of the system.

Wegner is credited for the profound insight that the LGW paradigm applies to the random matrix situation at hand, with the role of the order parameter being taken by the matrix $Q$. He argued that transport observables (such as the electrical conductivity) are governed by slow spatial variations of the $Q$-field inside the saddle-point manifold. Efetov skilfully implemented this insight in a supersymmetric variant of Wegner's method.

While the direct construction of the effective continuum field theory by gradient expansion of [14] is not an entirely easy task, the outcome of the calculation is predetermined by symmetry. On general grounds, the effective field theory has to be a nonlinear sigma model for the Goldstone bosons and fermions of $\mathcal{M}$: if $\{\phi^A\}$ are local coordinates for the bundle $V$ with metric $g_{AB}(\phi) = g(\partial/\partial\phi^A, \partial/\partial\phi^B)$, the action functional is

$$S = \sigma \int \mathrm{d}^d x \partial_\mu \phi^A g_{AB}(\phi) \partial_\mu \phi^B$$

The coupling parameter $\sigma$ has the physical meaning of bare (i.e., unrenormalized) conductivity. In the present model $\sigma = NW^2 a^{2-d}$, where $W$ is essentially the width of the band random matrix in units of the lattice spacing $a$ (the short-distance cutoff of the continuum field theory). $S$ is the effective action in the limit $z_1 = z_2$. For a finite frequency $\omega = z_1 - z_2$, a symmetry-breaking term of the form $\mathrm{i}\omega\nu \int \mathrm{d}^d x f(\phi)$, where $\nu = N(\pi\lambda)^{-1} a^{-d}$ is the local density of states, has to be added to $S$.

By perturbative renormalization group analysis, that is, by integrating out the rapid field fluctuations, one finds for $d = 2$ that $\sigma$ decreases on increasing the cutoff $a$. This property is referred to as "asymptotic freedom" in field theory. On its basis one expects exponentially decaying correlations, and hence localization of all states, in two dimensions. However, a mathematical proof of this conjecture is not currently available.

In three dimensions and for a sufficiently large bare conductivity, the renormalization flow goes toward the metallic fixed point ($\sigma \to \infty$), where $G$-symmetry is broken spontaneously. A rigorous proof of this important conjecture (existence of disordered metals in three space dimensions) is not available either.

#### Zero-Mode Approximation

For a system in a box of linear size $L$, the cost of exciting fluctuations in the sigma model field is estimated as the Thouless energy $E_{\mathrm{Th}} = \sigma/\nu L^2$. In the limit of small frequency, $|\omega| \ll E_{\mathrm{Th}}$, the physical behavior is dominated by the constant modes $\phi^A(x) = \phi^A$ (independent of $x$). By computing the integral over these modes, Efetov found the energy-level correlations in the small-frequency limit to be those of the GUE.

# Symmetric Hyperbolic Systems and Shock Waves

**S Kichenassamy**, Université de Reims Champagne-Ardenne, Reims, France

## Introduction

Many systems of partial differential equations arising in mathematical physics and differential geometry are quasilinear: the top-order derivatives enter only linearly. They may be cast in the form of first-order systems by introducing, if needed, derivatives of the unknowns as additional unknowns. For such systems, the theory of symmetric–hyperbolic (SH) systems provides a unified framework for proving the local existence of smooth solutions if the initial data are smooth. It is also convenient for constructing numerical schemes, and for studying shock waves. Despite what the name suggests, the impact of the theory of SH systems is not limited to hyperbolic problems, two examples being Tricomi's equation, and equations of Cauchy–Kowalewska type.

Application of the SH framework usually requires a preliminary reduction to SH form ("symmetrization").

After comparing briefly the theory of SH systems with other functional-analytic approaches, we collect basic definitions and notation. We then present two general rules, for symmetrizing conservation laws and strictly hyperbolic equations, respectively. We next turn to special features possessed by linear SH systems, and give a general procedure to prove existence, which covers both linear and nonlinear systems. We then summarize those results on shock waves, and on blow-up singularities, which are related to SH structure. Examples and applications are collected in the last section.

The advantages of SH theory are: a standardized procedure for constructing solutions; the availability of standard numerical schemes; a natural way to prove that the speed of propagation of support is finite. On the other hand, the symmetrization process is sometimes *ad hoc*, and does not respect the physical or geometric nature of the unknowns; to obviate this defect to some extent, we remark that symmetrizers may be viewed as introducing a new Riemannian metric on the space of unknowns. The search for a comprehensive criterion for identifying equations and boundary conditions compatible with SH structure is still the object of current research.

The most important fields of application of the theory today are general relativity and fluid dynamics, including magnetohydrodynamics.

### Context of SH Theory in Modern Terms

The basic reason why the theory works may be summarized as follows for the modern reader; the history of the subject is, however, more involved.

Let $H$ be a real Hilbert space. Consider a linear initial-value problem $\mathrm{d}u/\mathrm{d}t + Au = 0; u(0) = u_0 \in H$, where $A$ is unbounded, with domain $D(A)$. By Stone's theorem, one can solve it in a generalized sense, if the unbounded operator $A$ satisfies $A + A^* = 0$. This condition contains two ingredients: a symmetry condition on $A$, and a maximality condition on $D(A)$, which incorporate boundary conditions (von Neumann, Friedrichs). Semigroup theory (Hille and Yosida, Phillips, and many others) handles more general operators $A$: it is possible to solve this problem in the form $u(t) = S(t)u_0$ for $t > 0$, where $\{S(t)\}_{t\geq 0}$ is a continuous contraction semigroup, if and only if $(Au, u) \geq 0$, and equation $x + Ax = y$ has a solution for every $y$ in $H$ (this is a maximality condition on $D(A)$). One then says that $A$ is maximal monotone. For such operators, $A + A^* \geq 0$. SH systems are systems $Qu_t + Au = F$, satisfying two algebraic conditions ensuring formally that $A + A^*$ is bounded, and that $Q$ is symmetric and positive definite. This algebraic structure enables one to solve the problem directly, without explicit reference to semigroup theory. Precise definitions are given next.

We assume throughout that all coefficients, nonlinearities, and data are smooth unless otherwise specified.

### Definitions

Consider a quasilinear system

$$M_B^{A\alpha}(x,u)\partial_\alpha u^B = N^A(x,u) \qquad [1]$$

where $u=(u^A)_{A=1,\dots,m}$, $x=(x^\alpha)_{\alpha=0,\dots,n}$, and $\partial_\alpha = \partial/\partial x^\alpha$. The components of $u$ may be real or complex. We follow the summation convention on repeated indices in different positions; $x^0=t$ may be thought of as the evolution variable; we write $x=(t,\boldsymbol{x})$, with $\boldsymbol{x}=(x^1,\dots,x^n)$. Indices $A$, $B,\dots$ run from 1 to $m$, indices $j,k,\dots$ from 1 to $n$, and Greek indices from 0 to $n$. The complex conjugate of $u^A$ is written $\bar{u}^A$.

- Equation [1] is symmetrizable if there are functions $\sigma_{AB}(x,u)$ such that

$$M_{AB}^\alpha := \sigma_{AC}M_B^{C\alpha}$$

  satisfies the condition $M_{AB}^\alpha = \bar{M}_{BA}^\alpha$ for every $\alpha$.
- It is symmetric if it is symmetrizable with $\sigma_{AB}=\delta_{AB}$.
- It is symmetric-hyperbolic with respect to $k_\alpha$ if it is symmetric and if $k_\alpha M_{AB}^\alpha$ is positive definite: $k_\alpha M_{AB}^\alpha \xi^A\xi^B > 0$ for $\xi=(\xi^A)\neq 0$.

Thus, a symmetrizer $(\sigma_{AB})$ gives rise to a Riemannian metric $(k_\alpha\sigma_{AC}M_B^{C\alpha})$ on the space of unknowns, independent of any Riemannian structure on $x$-space. The system is SH with respect to $x^0$ if $k_\alpha=\delta_\alpha^0$.

The simplest class of SH systems is provided by real semilinear systems of the form

$$A^0(\boldsymbol{x})\partial_t u + A^i(\boldsymbol{x})\partial_i u = N(x,u) \qquad [2]$$

where the $A^\alpha$ are real symmetric matrices, $A^0$ is symmetric and positive definite, and $k_\alpha=\delta_{\alpha 0}$. Writing $A^0=P^2$, with $P$ symmetric and positive definite, one finds that $v=Pu$ solves a SH system with $A^0=I$ (identity matrix).

Conservation laws (with "reaction" or "source" term $N^A$) are usually defined as quasilinear systems of the form

$$\partial_\alpha f^{A\alpha}(x,u) = N^A(x,u) \qquad [3]$$

They are common in fluid dynamics and combustion. They are limiting cases of nonlinear diffusion equations of the typical form

$$\partial_\alpha f^{A\alpha}(x,u) = N^A(x,u) + \varepsilon\partial_j(B_B^{Ajk}\partial_k u^B) \qquad [4]$$

The determination of the form of the coefficients $B_B^{Ajk}$ is a nontrivial modeling issue; they may reflect varied physical processes such as heat conduction, viscosity, or bulk viscosity. They may depend on $x$, $u$, and the derivatives of $u$. The simplest case is $B_B^{Ajk}=D^{jk}\delta_B^A$ with $(D^{jk})$ diagonal. Some authors require the symmetry condition

$$\delta_{AC}B_B^{Cjk} = \delta_{BC}B_A^{Ckj} \qquad [5]$$

Equations in which $f^{A\alpha}=u^A\delta_0^\alpha$ are called reaction–diffusion equations; they arise in physical and biological problems in which chemical reactions and diffusion phenomena are combined, and in population dynamics.

A conservation law is symmetric if and only if $\partial f^{A\alpha}/\partial u^B$ is symmetric in $A$ and $B$, which means that there are, locally, functions $g^\alpha(x,u)$ such that $f^{A\alpha}=\partial g^\alpha/\partial u^A$.

A more fundamental derivation of conservation laws would take us beyond the scope of this survey.

## Symmetrization

Two general procedures for symmetrization are available: one for conservation laws, the other for semilinear strictly hyperbolic problems.

### Conservation Laws with a Convex Entropy

Consider, for simplicity, a conservation law of the form

$$\partial_t u^A + \partial_j f^{Aj}(u) = 0 \qquad [6]$$

We, therefore, assume that the $f^{A\alpha}=f^{A\alpha}(u)$ and $f^{A0}(u)=u^A$. We show that the following three statements are equivalent locally: (1) there is a strictly convex function $U(u)$ such that $\sigma_{AB}=\partial^2 U/\partial u^A\partial u^B$ is a symmetrizer; (2) eqn [6] implies a scalar relation of the form $\partial_\alpha U^\alpha=0$, with $U^0$ strictly convex; and (3) there is a change of unknowns $v_A=v_A(u)$ such that the system satisfied by $v=(v_A)$ is SH and $(\partial v_A/\partial u^B)$ is positive definite.

In fluid dynamics, $U^0$ may sometimes be related to specific entropy, and $U^j$ to entropy flux. For this reason, if (2) holds, one says that $U^0$ is an entropy for eqn [6], and that $(U^0,U^j)$ is an entropy pair. A system may have several entropies in this sense; this fact is sometimes useful in studying convergence properties of approximate solutions of eqn [6].

Let us now prove the equivalence of these properties.

Assume first (3): there are new unknowns $v_A=v_A(u)$ and functions $g^\alpha(v)$ such that $f^{A\alpha}=\partial g^\alpha/\partial v_A$. One finds that if eqn [6] holds,

$$\partial_\alpha U^\alpha = 0 \quad \text{where } U^\alpha = v_A\frac{\partial g^\alpha}{\partial v_A} - g^\alpha \qquad [7]$$

Furthermore, we have $f^{A0}=u^A$; therefore, eqn [7] gives: $U^0=v_Au^A-g^0$, so that $U^0$ is the Legendre

transform (familiar from mechanics) of $g^0$. It follows that $v_A = \partial U^0/\partial u^A$. Finally, $(\partial v_A/\partial u^B) = (\partial^2 U^0/\partial u^A \partial u^B)$ is positive definite, and $U^0$ is strictly convex.

We have proved that (3) implies (2). Next, assume (2): the entropy equality $U_t + \partial_j U^j = 0$ holds identically – and not just for the solution at hand. Using [6], we find

$$0 = \frac{\partial U}{\partial u^A}\partial_t u^A + \frac{\partial U^j}{\partial u^B}\partial_j u^B = \left[-\frac{\partial U}{\partial u^A}\frac{\partial f^{Aj}}{\partial u^B} + \frac{\partial U^j}{\partial u^B}\right]\partial_j u^B$$

Assumption (2), therefore, means that $U$ is strictly convex and satisfies

$$\frac{\partial U}{\partial u^A}\frac{\partial f^{Aj}}{\partial u^B} = \frac{\partial U^j}{\partial u^B} \qquad [8]$$

Now, letting $v_A = \partial U/\partial u^A$ and $g^j(v) = v_A f^{Aj} - U^j$, we find

$$\frac{\partial g^j}{\partial v_A} = f^{Aj} + \left[\frac{\partial U}{\partial u^A}\frac{\partial f^{Aj}}{\partial u^C} - \frac{\partial U^j}{\partial u^C}\right]\frac{\partial u^C}{\partial v_A} = f^{Aj} \qquad [9]$$

Let $\sigma_{AB} = \partial^2 U/\partial u^A \partial u^B$. Since $U$ is strictly convex, $(\sigma_{AB})$ is positive definite, and so is its inverse. We have now proved (3). Note that $u^A = \partial g^0/\partial v_A$, where $g^0(v) = u^A v_A - U(u)$ is the Legendre transform of $U$.

Next, using eqn [9], and the relations $\sigma_{AB} = \partial v_A/\partial u^B = \partial v_B/\partial u^A$, we find

$$\begin{aligned} 0 &= \sigma_{AB}[\partial_t u^B + \partial_j f^{Bj}] \\ &= \sigma_{AB}\partial_t u^B + \frac{\partial v_B}{\partial u^A}\frac{\partial^2 g^j}{\partial v^B \partial u^C}\partial_j u^C \\ &= \sigma_{AB}\partial_t u^B + \frac{\partial^2 g^j}{\partial u^A \partial u^C}\partial_j u^C \end{aligned}$$

which is SH; therefore, $\sigma_{AB}$ is a symmetrizer for eqn [6], and (1) is proved. Thus, (2) implies (1) and (3).

Finally, if (1) holds, $\sigma_{AC}\partial f^{Cj}/\partial u^B$ is symmetric in $A$ and $B$. It follows that

$$\frac{\partial}{\partial u^C}\left[\frac{\partial U}{\partial u^A}\frac{\partial f^{Aj}}{\partial u^B}\right] = \sigma_{AC}\frac{\partial f^{Aj}}{\partial u^B} + \frac{\partial U}{\partial u^A}\frac{\partial^2 f^{Aj}}{\partial u^B \partial u^C}$$

is symmetric in $B$ and $C$, so that there are, locally, functions $U^j$ such that eqn [8] holds. Therefore, $(U, U^j)$ is an entropy pair, and we see that (1) implies (2).

This completes the proof of the equivalence of (1), (2), and (3).

### Strictly Hyperbolic Equations

Consider the scalar equation $Pf = g(t, \boldsymbol{x})$, where $P$ is the linear operator

$$P = \partial_t^N - \sum_{j=0}^{N-1} p_{N-j}(t, \boldsymbol{x})\partial_t^j$$

of order $N$. Let $\Lambda = (1 - \Delta)^{1/2}$, where $\Delta$ is the Laplace operator on the space variables. Then $u = (u^A)$, where $u^A = \partial_t^{A-1}\Lambda^{N-A} f$ for $A = 1, \ldots, N$, solves a first-order pseudodifferential system of the form

$$u_t - Lu = G$$

If $P$ is strictly hyperbolic, the principal symbol $a_1(t, \boldsymbol{x}, \xi)$ of $L$ has a diagonal form with real eigenvalues $\lambda_j(t, \boldsymbol{x}, \xi)$, and there are projectors $p_j(t, \boldsymbol{x}, \xi)(p_j^2 = p_j)$ which commute with $a_1$, such that $1 = \sum_j p_j$, and $a_1 = \sum_j \lambda_j p_j$. Let $r_0 = \sum_j p_j^* p_j$, and $r_0(D)$ the corresponding operator. Equation

$$r_0(D)\partial_t u - r_0(D)Lu = r_0(D)G$$

is formally SH in the following sense: $r_0$ is positive definite and $r_0 a_1$ is Hermitian.

## Linear Problems

Consider a linear system

$$Lu := Q(t, \boldsymbol{x})\partial_t u + A^j(t, \boldsymbol{x})\partial_j u + B(t, \boldsymbol{x})u = f(t, \boldsymbol{x}) \qquad [10]$$

We assume that $Q$ and the $A^j$ are real and symmetric, $Q \geq c$ with $c$ positive, and all coefficients and their first-order derivatives are bounded.

### Energy Identity

Multiplying the equation by $u^{\mathrm{T}}$ (transpose of $u$), one derives the "energy identity"

$$\partial_t(u^{\mathrm{T}}Qu) + \partial_j(u^{\mathrm{T}}A^j u) + u^{\mathrm{T}}Cu = 2u^{\mathrm{T}}f(t, \boldsymbol{x}) \qquad [11]$$

where $C = 2B - \partial_t Q - \partial_j A^j$. $C$ is not necessarily positive. However, $v := u\exp(-\lambda t)$ satisfies a linear SH system for which $C$ is positive definite if $\lambda$ is large enough.

### Propagation of Support

A basic property of wave-like equations is finite speed of propagation of support: if the right-hand side vanishes, and if the solution at time 0 is localized in the ball of radius $r$, then the solution at time $t$ is localized in the ball of radius $r + ct$ for a suitable constant $c$.

This property also holds for SH systems. To see this, let us consider the set where a solution $u$

vanishes: if the initial condition vanishes for $|\boldsymbol{x}| \leq R$, we claim that $u$ at some later time vanishes for $|\boldsymbol{x}| \leq R - t/a$, for $a$ large enough.

Indeed, let us integrate the energy identity on a truncated cone $\Gamma := \{|\boldsymbol{x}| \leq a(t_0 - t)/t_0; 0 \leq t \leq t_1\}$ with $t_1 < t_0$. The boundary of $\Gamma$ consists of three parts: $\partial\Gamma = \Omega_0 \cup \Omega_1 \cup S$, where $\Omega_0$ and $\Omega_1$ represent the portions of the boundary on which $t = 0$ and $t_1$, respectively. The outer normal to $S$ is proportional to $(a, t_0 x^j/|\boldsymbol{x}|)$. Let $E(s)$ denote the integral of $u^{\mathrm{T}}Qu$ on $\Gamma \cap \{t = s\}$. Integrating eqn [11] by parts, we obtain

$$E(t_1) - E(0) + \int_S u^{\mathrm{T}}\Phi u \,\mathrm{d}s = \iint_\Gamma (2u^{\mathrm{T}}f - u^{\mathrm{T}}Cu)\mathrm{d}t\,\mathrm{d}\boldsymbol{x} \qquad [12]$$

where $\Phi$ is proportional to $aQ + t_0 \sum_j x^j A^j/|\boldsymbol{x}|$. Take $a$ so large that $\Phi$ is positive definite. The integral over $S$ is then non-negative. If $C$ is positive definite and $f \equiv 0$, so that $E(0) = 0$, we find that $E(t_1) \leq 0$. Since $Q$ is positive definite, this implies $u \equiv 0$ on $\Omega_1$, as claimed.

### A Numerical Scheme

System $Lu = f$ may be discretized, for example, by the Lax–Friedrichs method: let $h$ be the discretization step in space, and $k$ the time step; write $\tau_j u(t, \boldsymbol{x}) = u(t, x^1, \ldots, x^j + h, \ldots, x^n)$ (translation in the $j$ direction). One replaces $\partial_j u$ by the centered difference in the $j$ direction: $(\tau_j u - \tau_j^{-1}u)/2h$; and the time derivative by

$$[u(t+k, \boldsymbol{x}) - \frac{1}{2n}\sum_j (\tau_j u(t, \boldsymbol{x}) + \tau_j^{-1}u(t, \boldsymbol{x}))]/k \qquad [13]$$

For consistency of the scheme, we require $k/h = \lambda > 0$ to be fixed as $k$ and $h$ tend to zero; stability then holds if $\lambda$ is small.

## Nonlinear Problems and Singularities

We give a simple setup for proving the existence of smooth solutions to SH systems for small times. Such solutions may develop singularities. We limit ourselves to two types of singularities, on which SH structure provides some information: jump discontinuities and blow-up patterns. Caustic formation is not considered.

### Construction of a Smooth Solution

Consider a real SH system (eqn [1]). Recall that a function of $\boldsymbol{x}$ belongs to the Sobolev space $H^s$ if its derivatives of order $s$ or less are square-integrable. One constructs a solution defined for $t$ small, which is in $H^s$, $s > n/2 + 1$, as a function of $\boldsymbol{x}$, by the following procedure:

(1) Replace spatial derivatives by regularized operators, which should be bounded in Sobolev spaces; the regularized equation is an ODE in $H^s$; let $u_\varepsilon$ be its solution.
(2) Write the equation satisfied by derivatives of order $s$ of $u_\varepsilon$, and apply the energy identity to it.
(3) Find a positive $T$ such that the solution is bounded in $H^s$ for $|t| \leq T$, uniformly in $\varepsilon$; this implies a $C^1$ bound.
(4) Prove the convergence of the approximations in $L^2$.
(5) Prove the continuity in time of the $H^s$ norm; conclude that the $u_\varepsilon$ tend to a solution in $C(-T, T; H^s)$.

The result admits a local version, in which Sobolev spaces are replaced by Kato's "uniformly local" spaces. Uniqueness of the solution is proved along similar lines. We do not attempt to identify the infimum of the values of $s$ for which the Cauchy problem is well-posed.

### Jump Discontinuities: Shock Waves

A "shock wave" is a weak solution of a system of conservation laws admitting a jump discontinuity. By definition, weak solutions satisfy, for any smooth function $\phi_A(x)$ with compact support,

$$\iint \{f^{A\alpha}\partial_\alpha \phi_A + N^A \phi_A\}\,\mathrm{d}t\,\mathrm{d}\boldsymbol{x} = 0$$

The theory of shock waves is an attempt to understand solutions of conservation laws which are limits of solutions of diffusion equations; the hope is that the influence of second-derivative terms is appreciable only near shocks, and that, for given initial data, there is a unique weak solution of the conservation law which may be obtained as such a limit, if modeling has been done correctly. This problem may be difficult already for a single shock ("shock structure").

The theory of shock waves follows the one-dimensional theory closely. We therefore describe the main facts for a conservation law in one space dimension ($u = u(t, x)$):

$$\partial_t u + \partial_x f(u) = 0$$

If a shock travels at speed $c$, the weak formulation of the equations gives the Rankine–Hugoniot relation $c[u] = [f(u)]$, where square brackets denote jumps. There may be several weak solutions having the same initial condition. One restricts solutions by

making two further requirements: (1) the system admits an entropy pair $(U, F)$ with a convex entropy and (2) to be admissible, weak solutions must be limits of "viscous approximations"

$$\partial_t u + \partial_x f(u) = \varepsilon \partial_x^2 u$$

as $\varepsilon \to 0$. One then finds easily that the entropy equality $(\partial_t U + \partial_x F = 0)$ must be replaced, for such weak solutions, by the entropy condition: $\partial_t U + \partial_x F \leq 0$ in the weak sense. This condition admits a concrete interpretation if the gradient of each characteristic speed is never orthogonal to the corresponding right eigenvector ("genuine nonlinearity"); in that case, characteristics must impinge on the shock ("shock inequalities").

For the equations of gas dynamics with polytropic law $(pv^\gamma = \text{const.})$, there is a unique solution with initial condition $u = u_l$ for $x < 0, u = u_r$ for $x > 0$, where $u_l$ and $u_r$ are constant ("Riemann problem") which satisfies the entropy condition, provided $|u_l - u_r|$ is small. More generally, if the equation of state $p = p(v, s) > 0$ satisfies $\partial p/\partial v < 0$ and $\partial^2 p/\partial v^2 > 0$, the shock inequalities are equivalent to the fact that the entropy increases after the passage of a shock with $|u_l - u_r|$ small.

On the numerical side, one should mention: (1) the widely used idea of upstream differencing; (2) the Lax–Wendroff scheme, the complete analysis of which requires tools from soliton theory; and (3) the availability of general results for dissipative schemes for SH systems.

Recent trends include: (1) admissibility conditions when genuine nonlinearity does not hold and (2) other approximations of shock wave problems, most notably kinetic formulations.

Some of the ideas of shock wave theory have been applied to Hamilton–Jacobi equations and to motion by mean curvature, with applications to front propagation problems and "computer vision."

### Stronger Singularities: Blow-Up Patterns

The amplitude of a solution may also grow without bound. Examples include optical pulse propagation in Kerr media and singularities in general relativity. The phenomenon is common when reaction terms are allowed. As we now explain, this phenomenon is reducible to SH theory in many cases of interest.

Blow-up singularities are usually not governed by the characteristic speeds defined by the principal part, because top-order derivatives are balanced by lower-order terms. In many applications, a systematic process (Fuchsian reduction) enables one to identify the correct model near blow-up; as a result, one can write the solution as the sum of a singular part, known in closed form, and a regular part. If the singularity locus is represented by $t = 0$, the regular part solves a renormalized equation of the typical form

$$tMu + Au = t^\varepsilon N \qquad [14]$$

where $Mu = 0$ is SH. Under natural conditions, for any initial condition $u_0$ such that $Au_0 = 0$, there is a unique solution of eqn [14] defined for small $t$.

The upshot is an asymptotic representation of solutions which renders the same services as an exact solution, and is valid precisely where numerical computation breaks down.

Fuchsian reduction enables one in particular to study (1) the blow-up time; (2) how the singularity locus varies when Cauchy data, prescribed in the smooth region, are varied; and (3) expressions which remain finite at blow-up. It is the only known general procedure for constructing analytically singular spacetimes involving arbitrary functions, rather than arbitrary parameters, and is therefore relevant to the search for alternatives to the big bang.

## Examples and Applications

### Wave Equation with Variable Coefficients

Consider the equation

$$\partial_{tt} u + 2a^j(x)\partial_{jt} u - a^{jk}(x)\partial_{jk} u = f(t, \boldsymbol{x}, u, \nabla u)$$

with $(a^{jk})$ positive definite. Letting $v = (v_0, \ldots, v_{n+1}) := (u, \partial_j u, \partial_t u)$, we find the system

$$\begin{aligned} \partial_t v_0 &= v_{n+1} \\ \partial_t v_k - \partial_k v_{n+1} &= 0 \\ \partial_t v_{n+1} + 2a^k \partial_k v_{n+1} - a^{jk} \partial_k v_j &= f \end{aligned}$$

It is symmetrizable, using the quadratic form $\sigma_{AB} v^A v^B = v_0^2 + a^{jk} v_j v_k + v_{n+1}^2$.

One proves directly that, if $v_j = \partial_j v_0$ for $t = 0$, this relation remains true for all $t$.

### Maxwell's Equations

Maxwell's equations may be split into six evolution equations: $\partial_t \boldsymbol{E} - \operatorname{curl} \boldsymbol{B} + \boldsymbol{j} = 0$ and $\partial_t \boldsymbol{B} + \operatorname{curl} \boldsymbol{E} = 0$, and two "constraints" $\operatorname{div} \boldsymbol{E} - \rho = 0, \operatorname{div} \boldsymbol{B} = 0$. The system of evolution equations is already in symmetric form; the quadratic form $\sigma_{AB} u^A u^B$ is here $|\boldsymbol{E}|^2 + |\boldsymbol{B}|^2$.

### Compressible Fluids

Consider first the case of a polytropic gas:

$$\begin{aligned} \partial_t \boldsymbol{v} + (\boldsymbol{v}\cdot\nabla)\boldsymbol{v} + \rho^{-1}\nabla p = 0 \\ \partial_t \rho + \operatorname{div}(\rho \boldsymbol{v}) = 0 \end{aligned} \qquad [15]$$

with $p$ proportional to $\rho^\gamma$. Taking $(p, \boldsymbol{v})$ as unknowns, one readily finds the SH system

$$\frac{1}{\gamma p}\partial_t p + \frac{1}{\gamma p}(\boldsymbol{v}\cdot\nabla)p + \operatorname{div}\boldsymbol{v} = 0 \qquad [16]$$

$$\rho\partial_t \boldsymbol{v} + \nabla p + \rho(\boldsymbol{v}\cdot\nabla)\boldsymbol{v} = 0 \qquad [17]$$

Symmetrization for more general compressible fluids with dissipation, including bulk viscosity, so as to satisfy the additional condition [5] may be achieved if we take as thermodynamic variables $\rho$ and $T$, and assume pressure $p$ and internal energy $\varepsilon$ satisfy $\partial p/\partial\rho > 0$ and $\partial\varepsilon/\partial T > 0$, by taking as unknowns $(\rho, \rho\boldsymbol{v}, \rho(\varepsilon + |\boldsymbol{v}|^2/2))$. The specific entropy $s$ satisfies $\mathrm{d}\varepsilon = T\mathrm{d}s - p\mathrm{d}(1/\rho)$. If the viscosity and heat conduction coefficients are positive, one finds that $U = -\rho s$ is a convex entropy (in the sense of SH theory) on the set where $\rho > 0, T > 0$.

### Einstein's Equations

The computation of solutions of Einstein's equations over long times, in particular in the study of coalescence of binary stars, has recently led to unexplained difficulties in the standard Arnowitt–Deser–Misner (ADM) formulation of the initial-value problem in general relativity. One way to tackle these difficulties is to rewrite the field equations in SH form; we focus on this particular aspect of recent research.

Recall the problem: find a four-dimensional metric $g_{ab}$ with Lorentzian signature, such that $R_{ab} - \frac{1}{2}Rg_{ab} = \chi T_{ab}$, with $\nabla^a T_{ab} = 0$, combined with an equation of state if necessary. $R_{ab}$ is the Ricci tensor and $R = g^{ab}R_{ab}$ is the scalar curvature; they depend on derivatives of the metric up to order 2. In addition to the metric, $T_{ab}$ involves physical quantities such as fluid 4-velocity or an electromagnetic field. The conservation laws of classical mathematical physics are all contained in the relation $\nabla^a T_{ab} = 0$.

Now, the field equations cannot be solved for $\partial_t^2 g_{ab}$, and, as a consequence, the Taylor series of $g_{ab}$ with respect to time cannot be determined, even formally, from the values of $g_{ab}$ and $\partial_t g_{ab}$ for $t = 0$ (i.e., the Cauchy data). Furthermore, these data must satisfy four *constraint equations*. If the constraints are satisfied initially, they "propagate." But in numerical computation, these constraints are never exactly satisfied, and the computed solution may deviate considerably from the exact solution. Also, numerical computations depend heavily on the way Einstein's equations are formulated.

The simplest way to derive a SH system is to replace $R_{ab}$ by $R_{ab}^{(h)} = R_{ab} - \frac{1}{2}[g_{bc}\partial_a F^c + g_{ac}\partial_b F^c]$, where $F^c := g^{ab}\Gamma^c_{ab}$. It turns out that $R_{ab}^{(h)} = -\frac{1}{2}g^{cd}\partial_{cd}g_{ab} + H_{ab}(g, \partial g)$, where the expression of $H_{ab}$ is immaterial. Applying to each component of the metric the treatment of the first example above (wave equation with variable coefficients), one easily derives an SH system of 50 equations for 50 unknowns: the ten independent components of the metric, and their 40 first-order derivatives. Now, if the $\Gamma^c$ are initially zero (coordinates are "harmonic"), they remain so at later times.

Unfortunately, the harmonic coordinate condition does not seem to be stable in the large. More recent formulations start with one of the standard setups (ADM formalism, conformal equations, tetrad formalism, Newman–Penrose formalism) and proceed by adding combinations of the constraints to the equations, multiplied by parameters adjusted so as to ensure hyperbolicity or symmetric–hyperbolicity if needed. Another recent idea is to add a new unknown $\lambda$ which monitors the failure of the constraint equations; one adds to the equations a new relation of the form $\partial_t\lambda = \alpha C - \beta\lambda$, where $C = 0$ is equivalent to the constraints, and $\alpha$ and $\beta$ are parameters. One then adds coupling terms to make the extended system SH. It is expected that the set of constraints acts as an attractor.

Reported computations indicate that these methods have resulted in an improvement of the time over which numerical computations are valid.

### Tricomi's Equation

Let $\varphi(x, y)$ solve $(y\partial_x^2 - \partial_y^2)\varphi = 0$. Letting $u = \mathrm{e}^{-\lambda x}(\partial_x\varphi, \partial_y\varphi)$, one finds a symmetric system $Lu = 0$, with

$$L = \begin{pmatrix} y & 0 \\ 0 & 1 \end{pmatrix}(\partial_x + \lambda) - \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}\partial_y$$

If

$$Z = \begin{pmatrix} 1 & y \\ 1 & 1 \end{pmatrix}$$

we find that $K = ZL = A^1\partial_x + A^2\partial_y + B$, where

$$B - \tfrac{1}{2}(\partial_x A^1 + \partial_y A^2) = \begin{pmatrix} \frac{1}{2} + \lambda y & \lambda y \\ \lambda y & \lambda \end{pmatrix}$$

is positive definite if $y$ is bounded, of arbitrary sign, and $\lambda$ is small.

### Cauchy–Kowalewska Systems

Consider a complex system

$$\partial_t u = A^j(z,t,u)\frac{\partial u}{\partial z^j} + B(z,t,u) \qquad [18]$$

where $u = (u^A), z = (z^1, \ldots, z^n)$. The coefficients are analytic in their arguments when $z$ and $t$ are close to the origin and $u$ is bounded by some constant $K$. The Cauchy–Kowalewska theorem ensures that, for any analytic initial condition near the origin, this system has a unique analytic solution near $z = 0$, even without any symmetry assumption on the $A^j$. This result is a consequence of SH theory (Garabedian).

Indeed, write $z^j = x^j + iy^j$, $\partial_{z^j} = (1/2)(\partial_{x^j} - i\partial_{y^j})$, and $\partial_{\bar{z}_j} = (1/2)(\partial_{x^j} + i\partial_{y^j})$. Recall that analytic functions of $z$ satisfy the Cauchy–Riemann equations $\partial_{\bar{z}_j} u = 0$.

Adding $(\bar{A}^j)^{\mathrm{T}}\partial_{\bar{z}_j}$ to [18], and using the definition of $\partial_{z^j}$ and $\partial_{\bar{z}_j}$, we find the symmetric system

$$u_t = \frac{1}{2}(A^j + (\bar{A}^j)^{\mathrm{T}})\partial_{x^j} u + \frac{1}{2i}(A^j - (\bar{A}^j)^{\mathrm{T}})\partial_{y^j} u + B \qquad [19]$$

Solving this system, we find a candidate $u$ for a solution of eqn [18]. To show that $u$ is analytic if the data are, we solve a second SH system for $w = w^{(j)} := \partial_{\bar{z}_j} u$. If the data are analytic, $w$ vanishes initially, and therefore remains zero for all $t$. Therefore, $u$ is indeed analytic.

# Symmetries and Conservation Laws

**L H Ryder**, University of Kent, Canterbury, UK

## Introduction: Spacetime Symmetries

Symmetries have played, and continue to play, an important role in fundamental physics, but the part they play is today seen as more complicated and many-sided than it was in the early days of particle physics, just after the Second World War. The area in which symmetries have had their most dramatic consequences is elementary particle physics, or high-energy physics, and the majority of this article is concerned with this subject. The article concludes with some observations about symmetries and conservation laws in general relativity.

In the early days, considerations of symmetry were almost limited to Lorentz transformations: we begin by reviewing this crucially important topic. Invariance of the laws of nature under *translations* in space and time are actually necessary for the existence of science itself; if experiments did not yield the same results today and tomorrow, and in Paris and Moscow and on the Moon, then in effect there would be no laws of nature. Almost as strong

a statement could be made about invariance under *rotations*; if space were not isotropic, experimental results would depend on which direction the apparatus was aligned in, and again any laws would be extremely hard to find. Turning to the question of *motion*, Newton and Galileo realized that the laws of dynamics are the same in all inertial frames in relative motion. In the Newton–Galileo scheme, the rule for relating the space and time coordinates of two frames of reference is (for relative motion along the common $x$-axis)

$$x' = x - vt, \qquad t' = t \qquad [1]$$

This *principle of relativity* was reaffirmed by Einstein, but with the crucial modification that the rules for relating coordinates in two frames are given by Lorentz transformations, so that [1] is replaced by

$$x' = \gamma(x - vt), \qquad t' = \gamma\left(t - \frac{vx}{c^2}\right) \qquad [2]$$

Time is absolute in [1] but relative in [2]. Einstein was of course motivated by the fact that Maxwell's equations are covariant under Lorentz transformations, but not under Newton–Galileo ones.

The above considerations reveal that the laws of nature should be covariant under ten types of transformation: three translations in space, one in time, three parameters (angles) for rotations and three velocities. These transformations together form a group, the inhomogeneous Lorentz, or Poincaré group. It is a nonabelian group whose ten generators correspond to 4-momentum, angular momentum, and Lorentz boosts. The seminal work on the significance of this group in fundamental physics is that of Wigner in 1939. Assuming that the states of fundamental quantum systems (particles, atoms, molecules) form the basis states for *representations* of this group, these entities are described by two quantities, mass and spin. Spin, moreover, which was already familiar from earlier investigations in quantum physics, was described by the rotation group (SU(2), which is homomorphic to SO(3)) only for states with timelike momentum. For photons, for example, with null momentum, spin is described by the (noncompact) Euclidean group in the plane, with the consequence that there are only two polarization states for this massless particle.

Noether's theorem provides the crucial link between symmetries and *conservation laws*, via the principle of least action. Noether showed that the invariance of the action under a continuous symmetry operation implied the existence of a conserved quantity. The conserved quantities corresponding to invariance under translation in space and time are momentum and energy; conservation of angular momentum follows from invariance under rotations and invariance under Lorentz transformations gives rise to conservation of motion of the center of mass.

## Gauge Theories: Electromagnetism and Yang–Mills Theories

A quantity whose conservation has been well known for a long time is electric charge. The question may then be asked: invariance under what symmetry gives rise to conservation of electric charge? A classical complex field has the Lagrangian density

$$L = (\partial_\mu \phi)(\partial^\mu \phi^*) - m^2 \phi^* \phi \qquad [3]$$

which is invariant under

$$\phi \to \exp(-\mathrm{i}Q\,\Lambda)\phi \qquad [4]$$

$\Lambda$ being the parameter for the transformation. Noether's theorem then yields conservation of $Q$, interpreted as electric charge. With $\Lambda$ a constant, as above, the Lagrangian possesses a "global" symmetry. This becomes a "local" symmetry when $\Lambda$ becomes space and time dependent, $\Lambda(\boldsymbol{r}, t)$ or $\Lambda(x^\mu)$. In that case, however, the Lagrangian [3] is no longer invariant under [4], because of the derivative terms. To preserve invariance an extra field $A_\mu$ must be introduced, so that [4] then becomes

$$\begin{aligned} \phi &\to \exp(-\mathrm{i}Q\,\Lambda(x^\mu))\phi \\ A_\mu &\to A_\mu + \frac{1}{Q}\partial_\mu \Lambda \end{aligned} \qquad [5]$$

and the Lagrangian acquires extra terms, involving $A_\mu$. The field $A_\mu$ is called a *gauge field* and is identified with the electromagnetic potential. The transformation [5] is called a *gauge transformation*, and since the phase factor $\exp(-\mathrm{i}Q\,\Lambda)$ may be regarded as a unitary $1 \times 1$ matrix, we have here a theory with U(1) gauge invariance, which describes electromagnetism and conservation of charge.

The notion of isospin had been introduced by Heisenberg in 1932. Isospin (then called isotopic spin) was a vector-like quantity conserved in strong (nuclear) interactions. Yang and Mills in 1954 made the pioneering suggestion that isospin conservation could also be recast as a gauge theory, by enlarging the U(1) group of electromagnetism to SU(2) (corresponding to rotations in "isospin space"), and at the same time treating the rotation angles as functions of spacetime. Then, eqn [4] will change: if

for example ψ is an isospinor field, then local isospin rotations are given by

$$\psi(x) \to \exp\left\{-i\frac{\tau}{2}\cdot\theta(x)\right\}\psi(x) = U(x)\psi(x) \quad [6]$$

where τ are the Pauli matrices: τ/2 are the generators of SU(2). The gauge field then has three components $A^i_\mu (i = 1, 2, 3)$ which may be written as a matrix

$$\boldsymbol{A}_\mu = A^i_\mu \frac{\tau^i}{2}$$

transforming as

$$\boldsymbol{A}_\mu \to \boldsymbol{A}'_\mu = U(x)\boldsymbol{A}_\mu\, U^{-1}(x) - \frac{i}{g}(\partial_\mu\, U(x))U^{-1}(x) \quad [7]$$

where $g$ is the coupling constant, analogous to electric charge. The problem with this idea was that the isospin gauge field, analogous to the photon in electrodynamics, should, like the photon, be massless and have polarization states ±1 (commonly, but inaccurately – see the work of Wigner (1939) – called spin 1); whereas the Yukawa particle, identified as the $\pi$ meson, was massive and had spin 0, so could not act as the isospin gauge field.

The Yang–Mills idea really came into its own with the standard model (SM) of particle physics. This (gauge) model has an invariance group SU(2) ⊗ U(1) ⊗ SU(3), the first two groups corresponding to electroweak interactions (a unification of weak interactions and electromagnetism) and the final SU(3) to quantum chromodynamics (QCD), the gauge theory describing quark interactions, which "glues" them together to make hadrons – protons, neutrons, pions, etc. This model is a dramatically successful one. The QCD sector of the theory requires essentially no further elaboration on the Yang–Mills idea than replacing the group SU(2) by SU(3). This is a straightforward matter of replacing the generators τ/2 of SU(2) with the eight generators (3 × 3 matrices) of SU(3). U($x$) then also becomes a 3 × 3 matrix. The three degrees of freedom are the three quark "colors," for which there is good experimental evidence, and the gluons, the quanta of the gauge fields, are indeed massless and have good experimental support. In the electroweak sector, however, the gauge fields, the ***W*** and ***Z*** bosons, were found with the predicted masses of 80.3 and 91.2 GeV respectively (the proton mass, for comparison, is 0.98 GeV). They are certainly not massless, as the straightforward Yang–Mills theory would require, and the explanation for this requires the introduction of the concept of spontaneous symmetry breaking.

## Spontaneous Symmetry Breaking

The general idea of spontaneous symmetry breaking is that the *vacuum* – the state of lowest energy – is not invariant under the symmetry in question. A simple and common illustration is a pencil balanced vertically on its tip on a horizontal plane. The pencil is in unstable equilibrium but the system has a symmetry under rotations in the plane about the axis coincident with the pencil. Eventually, the pencil will fall into its lowest-energy state (vacuum), lying on the table in some direction – and the rotational symmetry is then lost. In fact, under rotations the actual lowest-energy (vacuum) state will be changed into another such state. There is a *degenerate vacuum*.

A similar scenario may be constructed in a complex scalar field theory. Consider such a theory with a Lagrangian given by

$$L = (\partial_\mu\phi)(\partial^\mu\phi^*) - m^2\phi^*\phi - \lambda(\phi^*\phi)^2 \quad [8]$$

that is, with a potential energy function given by

$$V(\phi, \phi^*) = m^2\phi^*\phi + \lambda(\phi^*\phi)^2 \quad [9]$$

where $m$ is the mass of the field (quantum) and $\lambda$ is the coupling of its self-interaction. The ground state is obtained by minimizing $V$, hence $\partial V/\partial\phi = 0$, giving (assuming that $m^2 > 0$) a minimum at $\phi = \phi^* = 0$. If, however, $m^2 < 0$, there is a local maximum at $\phi = 0$ and a minimum at $|\phi|^2 = -m^2/2\lambda > 0$. In quantum theory language, the vacuum expectation value $< 0|\phi|0 >$ of the field is nonzero. Goldstone showed that this implied the presence of a massless scalar particle – a Goldstone boson. There was some interest in this result in particle physics, where the hypothesis of "partial conservation of the axial vector current" (PCAC) might result in a Goldstone boson that could be identified with the pion; although not massless, the pion is the lightest hadron, so "almost" massless.

Higgs analyzed what happens to the Goldstone model if electromagnetism is included. The Lagrangian [8] is invariant under the global transformation [4], but if this is made local, as in [5], a gauge field must be introduced and it is found that the massless Goldstone boson disappears and the massless gauge field (photon) becomes massive. Thus, spontaneous symmetry breaking of a gauge theory results in the appearance of a massive, rather than massless, gauge particle. (It is relevant to remark that a massless photon possesses two polarization states, but a massive one possesses three, so the number of spin-polarization states is preserved – the massless photon "eats" the Goldstone boson and becomes massive.) The Higgs model was generalized to the

case of a nonabelian symmetry group by Guralnik, Hagen, and Kibble and invoked by Weinberg in his 1971 model for the electroweak interaction in which the gauge quanta were massive.

Higgs' work was motivated by the theory of superconductivity, where the Meissner effect (expulsion of magnetic flux from a superconductor), when relativistic, implies that the effective mass of a photon in a superconductor is nonzero – this is, the "reason" that the flux does not penetrate. In the theory of Bardeen, Cooper, and Schrieffer (BCS), a superconductor is described by an effective scalar field, a composite of electron pairs (though paired in momentum space rather than coordinate space), and this provides a physical analogy with the model above. The SM of particle physics postulates a Higgs scalar field analogous to the BCS composite scalar field. If this field exists, Higgs particles should also exist, but they have not yet been found. This is an outstanding problem for the SM.

## Baryon and Lepton Numbers

The fact that the proton $p$ does not decay into positron plus photon, $e^+ + \gamma$, or muon plus photon, $\mu^+ + \gamma$, implies a conservation law of baryon number $B$ (the proton possessing $B = 1$ and the others $B = 0$). Furthermore, the stability of $\mu^-$ and $\tau^-$ against decay into $e^- + \gamma$ implies conservation of lepton numbers $L_e$, $L_\mu$, and $L_\tau$. These are regarded as global, not local, symmetries, so there are no associated gauge fields or interactions. Interestingly, however, these symmetries are not built into the SM, so are not guaranteed by it. More interestingly, these symmetries are actually destroyed in one attempt to go beyond the SM. This is the hypothesis that QCD may be unified with electroweak interactions to produce a "grand unified" theory (GUT). The simplest GUT is the one in which the SU(2) $\otimes$ U(1) $\otimes$ SU(3) symmetry is assumed to be a subgroup of the much tighter symmetry SU(5), and in that theory the proton is unstable:

$$p \to e^+ + \pi^0 \qquad [10]$$

The predicted lifetime is $10^{30\pm1}$ years, while a recent estimate of the lifetime for this decay mode is $> 5 \times 10^{32}$ years. It may be that GUTs do not exist in nature, but since the decay [10] violates conservation of the quantities $B$ and $L_e$, even entertaining the idea that the decay might take place begs the question, "are these conservation laws sacrosanct?"

Another recent development which leads to the same question is the subject of neutrino oscillations. A strong motivation for this is the solar neutrino problem; this is the problem that the number of electron neutrinos detected on Earth, originating in the Sun, is less than the number predicted, by a factor close to 3. The mismatch could be at least partly, and perhaps completely, explained if electron neutrinos "oscillated" into muon and/or tau neutrinos on their passage from the Sun to the Earth, since the reaction which detects the neutrinos on Earth is sensitive only to electron neutrinos, and not to the other species. But oscillation is only permitted if $L_e, L_\mu$, and $L_\tau$ are not separately conserved quantities. Oscillation can also only take place if the masses of the different neutrinos are different – the oscillation rate depends on $\Delta m^2$ – hence not all the neutrinos may be massless.

## Discrete Symmetries

Ever since parity violation was discovered in weak interactions (nuclear beta decay) by Wu in 1957, the whole subject of discrete symmetries has presented problems which are still not resolved. The symmetries in question are

$P$ (space inversion): $(x, y, z) \to (-x, -y, -z)$
$T$ (time reversal): $t \to -t$
$C$ (particle–antiparticle conjugation): particle $\leftrightarrow$ antiparticle

Are the laws of physics invariant under these operations? The Wu experiment revealed that weak interactions are not invariant under $P$, but what about other interactions and other operations? In this context, the $CPT$ theorem is highly important. According to this theorem (based on very general assumptions), all laws of nature must be invariant under the combined operation $CPT$, so that, for example, the fact that weak interactions are not invariant under $P$ means that they are not invariant under the product $CT$ either.

The violation of $P$ invariance in beta decay was soon related to the fact that the neutrino involved (the electron neutrino – or, to be precise, antineutrino) was massless. Spin-1/2 particles like the electron and neutrino obey the Dirac equation, which may be written out as a pair of coupled equations for left- and right-handed states. In the case $m = 0$, however, these equations decouple so it is possible to have a massless spin-1/2 particle which is either left-handed or right-handed. Any interaction involving this particle would automatically violate parity (which turns a left-handed state into a right-handed one). Experiments have verified that the neutrino is indeed left-handed. The SM incorporates this in the sense that the left-handed electron $e^-{}_L$ and the electron neutrino $\nu_e$ are assigned to a

weak isospin SU(2) doublet, while the right-handed electron $e^-_R$ transforms as a singlet. A similar pattern is repeated for the $\mu$ and $\tau$ particles and their neutrinos. The phenomenon of neutrino oscillations, on the other hand, does not allow all the neutrino states also to be purely left-handed (since they cannot be massless). This poses a potential problem for the SM.

For a few years after 1957 it was believed that beta decay violated $C$ as well as $P$, but conserved the product $CP$; and indeed that all weak interactions were $CP$ invariant. In 1964, however, it was found that there is a small element of $CP$ violation in $K^0$ decay. CP-violating effects are also expected in $B^0$ decays. The physical origin of $CP$ violation is still not understood, but its importance is that it implies $T$ violation, so that in (at least some) weak interactions, there is an "arrow of time" on the subnuclear scale. (Such an arrow of time is, of course, familiar in thermodynamics.) This is used in a cosmological context to explain baryon–antibaryon asymmetry in the Universe.

#### Baryon–Antibaryon Asymmetry

In the standard model of cosmology it is shown that applying the known laws of physics to the early Universe (the first few minutes) leads to the conclusion that at an age of 226 s nuclear fusion reactions took place resulting in a mixture of 74% protons and 26% $\alpha$ particles, so that, hundreds of thousands of years later, when galactic condensation took place, it would involve precisely this admixture of hydrogen and helium gases. Just this amount of helium has been found in the Sun, giving great confidence to the "big bang" model. Assuming that at extremely small times the baryon number of the Universe was zero, $B = 0$, and assuming also (a big assumption, but one nevertheless made by cosmologists) that the Universe is made of matter and not antimatter, we may then ask, why is this – where has the antimatter gone?

Surprisingly, this question was addressed as early as 1966 by Sakharov, who showed that, starting with an initial state with $B = 0$, it would be possible to reach a state with $B \neq 0$ as long as three conditions obtained: $B$ violating interactions, $CP$ and $C$ violating interactions, and lack of thermal equilibrium. GUTs and ordinary weak interactions already provide possibilities for the first two of these conditions. Breakdown of thermal equilibrium will be expected to occur as the Universe expands. When the particle density is high, reactions such as $p + \bar{p} \to \gamma + \gamma$ will ensure an equal population of baryons and antibaryons, even in the presence of $B$ violating interactions, but as the density increases and this reaction rate becomes less than the expansion rate, thermal equilibrium can no longer be maintained. Thus, GUTs offer an explanation of why there is no antimatter in the Universe. It might be thought that this sort of explanation is implausible, since the $B$-violating and $CP$-violating forces are so weak, but actually this is not a problem, since the ratio of baryon number to photon number in the Universe is of the order $N_B/N_\gamma \approx 10^{-9}$; so we may conjure up a scenario in which the $B$ and $CP$ violating forces give rise to a volume of space in which there are, say, $10^9$ antibaryons, $10^9 + 1$ baryons and approximately the same number of photons. Then, all the antibaryons become annihilated leaving one baryon and $10^9$ photons – as observed.

A recent development in the area of discrete symmetries has been the suggestion by Kostelecky and coworkers that there might exist spontaneous violation of $CPT$ and Lorentz symmetry.

### Topological Charges

Conserved quantities of a quite different type have received a lot of attention in recent decades. Their conservation is a consequence of nontrivial boundary conditions for the fields. A famous example is the sine-Gordon "kink." The sine-Gordon equation

$$\frac{\partial^2\phi}{\partial t^2} - \frac{\partial^2\phi}{\partial x^2} + \frac{1}{b^2}\sin(b\phi) = 0 \qquad [11]$$

describes a scalar field in one space and one time dimension. It is a nonlinear equation which possesses, among others, the interesting solution

$$f(\xi) = \frac{4}{b}\ \arctan\exp[\pm(\gamma/\sqrt{b})\xi]$$

where $\xi = x - vt$ and $\gamma = (1 - v^2)^{-1/2}$. This corresponds to a solitary wave which moves, preserving its shape and size – in distinction to usual waves, which spread out and dissipate. Waves of this type are called solitons, and solitons have in fact been observed moving along canals. In this case, they are solutions to the Korteveg de Vries equation. Equation [11] clearly possesses the constant solutions

$$\phi = \frac{2\pi n}{b}, \quad n = 0, \pm1, \pm2, \ldots$$

which, it may be shown, all have zero energy. We may then construct a solution of the above type, but with $n = 0$ as $x \to -\infty$ and $n = N$ as $x \to +\infty$. This so-called "kink" solution has finite energy and is not continuously deformable into a solution with $n = 0$ everywhere, since this would involve overcoming an

infinite energy barrier. The "kink number" may be characterized as a charge: defining the current

$$J^{\mu} = \frac{b}{2\pi}\varepsilon^{\mu\nu}\partial_{\nu}\phi$$

with $\varepsilon^{\mu\nu}$ the totally antisymmetric symbol, it is clear that this is identically conserved, $\partial_{\mu}J^{\mu} = 0$. This is a consequence of the definition of $\varepsilon^{\mu\nu}$; it is not a consequence of invariance of the sine-Gordon Lagrangian under a symmetry operation, so the current $J^{\mu}$ is not a Noether current. The associated conserved charge is

$$\begin{aligned} Q &= \int J^0\,\mathrm{d}x = \frac{b}{2\pi}\int \frac{\partial\phi}{\partial x}\,\mathrm{d}x \\ &= \frac{b}{2\pi}[\phi(\infty) - \phi(-\infty)] = N \end{aligned}$$

Models of the above type may be written down in a spacetime with more than two dimensions. In that case the above solution depends only on one coordinate, so represents an infinite planar "domain wall," on the two sides of which the field assumes different values. Such domain walls, as well as "cosmic strings," are considered as serious possibilities in cosmology.

Nonabelian gauge theories and the sigma model also provide a fertile ground for topological excitations – field configurations which for topological reasons do not decay. Gauge theories with spontaneous symmetry breaking have two-dimensional solutions corresponding to vortex lines and three-dimensional solutions corresponding to magnetic monopoles. In spacetime ($3+1$ dimensions), there is a solution to the gauge field equations, with no spontaneous symmetry breaking, corresponding to an "instanton," a finite-energy field configuration, localized in time as well as in space (hence the name). The gauge group here is SU(2), whose group space is $S^3$. Spacetime is "Euclideanized" into $R^4$, whose boundary is then $S^3$. Asymptotic field configurations may then be characterized by mappings of $S^3$ in field space into $S^3$ in parameter space, and since the third homotopy group of $S^3$ is nontrivial, $\pi_3(S^3) = Z$, these field configurations belong to different classes and are not deformable into each other. These define "degenerate vacua" of the gauge field equations. In quantum theory, tunneling between these vacua is allowed and 't Hooft has shown how this may give rise to deuteron decay $d \to e^+ + \bar{\nu}_{\mu}$. Other examples of topologically nontrivial configurations are so-called sphalerons, which may also contribute to baryon number violation in the early Universe, and skyrmions, constructs in the nonlinear sigma model which serve as a model for baryon number.

## Supersymmetry

Supersymmetry is a fermion–boson symmetry, postulating that multiplets of fundamental particles contain both fermions and bosons. Thus, for example, since electrons exist there should also be "selectrons" – "scalar" electrons, with spin 0. There should also be photinos, with spin 1/2, to take their place alongside photons, and so on. If supersymmetry were exact, these particles would have the same mass as their partners and would have all been found, but in fact none have yet been discovered, so presumably supersymmetry is a broken symmetry. The feature that makes supersymmetry attractive is that it holds some promise for solving divergence problems in quantum field theory, since the radiative corrections from fermion and boson loops are opposite in sign and may exactly cancel. Supersymmetric models can also help to solve the so-called hierarchy problem in quantum field theory.

If supersymmetry is made into a local symmetry, rather than simply a global one, extra fields must be introduced (as the photon field was introduced above), and it turns out that one of these is a spin-2 field, which may be identified with the *graviton*. Local supersymmetry thus becomes supergravity.

## General Relativity

Symmetries and conservation laws take on new aspects when general relativity is considered. Einstein's field equations relate the energy–momentum tensor of matter (and radiation) to the Ricci tensor of spacetime. The Ricci tensor has vanishing *covariant* divergence, which means that the energy–momentum tensor possesses the same property, but conservation of energy and momentum requires that it is the ordinary derivative, not the covariant one, of this tensor that should vanish. It might be expected that this problem could be alleviated by including the contribution of the gravitational field itself in energy–momentum tensor. This is quite reasonable, but then problems of interpretation arise, since at any one point in a general spacetime, a coordinate system might be found which is inertial (this is the force of the equivalence principle), corresponding to no gravitational field, and therefore no energy. The usual procedure is to introduce an energy–momentum "pseudotensor," and to conclude that energy in a gravitational field is not localizable.

The role of symmetries in general relativity is rather different from its role in particle physics, which is set in Minkowski spacetime. In a general spacetime there are no symmetries, but many examples of particular spacetimes with their own symmetries are now known. The symmetry operations involved are

*isometries*, with corresponding groups of motion (so that the isometry group of Minkowski space is the Poincaré group). These groups are an important subject of study in cosmology; for example, there is a classification of homogeneous cosmological models, labeled according to the Bianchi classification.

# Symmetries in Quantum Field Theory of Lower Spacetime Dimensions

**J Mund**, Universidade de São Paulo, São Paulo, Brazil
**K-H Rehren**, Universität Göttingen, Göttingen, Germany

## Symmetries in Quantum Field Theory

Symmetries have proved to be one of the most powerful concepts in quantum theory, and in quantum field theory in particular. From the beginnings of quantum mechanics, it is well known that the presence of a symmetry allows one to predict relations between different measurements, to classify spectra (energy or other), and to understand the Pauli exclusion principle, to name only a few applications. Much more remarkably, in modern relativistic quantum field theory, designed to describe the interactions of elementary particles, fundamental interactions have been found to be induced by the principle of local gauge invariance.

One distinguishes spacetime symmetries (Poincaré or conformal transformations), which change the position and orientation of the system in space and time, and internal symmetries, which preserve the localization, acting on certain internal degrees of freedom. The Coleman–Mandula (1967) theorem states that internal and spacetime symmetries cannot be mixed, in the sense that the generators of internal symmetries must be Lorentz scalars, hence the total group of symmetries factorizes into a direct product. Supersymmetries are an exception of this theorem because their generators do not form a Lie algebra, and they were in fact designed to circumvent the Coleman–Mandula theorem.

It is well known that the structure of symmetries of quantum systems in low-dimensional spacetime differs significantly from that in four-dimensional spacetime. ("Low" means in our context two or three, depending on the type of charge localization, c.f. below.) To name some examples:

- Two-dimensional quantum systems may have much higher symmetries than four-dimensional ones:
  - In two dimensions, there exist massive integrable models with infinitely many conservation laws and factorizable scattering matrices (*see* Integrability and Quantum Field Theory). These models exhibit solitonic superselection sectors, c.f. below.
  - The conformal group of two-dimensional spacetime is infinite dimensional, allowing for

the exact computation of correlation functions by the help of Ward identities (Belavin, Polyakov, and Zamolodchikov 1984). Only the finite-dimensional Möbius group, however, is also a symmetry of the vacuum state. Möbius covariance implies that the theory contains two subtheories of chiral fields defined on the light rays $t - x = \text{constant}$, resp. $t + x = \text{constant}$, and that these can be extended to fields defined on a circle, by adding a "point at infinity" to the light ray (Lüscher and Mack 1976). One arrives thus at one-dimensional chiral quantum field theories on a circle, which will play an important role in the discussion below.

- Continuous symmetries cannot be spontaneously broken in two dimensions. The latter is true not only for relativistic quantum field theory (Coleman 1973), but also in quantum statistical mechanics (Mermin and Wagner 1966) where it is responsible for the absence of ferromagnetism (*see* Symmetry Breaking in Field Theory). Spontaneous symmetry breakdown requires long-range order which is overcome by thermal fluctuations down to zero temperature, because these diverge logarithmically (in the thermodynamical limit) in two dimensions. This theorem thus illustrates how the spacetime dimension-dependent size of phase space has an effect on internal symmetries of quantum systems. A detailed mathematical analysis of the balance between phase space (thermal fluctuations) and long-range order (symmetry breakdown) has been given in a recent discussion of the Goldstone theorem (Buchholz, Doplicher, Longo and Roberts 1992).
- The Coleman–Mandula theorem, excluding a mixing between internal and spacetime symmetries (see above), is valid only in higher dimensions.

In more recent times, it has become apparent that low-dimensional quantum systems do not only admit more symmetries, but they may exhibit internal symmetries of an entirely new type, not describable by groups of transformations. In this article, we shall focus on the various ways in which the new symmetries can arise, and how they can be understood. In order to properly appreciate these issues, let us first recall some basic symmetry concepts in the conventional case.

In the traditional setting, symmetries arise in the form of groups of transformations of the quantum system which leave observable quantities (e.g., vacuum expectation values and correlation functions) invariant. The symmetries form a group of $*$-automorphisms of the algebra of fields:

$$\begin{aligned} \alpha_g(\phi_1\phi_2) &= \alpha_g(\phi_1)\alpha_g(\phi_2) \\ \left(\alpha_g(\phi)\right)^* &= \alpha_g(\phi^*) \\ \alpha_{g_1}\alpha_{g_2} &= \alpha_{g_1 g_2} \end{aligned} \qquad [1]$$

(typically given by linear transformations of field multiplets). In the strongest case, the automorphisms are implemented by unitary operators on the state space

$$U(g)\phi U(g)^* = \alpha_g(\phi) \qquad [2]$$

The implementers form a representation of the group of automorphisms,

$$U(g_1)U(g_2) = U(g_1 g_2) \qquad [3]$$

and there is an invariant vector state (a ground state, or the vacuum state in relativistic quantum field theory),

$$U(g)\Omega = \Omega \qquad [4]$$

However, depending on the dynamics of the quantum system, these relations cannot always be fully realized. One therefore considers several weaker or more general notions of symmetries relevant in four dimensions:

- *Spontaneously broken symmetries.* The transformations are given as automorphisms of an algebra, but which are not unitarily implemented in a given irreducible representation of the algebra. Invariant pure states do not exist.
- *Projective representations.* The symmetries are unitarily implemented, but the implementers fail to satisfy the group law [3]. They give rise to ray (projective) representations or representations of a covering group. In particular, an invariant state vector as in [4] cannot exist in an irreducible representation.
- *Infinitesimal symmetries.* Lie algebras of infinitesimal transformations, given as derivations of an algebra, which cannot be integrated to finite transformations. Derivations may or may not be implemented in a given representation of the algebra by commutators with self-adjoint generators.
- *Supersymmetry.* The infinitesimal transformations form a graded Lie algebra.
- Local gauge symmetries form an infinite-dimensional group which are, however, not realized as automorphisms of the quantum algebra. Quantization of classical gauge interactions usually proceeds by breaking the gauge invariance in some way and restoring it at a later stage.

## The Connection between Symmetry and Superselection Sectors

It is often convenient to describe a model in terms of localized fields which do not represent an observable (in the sense of quantum mechanics that an operator corresponds to some measurement prescription). For example, Fermi fields which violate the principle of causality because they anticommute with each other at spacelike distance rather than commute are not observables. Only fields which are quadratic in the Fermi fields (densities of charge, current, energy) are observables. This means that an internal symmetry is used in order to distinguish the observables as those operators which are invariant under the symmetry: in the example, the symmetry transformation multiplies each Fermi field by –1 (by the spin-statistics theorem, this transformation coincides with the univalence of the Lorentz group). We characterize this situation by writing

$$A(O) = F(O)^G \qquad [5]$$

where $A(O)$ and $F(O)$ stand for the algebras of observables and fields localized in some spacetime region $O$, respectively, $G$ is the internal symmetry group acting by automorphisms on each $F(O)$ without affecting the localization, and $F(O)^G \equiv \{a \in F(O), \alpha_g(a) = a$ for all $g \in G\}$ denotes the subalgebra of invariants. The internal symmetry group $G$ which distinguishes the observables according to [5] is usually called the "(global) gauge group."

If the gauge symmetry $G$ is unbroken in the vacuum state, then there is a well-known connection between symmetry and superselection rules (*see* Symmetries and Conservation Laws): namely, the observables act reducibly on the vacuum Hilbert space representation of $F$ because they commute with the unitary operators which implement the symmetry (or with their infinitesimal generators, usually called charges). As a consequence, the validity of the superposition principle is restricted because two eigenstates of different eigenvalues of the charges cannot exhibit interference. In other words, they belong to different superselection sectors. Wick, Wightman, and Wigner (1952) were the first to point out this relation. We therefore call this scenario the "WWW scenario" for brevity.

In the WWW scenario, the decomposition of the Hilbert space is determined by the central decomposition of the internal symmetry group (the eigenvalues of the Casimir operators). In this way, the superselection sectors are in one-to-one correspondence with the irreducible representations of the internal symmetry group.

Superselection sectors of two-dimensional models do not follow this scheme expected by the WWW scenario (see below). This was most strikingly demonstrated through the classification of the unitary highest-weight representations of the Virasoro algebra (Friedan, Qiu, and Shenker) which is nothing other than the classification of the superselection sectors of the observable algebra generated by the chiral stress–energy tensor, and through the determination of their fusion rules by Belavin, Polyakov, and Zamolodchikov (1984).

In two dimensions, one is therefore lacking a compelling *a priori* ansatz, like the WWW scenario, for describing the system in terms of auxiliary nonobservable charged fields. At this point, one may argue that from an operational point of view, a quantum field theory, and in particular its symmetries, should be understood entirely in terms of its observables. (This viewpoint is emphasized in the algebraic approach to QFT, *see* Algebraic Approach to Quantum Field Theory.) We shall therefore now ask the opposite question: suppose we are given an algebra $A$ of local observables (without knowledge of a field algebra and its gauge group). We define the superselection sectors intrinsically as (the unitary equivalence classes of) the positive-energy representations of $A$. Then the question is: do these sectors arise through a WWW scenario from some field algebra and a gauge symmetry, and if so, can the latter be reconstructed from the given observables alone?

The answer in four dimensions is positive, thanks to a deep result due to Doplicher and Roberts (1990). Let us sketch the line of reasoning leading to this result in some detail, because it shows how the connection between (global) gauge symmetry on the one hand and spacetime geometry on the other hand emerges through the principle of causality (locality) of relativistic quantum field theory, and because it makes apparent what is different in low-dimensional spacetime.

The analysis is based on the general structure theory of superselection sectors due to Doplicher, Haag, and Roberts (DHR, 1971). The latter starts with a selection criterion invoking the concept of a localized charge: a superselection sector which by measurements within the causal complement of some spacetime region $O$ cannot be distinguished from the vacuum sector. The heuristic idea is, of course, that the sector is obtained from the vacuum sector by placing some charge in the region $O$ (e.g., by the application of a localized charged field operator to the vacuum vector).

It has been shown (Buchholz and Fredenhagen 1982) that positive-energy representations of

massive theories always satisfy this selection criterion with a localization region $O$ of the form of a narrow cone extending in spacelike direction. (In massless theories with long-range interactions, such as QED, the situation is more complicated because the charge creates an electric field whose flux at infinity does not vanish (Gauss' law) and is not Lorentz invariant.) DHR assume that the localization region is even compact, and can be chosen arbitrarily within the unitary equivalence class of the representation.

Exploiting a strong version of locality (Haag duality) for the vacuum representation of the observables, DHR proceed to define an associative composition (or fusion) law for positive-energy representations. This law is commutative only up to unitary equivalence. The crucial point is that the unitary intertwiner establishing this equivalence (the statistics operator) can be chosen in a unique way provided any pair of spacelike disconnected localization regions can be continuously deformed into any other such pair.

This point marks the separation between high and low dimensions. In two dimensions, in each pair of spacelike disconnected regions, one region is to the left of the other, thus distinguishing the pair $(O_1, O_2)$ from $(O_2, O_1)$. Consequently, they cannot be deformed into each other, and there arise two statistics operators. The same holds in three dimensions when the localization regions are spacelike cones, and $O_1, O_2$ are taken within (the causal complement of) some larger spacelike cone. If the spacetime dimension is at least 4, or if in three dimensions the localization regions are compact, then the statistics operator is unique and, as a consequence, coincides with its inverse.

The (non-)uniqueness of the statistics operator has far-reaching consequences concerning our original question about the underlying gauge symmetry. Namely, the DHR analysis proceeds to show that the set of positive-energy representations equipped with the composition law, and the linear spaces of inertwiners between different representations, together form the mathematical structure of a $C^*$ tensor category. The statistics operators which are distinguished intertwiners give additional structure to this category: this structure is called a (permutation) symmetry if the statistics operators coincide with their inverse, and it is called a braiding otherwise. (It gives rise to a representation of the permutation group or the braid group, respectively.) In other words, the spacetime topology, through the intervention of the uniqueness of the statistics operator, causes the tensor category to be symmetric in high dimensions, and braided in low dimensions.

At a more elementary level, one may think of statistics operators as reflecting commutation relations between the searched-for charged fields. Making an ansatz for the commutation relations at spacelike separation, essentially the same topological argument as before implies, together with Poincaré invariance, that the coefficients appearing in this relation should form a representation of the permutation group, or of the braid group, respectively. The DHR approach, however, is entirely intrinsic, avoiding any *a priori* assumption of charged fields.

The duality theorem due to Doplicher and Roberts (1990) now states that every symmetric $C^*$ tensor category (with some further qualifications valid in the DHR setting) is isomorphic to the category of unitary representations of a compact group, in which the composition law is the tensor product and the (permutation) symmetry is the natural one. Moreover, the category uniquely determines the group, and by a crossed product construction (an action of the category on the algebra $A$) one reconstructs a field algebra $F$ such that [5] holds. If fermionic sectors are present, then there is some arbitrariness in the commutation relations among the corresponding fermionic fields, which can be exploited to produce the normal commutation relations (fermionic fields anticommute among each other, and bosonic fields commute with any field at spacelike separation). This fixes the field algebra $F$ up to unitary equivalence. The conclusion is that the WWW scenario is the most general in four dimensions (apart from the reservations due to long-range forces, see above).

## Generalized Symmetries in Low Dimensions

In view of the success of this program in four dimensions and the advantage of the WWW scenario for model building, the obvious challenge is to search for an analogous understanding of superselection sectors (charges) in low dimensions in terms of an algebra of charged fields and a gauge symmetry distinguishing the observables. This gauge symmetry cannot, in general, be a group for several reasons:

- As stated before, the tensor category of superselection sectors possesses only a braiding, rather than a (permutation) symmetry, hence the duality theorem fails.
- One can associate a (statistical) dimension $d_\pi$ to each superselection sector $[\pi]$ which is multiplicative under the composition law (fusion), and additive under direct sums. In a symmetric

category, the dimensions are necessarily positive integers. Indeed, in the WWW scenario, they coincide with the naive dimension of the associated representation of the gauge group. But in the low-dimensional models, the dimensions turn out to be nonintegers in general.

- Moore and Seiberg (1988) have axiomatized the superselection structure of chiral and two-dimensional conformal field theories in terms of a system of recoupling and braiding coefficients controlling the fusion of sectors and its noncommutativity. (In fact, this system is basically equivalent to the DHR category.) For models such as SU(2) current algebras at level $k$, these coefficients turn out to coincide with the recoupling and braiding coefficients one can associate with a quantum group deformation (Drinfel'd 1986) of SU(2) with deformation parameter $q = -\exp \mathrm{i}\pi/k$. Representations of quantum groups (quasitriangular Hopf algebras, *see* Hopf Algebras and $q$-Deformation Quantum Groups) have a tensor product defined in terms of a noncocommutative coproduct. Moreover, they possess a quantum dimension which is a $q$-deformation of an integer. The quantum dimensions precisely match the statistical dimensions of the superselection sectors. All this strongly suggests that quantum groups appear as generalized symmetries in two dimensions, at least in a large class of models.

A natural testing ground for the search for appropriate generalized symmetry concepts in low dimensions is the abundance of models in chiral and two-dimensional conformal QFT (*see* Two-Dimensional Models). As mentioned before, conformal symmetry in two dimensions has far-reaching consequences, especially the existence of chiral quantum fields which are defined on a one-dimensional light ray. As a null direction in the two-dimensional spacetime, this ray unites both the spacelike property of carrying a causal structure, and the timelike property that the generator of translations has positive spectrum (energy). These two features together with Möbius covariance are so powerful that they allow for the exact construction of large classes of models. The most elementary ones (minimal models) are completely described by the chiral stress–energy density field, that is, the local generator of the conformal symmetry. Other models also contain currents which are the local generators of internal symmetries. These models exhibit many nontrivial superselection structures, which illustrate the wide range of possible deviations from higher-dimensional QFT, and at the same time exhibit possible approaches to appropriate symmetry concepts in low dimensions.

Attempts to classify the possible algebraic structures of generalized internal symmetries in a model-independent setting start from the idea that the representation category of the internal symmetries of a given model should be equivalent to the tensor category of its superselection sectors. Several algebraic structures have been proposed as candidates, complying with this idea. They all assume specific modifications or deformations of eqns [1]–[5] above, highly constrained by self-consistency. Among these proposals are:

- quantum groups (see e.g., Fröhlich and Kerler 1993),
- weak quasiquantum groups (Mack and Schomerus 1992) and rational Hopf algebras (Fuchs *et al.* 1994),
- weak C* Hopf algebras (Rehren 1997, Böhm and Szlachányi 1996) or quantum groupoids (Nikshych and Vainerman 1998), and
- braided groups (Majid 1991).

In several cases, the respective "symmetry algebra" can be reconstructed from the tensor category of superselection sectors, and a field algebra with linear transformation behavior can be constructed which contains the observables as invariant elements as in [5]. However, the situation is unsatisfactory for various reasons. First, the class of QFT models for which these constructions have been performed is quite restricted (most constructions work only for rational models, i.e., models with a finite set of charges); second, the reconstructed symmetry algebra is not unique and finally, the constructed field algebras have features which diverge significantly from the WWW scenario. For example, it is not always warranted that the quantum symmetries are consistent with the *-structure, indispensable for Hilbert space positivity (a necessary prerequisite for the probability interpretation of quantum theory). Moreover, typically there are global gauge transformations which are implemented by localized field operators, thus exhibiting a mixing of local and global concepts. It also happens that this holds for elements in the center of the symmetry algebra, which implies that the field algebra is not local relative to its gauge invariant elements, that is, the charged fields do not commute with the gauge-invariant elements at spacelike separation. In other constructions, the field algebra is not associative, or there are no finite field multiplets.

Historically, the first candidate for a "symmetry algebra" compatible with braid group statistics has

been the structure of a quantum group, as mentioned above. However, in physically interesting models, the quantum group is not semisimple and thus has too many (namely, indecomposable) representations. Solutions to this problem have been:

1. A BRS approach in an indefinite-metric framework (Hadjiivanov *et al.* 1991),
2. "Truncation," that is, discarding the "unphysical" representations. Fröhlich and Kerler (1993) have done this consistently in a categorical framework. In fact, they have given a complete classification of the possible braided tensor categories generated by a single irreducible object with statistical dimension $d$ satisfying $1 < d < 2$, in terms of categories constructed from the "truncated" representations of $U_q(\mathrm{sl}_2)$. Truncation can also be performed by dividing the quantum group itself through the ideal which is annihilated by all "physical" representations, leading to a weak quasiquantum group (Mack and Schomerus 1992).
3. Relaxing the axioms, thus admitting the more general structures mentioned above.

All the above approaches assume a given generalized symmetry concept and show to what extent field algebras complying with it can be constructed. They thus concern nonobservable objects, and it is no contradiction if different symmetry concepts can be associated with the same observable data.

A more radical concept of global gauge symmetry, applicable to the low-dimensional case, has been developed by Longo and Rehren (1995). Its point of departure is the notion of a conditional expectation, which has the same abstract properties as a group average. In the WWW scenario, the Haar measure of the compact gauge group defines an average

$$\mu : F \ni \phi \mapsto \int \mathrm{d}\mu(g)\, \alpha_g(\phi) \in A \qquad [6]$$

which is a positive linear map respecting the localization, and the observables are invariant, $\mu(a) = a$. In fact, the observables are exactly the image of this map, that is, [5] is equivalently formulated, but without reference to the group transformations, as

$$A(O) = \mu(F(O)) \qquad [7]$$

Turning to the observables $A$ of a quantum field theory in low dimensions, one looks for a quantum field theory $F$, containing $A$ and equipped with a conditional expectation $\mu$ such that [7] holds, and which preserves the vaccum state. $F$ may not satisfy local commutativity, but it should be local relative to the observables in the sense mentioned before. In rational chiral CFT, such extensions can be classified (and indeed constructed) in terms of the superselection category of $A$, giving direct access to the decomposition of the vacuum Hilbert space of $F$ into superselection sectors of $A$. The advantage here is that no problems with Hilbert space structure can arise (because the approach is entirely in terms of operator algebras); a drawback is that in general $F$ is not unique, and nonvacuum representations of $F$ also have to be considered in order to generate all sectors of $A$.

The method can be used to classify and construct both nonlocal chiral extensions as candidates for sector-generating field algebras for a theory $A$ of chiral observables, and local two-dimensional quantum field theories containing two given chiral subtheories, that is, observable algebras of two-dimensional models (Kawahigashi and Longo 2004). The chiral sector structure of the latter models is described by a "modular invariant." In many cases, this means that their thermal partition functions are invariant under the group $\mathrm{PSL}(2, \mathbb{Z})$ of modular transformations of the temperature (see below).

At this point, another link between spacetime and internal symmetries may be noted. The modular theory of von Neumann algebras (*see* Tomita–Takesaki Modular Theory) associates a one-parameter group of automorphisms (called the "modular group") with a state and an algebra "in standard position." In quantum field theory, for the vacuum state and an algebra of observables localized in certain wedge regions of Minkowski spacetime, this group can be identified with a boost subgroup of the Lorentz group (Bisognano and Wichmann 1975). Similarly, in chiral CFT on the circle, the modular group associated with the observables in an interval and the vacuum coincides with a subgroup of the Möbius group. For nonlocal theories, there may be an obstruction, however. On the other hand, if a subalgebra is stable under the modular group of some algebra, then there is a conditional expectation from the larger algebra onto the smaller algebra. Combining these general theorems, the Möbius covariance of the inclusions $A(O) \subset F(O)$ implies the existence of a conditional expectation, that is, the above generalization of the average over the internal symmetry. Moreover, assuming a generalized notion of compactness ("finite index") for the generalized internal symmetry, the Bisognano–Wichmann property holds also for nonlocal theories (Longo and Rehren 2004).

Of course, there is also a WWW scenario in chiral theories, that is, one may restrict a local theory to its invariants under some group of internal gauge

symmetries ("orbifold models"). It then happens that the invariants not only have the expected superselection sectors in correspondence with the representations of the gauge group, but in addition "twisted" sectors appear which, together with the former, constitute a "quantum double" structure. The twisted sectors arise by restriction of solitonic sectors of the original theory, which are in one-to-one correspondence with the elements of the gauge group (Müger 2005). Solitonic sectors are localizable with respect to two different vacua, and do not admit an unrestricted composition law.

## Special Issues

A particularly simple situation is the case of anyons, that is, when all sectors have statistical dimension 1. Then the sectors form an abelian group $\hat{G}$ under fusion, and one can construct a WWW scenario with global gauge group $G$ the dual of $\hat{G}$. The ensuing quantum fields satisfy generalized commutation relations at spacelike separation, given by an abelian representation of the braid group, where the coefficients can be arbitrary complex phases (responsible for the name "anyons"). However, it is known that there can arise an obstruction, which enforces the "local" global gauge transformations (mentioned before) to be present. In this case, the gauge symmetry can also be described by a quasiquantum group. It is noteworthy that free anyon fields have been constructed in two-dimensional spacetime, while in three dimensions there can be no (cone-) localized massive anyon fields which are free in the sense that they generate only single-particle states from the vacuum (Mund 1998).

The charge structure of massive quantum field theories in two dimensions is very different both from that encountered in conformal quantum field theories, and from the charge structure in high dimensions. It has been observed long ago that, in contrast to four dimensions, the strong locality property (Haag duality) which is necessary to set up the DHR analysis of superselection sectors, fails for the algebra of invariants under an internal gauge group in two dimensions. This algebraic feature can be traced back to the fact that the causal complement of a point is disconnected in two dimensions, or, in physical terms, that "a charge cannot be transported around a detector" without passing through its region of causal dependence. Müger (1998) has shown that any algebra of observables which satisfies Haag duality, cannot possess any nontrivial DHR superselection sectors at all, and that the only sectors which can exist are solitonic sectors. This general result nicely complies with the experience with integrable models, as mentioned before.

There are also some results giving interesting insight, which can be obtained intrinsically in terms of the observables. One of them concerns "central" observables (generalized Casimir operators).

Casimir operators in the WWW scenario are functions of the generators of the internal symmetry which usually are integrals over densities belonging to the field algebra $F$ (Noether's theorem). Since they also commute with the generators, they can be approximated by local observables, and are therefore defined in each representation of the latter. By Schur's lemma, they are multiples of the identity in each irreducible sector. Since the eigenvalues of Casimir operators distinguish the representations of the gauge group, they also distinguish the sectors.

In chiral CFT extended to the circle (see above), one can find global "charge measuring operators" $C_i$, one for each sector $\pi_i$, in the center of the observable algebra (Fredenhagen *et al.* 1992) which have similar properties. They arise as a consequence of an algebraic obstruction to define the charged sectors on the circle, related to a nontrivial effect if a charge is "transported once around the circle," and form an operator representation of the fusion rules within the global algebra of observables. Under rather natural conditions clarified by Kawahigashi, Longo, and Müger (2001), the matrix of eigenvalues $\pi_j(C_i)$ is nondegenerate, that is, the generalized Casimir operators completely distinguish the superselection sectors. In this case, the superselection category is a modular category (*see* Braided and Modular Tensor Categories): the matrix with entries $d_{\pi_j}\pi_j(C_i)$ and the diagonal matrix with entries $\pi_j(U)$ (where $U$ is the Möbius rotation by $2\pi$) are multiples of the generators $S$ and $T$ of the "modular group" $PSL(2, \mathbb{Z})$, in a matrix representation labeled by the superselection sectors of the chiral observables. The physical significance of this matrix representation is that it relates thermal expectation values for different values of the temperature (Cardy 1986, Kac and Peterson 1984, Verlinde 1988)

These examples, together with the failure of the Coleman–Mandula theorem, may illustrate the intricate relations among spacetime geometry, covariance, and internal symmetry (charge structure) in low dimensions. In relativistic quantum field theory, the link is provided by the principle of locality, which "turns geometry into algebra."

# Symmetries in Quantum Field Theory: Algebraic Aspects

**J E Roberts**, Università di Roma “Tor Vergata,” Rome, Italy

## Introduction

This article treats the most important results and concepts relating to symmetry and conservation laws in quantum field theory. It includes such results as Wigner’s theorem, Goldstone’s theorem, the Bisognano–Wichmann theorem, the quantum Noether theorem, and the theorem on the existence of gauge groups and a field net. It is written within the framework of algebraic quantum field theory, this being the simplest setting capable of expressing all these concepts and results.

Symmetries come in many guises. They are to a physical system what automorphisms are to a mathematical theory. In fact, when a physical system is described in mathematical terms, its symmetries correspond to the automorphisms of the mathematical structure and in particular form a group, its symmetry group. The reader should bear in mind this simple picture throughout its diverse variations. Readers unfamiliar with the mathematical terminology should consult the appendix.

## Elementary Quantum Mechanics

Before turning to quantum field theory, let us comment on symmetries in elementary quantum mechanics. These systems have the density matrices, that is, positive operators of trace 1, on an infinite-dimensional separable Hilbert space as states, the self-adjoint operators as observables. The expectation value of the bounded observable $A$ in the state determined by $\rho$ is given by $\mathrm{tr}\,\rho \mathrm{A}$. Having specified the mathematical structure, the notion of symmetry follows. With a suggestive notation, it is a pair of mappings $A \mapsto \alpha A, \rho \mapsto \rho\alpha^{-1}$ such that

$$\mathrm{tr}\,\rho\alpha^{-1}\alpha \mathrm{A} = \mathrm{tr}\,\rho \mathrm{A}$$

for all observables $A$ and states $\rho$.

If we take $\rho$ and $A$ to be the projections onto $\mathbb{C}\phi$ and $\mathbb{C}\psi$ for unit vectors $\phi$ and $\psi$, then the above condition corresponds to the conservation of

transition probabilities $|(\phi,\psi)|^2$. This formed the starting point for Wigner's analysis, who concluded:

**Theorem** *Every symmetry is of the form* $A \mapsto UAU^{-1}$ *and* $\rho \mapsto U\rho U^{-1}$, *where* $U$ *is a unitary or antiunitary operator.*

As could have been foreseen from the outset, this simple result in no way distinguishes one elementary quantum-mechanical system from another. A more useful notion of symmetry results if the Hamiltonian is reckoned as part of the information describing the system and, therefore, has to be left invariant by a symmetry. The operator $U$ above must therefore satisfy the condition $UHU^{-1} = H$ and it commutes with the Hamiltonian. As the Hamiltonian is the generator of time translations, $U$ is a constant of motion. This is the genesis of the relation between symmetries and conservation laws.

## Quantum Field Theories

The simplest types of quantum field theories can be described by von Neumann algebras $\mathfrak{A}(\mathcal{O})$ depending on double cones $\mathcal{O}$ and subject to

$$\mathcal{O}_1 \subset \mathcal{O}_2 \Rightarrow \mathfrak{A}(\mathcal{O}_1) \subset \mathfrak{A}(\mathcal{O}_2)$$

a structure referred to as the net of observables.

An alternative approach would be to use the Wightman formalism. This would need a discussion of pointlike fields and the domains of definition of unbounded operators, thus complicating a general exposition of symmetry.

Comparing this description of a quantum field theory with that of an elementary quantum-mechanical system, the net clearly substitutes observables but nothing has yet been said about states. Since the set of double cones is directed under inclusion, the union of the $\mathfrak{A}(\mathcal{O})$ is a $*$-algebra $\mathfrak{A}$ and a state of our system is a state on this algebra.

Most states are of no physical relevance. A characterization of the states of physical relevance, even say to elementary particle physics, is not known although some progress has been made.

The net structure is the hallmark of a field theory and allows us to distinguish two important classes of symmetries. An internal symmetry $\alpha$ satisfies the condition

$$\alpha(\mathfrak{A}(\mathcal{O})) = \mathfrak{A}(\mathcal{O})$$

for all double cones $\mathcal{O}$. By contrast, a spacetime symmetry is an automorphism $\alpha_L$ implementing a Poincaré transformation $L$ and hence satisfying the condition

$$\alpha_L(\mathfrak{A}(\mathcal{O})) = \mathfrak{A}(L\mathcal{O})$$

for every double cone $\mathcal{O}$. It is usually the case that internal symmetries commute with spacetime symmetries.

The state of prime relevance to elementary particle physics is the vacuum state $\omega_0$. The corresponding Gelfand–Naimark–Segal (GNS) representation $\pi_0$ is called the vacuum representation. Now the vacuum state of a quantum field theory is typically unique and as such invariant under a symmetry of the system $\omega_0\alpha^{-1} = \omega_0$.

## Spacetime Symmetries

Since the vacuum state is invariant, we have a unitary representation of the Poincaré group implementing the spacetime symmetries in the vacuum representation. To illustrate the role of representations up to a factor, we take instead the GNS representation of a pure state corresponding to a particle of half-integral spin. Here we need a unitary representation of the covering group of the Poincaré group, inhomogeneous $SL(2,\mathbb{C})$ to implement the symmetries. The situation for the subgroup of rotations is the same.

The most important property of these representations is positivity of the energy. More precisely, in a representation of relevance to elementary particle physics such as the vacuum representation, the generator $P^0$ of time translations is a positive operator $P^0 \geq 0$. Expressed in a frame-independent way, the spectrum of spacetime translations is contained in the closed forward light cone. It is one of the basic principles to be exploited in applying quantum field theory to elementary particle physics. Notice that the principle is no longer valid for an equilibrium state.

A similar situation arises in conformal field theory. Here the role of double cones in Minkowski space is played by intervals on the circle and that of the Poincaré group by the Möbius group on the circle $PSL(2,\mathbb{R})$. Again, the Möbius group cannot always be unitarily implemented and conformal invariance is defined via a continuous unitary representation of its covering group. Most importantly, there is an analog of positivity of the energy. The generator of rotations of the circle is a positive operator.

A remarkable aspect of spacetime symmetries was discovered by Bisognano and Wichmann in an application of modular theory in the field-theoretical context looking not at double cones but at wedges. A wedge $\mathcal{W}$ is a Poincaré transform of the standard wedge $x^1 > |x^0|$. They found that the modular automorphisms of $\mathfrak{A}(\mathcal{W})$ and the vacuum vector $\Omega_0$

have a geometric significance. For the standard wedge, they got the following result.

**Theorem** *If the net is derived from Wightman fields, the modular operator is* $e^{-2\pi K}$, *where K is the generator of boosts in the* 1*-direction and the modular conjugation is* $ZR\Theta$, *where* $\Theta$ *is the* TCP-*operator, R is the rotation through* $\pi$ *about the* 1*-axis, and Z is the unitary operator equal to* 1 *on the Bose subspace and* $-\mathrm{i}$ *on the Fermi subspace.*

The modular data for $\mathfrak{A}(\mathcal{O})$ and $\Omega_0$ also admit a geometric interpretation for the free massless scalar field.

These facts enhance our understanding of spacetime symmetries. The ideas have meanwhile been applied to curved spacetime to select a state with vacuum-like properties using the principle of the geometric action of the modular conjugation.

## Gauge Symmetry

Gauge symmetries do not fit into our scheme in that they act trivially on the observable algebra $\mathfrak{A}$. To exhibit a gauge symmetry we need a larger net $\mathfrak{F}$ called the field net. The gauge group will be the group of automorphisms of $\mathfrak{F}$ leaving the subnet $\mathfrak{A}$ pointwise fixed and $\mathfrak{A}$ the subnet of $\mathfrak{F}$ of fixed points under $G$. This has the merit of indicating the mathematical framework for gauge symmetry but otherwise begs important questions. *A priori* one does not know what properties $\mathfrak{F}$ should have nor how it should be constructed.

The right approach is to understand what intrinsic structure of $\mathfrak{A}$ governs the existence of a nontrivial gauge group. This brings us back to the states or representations relevant to elementary particle physics. A condition for selecting some of these relevant representations is that asymptotically they be like the vacuum in spacelike directions. More precisely, $\pi$ must be unitarily equivalent to the vacuum representation $\pi_0$ on the spacelike complement of every double cone.

The resulting theory of superselection sectors hinges on the property of Haag duality that, for each double cone $\mathcal{O}$,

$$\mathfrak{A}(\mathcal{O}) = \mathfrak{A}(\mathcal{O}')'$$

where $\mathcal{O}'$ denotes the spacelike complement of $\mathcal{O}$. It implies that every representation satisfying the selection criterion is unitarily equivalent to one of the form $\pi_0\rho$, where $\rho$ is an endomorphism of $\mathfrak{A}$ localized in some fixed but arbitrary double cone, that is, $\rho(A) = A$ if $A \in \mathfrak{A}(\mathcal{O}')$. The endomorphisms thus obtained are closed under composition and hence the objects of a full tensor subcategory $\mathcal{T}$ of the category of all endomorphisms and their intertwiners. There is a dimension function $d$ defined on the objects of $\mathcal{T}$, $d(\rho) = 1, 2, \ldots, \infty$. If $\mathcal{T}_f$ denotes the full subcategory whose objects have finite dimension, then the following result holds.

**Theorem** $\mathcal{T}_f$ *is equivalent to the tensor category of finite-dimensional continuous unitary representations of a canonical compact group G. There is a canonical field net* $\mathfrak{F}$ *with Bose–Fermi commutation relations extending* $\mathfrak{A}$ *such that G is the group of automorphisms of* $\mathfrak{F}$ *leaving* $\mathfrak{A}$ *pointwise fixed.*

The first step in the proof is to define and analyze the statistics of the representations in question. The statistics of an irreducible representation $\rho$ can be classified as being para-Bose or para-Fermi of order $d(\rho)$. The second step is to show that each $\rho$ of finite dimension has a well-defined conjugate up to equivalence. The third and most difficult step is showing that $\mathcal{T}_f$ can be embedded in the tensor category of Hilbert spaces.

## The Local Implementation of Symmetries

Gauge symmetry has its associated conservation laws in that the different sectors of the last section are labeled by conserved quantities such as baryon number, lepton number, or electric charge, generically called charges. The theory is built round the idea of creating charge and elements of the field net carry charges. But there should be a dual approach based on measuring charges. One would like to prove the existence of local conserved currents corresponding to these charges. This has not proved possible but there is a good substitute, described below, which can be regarded as a weak version of a quantum Noether theorem.

If $\mathcal{O}_1 \subset \mathcal{O}_2$ is a strict inclusion of double cones, then the theory is said to satisfy the split property if there is a type I factor $\mathcal{M}$ such that

$$\mathfrak{A}(\mathcal{O}_1) \subset \mathcal{M} \subset \mathfrak{A}(\mathcal{O}_2)$$

where a type I factor is a von Neumann algebra isomorphic to some $\mathcal{B}(\mathcal{H})$. In this case $\mathcal{M}$ can be chosen in a canonical fashion and there is an isomorphism $\psi$ called the universal localizing map of $\mathcal{B}(\mathcal{H})$ onto $\mathcal{M}$, where $\mathcal{H}$ is the underlying Hilbert space. We have $\psi(A) = A$ for $A \in \mathfrak{A}(\mathcal{O}_1)$.

**Theorem** *If U is an implementing representation of the internal symmetry group G,* $\psi(U)$ *will be a representation of G in* $\mathcal{M}$ *that continues to implement the symmetry on* $\mathfrak{A}(\mathcal{O}_1)$. *If G is a Lie group*

*then the infinitesimal generators in the representation are an analog of locally integrated current densities.*

## Spontaneously Broken Symmetry

The standard physical example of a spontaneously broken symmetry is magnetization. Despite the overall rotational symmetry, a magnet picks out a preferred direction as its direction of magnetization. The chosen state breaks the symmetry.

The phenomenon of spontaneously broken symmetry involves an interplay of symmetries and certain classes of states, vacuum states, ground states, or equilibrium states. If such an $\omega$ is induced by a vector cyclic and separating for a local algebra $\mathfrak{A}(\mathcal{O})$, then, as explained in the appendix, given $\mathcal{O}$, modular theory yields a canonical unitary representation $V$ of the internal symmetry group $G$:

$$gA = V_g A V_g^*, \quad A \in \mathfrak{A}(\mathcal{O})$$

The results concern the breaking of a one-parameter group $\lambda \mapsto \alpha_\lambda$ of symmetries. More precisely, one asks whether $\omega\delta = 0$ or not, where $\delta$ is the infinitesimal generator of $\lambda \mapsto \alpha_\lambda$,

$$\delta(F) = \lim_{\lambda \to 0} \lambda^{-1}(\alpha_\lambda(F) - F)$$

where norm convergence is understood and holds on a dense domain. $\delta$, the derivation, is an infinitesimal symmetry. Goldstone first showed that the spontaneous breaking of such symmetries requires the presence of massless bosons. The following result is taken from a more modern treatment. $\mathcal{O}_R$ here denotes the double cone whose base is the ball in $t = 0$ of radius $R$ centered on the origin and $\mathcal{D}$ the domain of $\delta$.

**Theorem** *Let $\delta$ be a derivation on a field net $\mathfrak{F}$ in $s > 1$ spatial dimensions such that for $F \in \mathfrak{F}(\mathcal{O}_R) \cap \mathcal{D}$*

$$|\omega_0 \delta F| \leq c_{R,\varepsilon}(\|F\Omega\| + \|F^*\Omega\|) + \varepsilon\|\delta F\|$$

(i) *If $\liminf_{R\to\infty} c_{R,\varepsilon} R^{-(s-1)/2} = 0$, then $\omega_0\delta = 0$.*
(ii) *If $\liminf_{R\to\infty} c_{R,\varepsilon} R^{-(s-1)/2} < \infty$, then $\omega_0\delta \neq 0$ is only possible if the spectrum of the translations coincides with the forward light cone $V_+$ and the boundary $\partial V_+/\{0\}$ has non-trivial spectral measure (i.e., there are massless particles in the theory).*
(iii) *If $c_{R,\varepsilon}$ is polynomially bounded in $R$, then $\omega_0\delta \neq 0$ is only possible if the spectrum of translations coincides with $V_+$ but there are not necessarily any massless particles.*

## Symmetries of the *S*-matrix

Scattering theory not only allows one to construct the multiparticle scattering states but also shows that internal symmetries and spacetime symmetries continue to act on these states and are therefore symmetries of the *S*-matrix. We can, however, ask what are all the symmetries of the *S*-matrix. An answer was provided by Coleman and Mandula, who showed that, when there is nontrivial scattering, there are no further symmetries of the *S*-matrix.

## Appendix

In an effort to make this article more self-contained, this appendix collects together a few simple pertinent concepts and results from the theory of operator algebras. A C*-algebra is a $*$-algebra $\mathcal{A}$ with a norm $\|\cdot\|$ making it into a Banach algebra and satisfying

$$\|A^*A\| = \|A\|^2$$

for every $A \in \mathcal{A}$. Any C*-algebra can be realized as a norm closed $*$-subalgebra of the C*-algebra $\mathcal{B}(\mathcal{H})$ of all bounded operators on a Hilbert space $\mathcal{H}$. A von Neumann algebra $\mathcal{R}$ is a C*-algebra that is the dual space of a Banach space. This Banach space $\mathcal{R}_*$, the predual of $\mathcal{R}$, is intrinsically defined. The topology on $\mathcal{R}$ determined by duality with $\mathcal{R}_*$ is called the $\sigma$-topology. $\mathcal{B}(\mathcal{H})$ is a von Neumann algebra and its predual is the set of trace class operators. Any von Neumann algebra can be realized as a $\sigma$-closed unital $*$-subalgebra of some $\mathcal{B}(\mathcal{H})$.

A state on a C*-algebra $\mathcal{A}$ is a positive linear functional $\omega$ of norm 1. If $\mathcal{A}$ has a unit $I$ the normalization condition can be expressed as $\omega(I) = 1$. Of fundamental importance is the relation between representations and states. A representation of $\mathcal{A}$ on a Hilbert space $\mathcal{H}$ is just a structure-preserving mapping or morphism of $\mathcal{A}$ into $\mathcal{B}(\mathcal{H})$. For simplicity, we suppose that $\mathcal{A}$ has a unit. Given a state $\omega$, there is an associated representation $\pi_\omega$ defined by a vector $\Omega$ such that $\pi_\omega(\mathcal{A})\Omega$ is dense in the Hilbert space in question, that is, it is a cyclic vector for the representation and

$$\omega(A) = (\Omega, \pi_\omega(A)\Omega), \quad A \in \mathcal{A}$$

that is, the cyclic vector implements the given state. This is referred to as the GNS construction. Given any two such representations, there is a unique unitary operator mapping the one cyclic vector onto the other and realizing the equivalence of the representations.

A state of a von Neumann algebra is said to be normal if it is continuous in the $\sigma$-topology. If $\omega$ is normal, then $\pi_\omega(\mathcal{R})$ is $\sigma$-closed.

An inclusion of unital von Neumann algebras has the split property if there is an intermediate type I factor, that is, if it has the form $\mathcal{R}_1 \subset \mathcal{B}(\mathcal{H}) \subset \mathcal{R}_2$.

The following elementary observation is often used in treating symmetries. If $\alpha$ is an automorphism of $\mathcal{A}$ with $\omega\alpha^{-1} = \omega$, there is a unique unitary operator leaving the cyclic vector $\Omega$ invariant and inducing $\alpha$ in the representation $\pi_\omega$. In other words, $U\Omega = \Omega$ and

$$U\pi_\omega(A)U^{-1} = \pi_\omega(\alpha A)$$

If we apply the above lemma to a group $G$ of symmetries leaving a state invariant, it yields a group $U(g)$ of unitaries satisfying the condition

$$U(gh) = U(g)U(h), \quad g, h \in G$$

since $U(g)$ is uniquely defined by the above conditions.

When there is no invariant state, the situation is more complicated. Suppose there is a group $G$ of symmetries and a representation $\pi$ of $\mathfrak{A}$ where each $g$ is unitarily implemented. Thus, there is a unitary $U(g)$ with

$$U(g)\pi(A)U(g)^{-1} = \pi(gA), \quad A \in \mathfrak{A}$$

All we can now conclude is that

$$U(gh) = Z(g, h)U(g)U(h)$$

where $Z(g, h)$ is a unitary in $\mathfrak{A}'$, the commutant of $\mathfrak{A}$, satisfying the 2–cocycle identity

$$Z(gh, k)Z(g, h) = Z(g, hk)^g Z(h, k)$$

where ${}^g X = U(g)XU(g)^{-1}$. $U$ is said to be a representation up to a factor. It can be chosen to be a representation if the cocycle $Z$ is a coboundary, that is, if there is a unitary $Y(g)$ in $\mathfrak{A}'$ such that

$$Y(g)^g Y(h) = Y(gh)Z(g, h)$$

In general, little is known about solving problems of this kind, but there are a number of results when $\pi$ is irreducible and the unitary group of its commutant reduces to the circle.

We turn now to consider the modular theory of von Neumann algebras. A vector $\Omega$ is said to be separating for a von Neumann algebra $\mathcal{R}$ if $A\Omega = 0$ and $A \in \mathcal{R}$ implies $A = 0$. If $\Omega$ is both cyclic and separating, there is a uniquely determined closed antilinear involution $S$ with $SA\Omega = A^*\Omega$ for $A \in \mathcal{R}$. If $S = J\Delta^{1/2}$ is the polar decomposition of $S$, then the unitary operators $\Delta^{it}$ induce automorphisms $\delta^{it}$ of $\mathcal{R}$ and $J\mathcal{R}J = \mathcal{R}'$. $J$ is called the modular conjugation, $\Delta$ the modular operator, and $\delta^{it}$ the modular automorphisms. The closure of $\{\Delta^{1/4}A\Omega : A \in \mathcal{R}, A \geq 0\}$ is a cone, called the natural cone. Every normal state of $\mathcal{R}$ is implemented by a unique vector in the natural cone. If $\alpha$ is an automorphism of $\mathcal{R}$, there is therefore a unique vector $\Omega_\alpha$ in the natural cone such that, for every $A \in \mathcal{R}$,

$$(\Omega, \alpha^{-1}(A)\Omega) = (\Omega_\alpha, A\Omega_\alpha)$$

There is now a canonical unitary operator $V_\alpha$ defined by

$$V_\alpha A\Omega = \alpha(A)\Omega_\alpha$$

$V_\alpha$ maps the natural cone into itself and $\alpha \mapsto V_\alpha$ is an implementing representation of the group of automorphisms of $\mathcal{R}$. Under these circumstances, we do not have to deal with representations up to a factor.

# Symmetry and Symmetry Breaking in Dynamical Systems

**I Melbourne**, University of Surrey, Guildford, UK

## Introduction

The same symmetries may underlie diverse contexts such as phase transitions of crystals (Landau theory), fluid dynamics, and problems in biology and chemical engineering. Hence, seemingly unrelated systems may exhibit similar phenomena in regard to symmetries of patterns and transitions between patterns (spontaneous symmetry breaking). It is natural to focus attention on aspects of pattern formation that are universal or model independent – aspects depending on underlying symmetries rather than model-specific details.

The general framework is that the underlying system is governed by an evolution equation

$$\dot{x} = f(x) \qquad [1]$$

with symmetry group $\Gamma$. To avoid technicalities, we assume that [1] is an ordinary differential equation (ODE), the vector field $f:\mathbb{R}^n \to \mathbb{R}^n$ is as smooth as desired, and $\Gamma$ is a compact Lie group acting linearly on $\mathbb{R}^n$. An inner product may be chosen so that $\Gamma$ acts orthogonally. The vector field in [1] is $\Gamma$-equivariant if

$$f(\gamma x) = \gamma f(x) \quad \text{for all } x \in \mathbb{R}^n,\ \gamma \in \Gamma \qquad [2]$$

Equivalently, if $x(t)$ is a solution and $\gamma \in \Gamma$, then $\gamma x(t)$ is a solution.

In this article, we are interested in the dynamics to be expected for equivariant vector fields, and transitions that arise as parameters are varied. The symmetry group $\Gamma$ is taken as given, whereas $f$ is a general $\Gamma$-equivariant vector field. (Other features such as energy conservation or time reversibility must be built into the general setup, but are excluded in this article.)

## Isotropy Subgroups and Commuting Linear Maps

Let $\Gamma$ be a compact Lie group acting linearly on $\mathbb{R}^n$. The isotropy subgroup of $x \in \mathbb{R}^n$ is defined to be

$$\Sigma_x = \{\gamma \in \Gamma:\ \gamma x = x\}$$

Note that $\Sigma_{\gamma x} = \gamma \Sigma_x \gamma^{-1}$ for all $x \in \mathbb{R}^n$, $\gamma \in \Gamma$.

Given an isotropy subgroup $\Sigma \subset \Gamma$, define the fixed-point subspace

$$\mathrm{Fix}\,\Sigma = \{y \in \mathbb{R}^n\colon \sigma y = y \text{ for all } \sigma \in \Sigma\}$$

If $f:\mathbb{R}^n \to \mathbb{R}^n$ is a $\Gamma$-equivariant vector field, then $f(\mathrm{Fix}\,\Sigma) \subset \mathrm{Fix}\,\Sigma$ for each isotropy subgroup $\Sigma$. Hence $\mathrm{Fix}\,\Sigma$ is flow invariant.

The normalizer $N(\Sigma) = \{\gamma \in \Gamma : \gamma\Sigma\gamma^{-1} = \Sigma\}$ is the largest subgroup of $\Gamma$ that acts on $\mathrm{Fix}\,\Sigma$, and $f_\Sigma = f|_{\mathrm{Fix}\Sigma}$ is $(N(\Sigma)/\Sigma)$-equivariant.

An isotropy subgroup $\Sigma$ is axial if $\dim \mathrm{Fix}\,\Sigma = 1$, and then $N(\Sigma)/\Sigma \cong \mathbb{Z}_2$ or $\mathbf{1}$. More generally, $\Sigma$ is maximal if there are no isotropy subgroups $T$ with $\Sigma \subset T \subset \Gamma$ other than $T = \Sigma$ and $T = \Gamma$. Then $N(\Sigma)/\Sigma$ acts fixed-point freely on $\mathrm{Fix}\,\Sigma$ and the connected component of the identity $(N(\Sigma/\Sigma)^0 \cong \mathbf{1}$, SO(2) or SU(2). Correspondingly $\Sigma$ is called real, complex, or quaternionic. In the complex case $\dim \mathrm{Fix}\,\Sigma$ is even; in the quaternionic case $\dim \mathrm{Fix}\,\Sigma \equiv 0 \bmod 4$.

The dihedral group $\Gamma = \mathbb{D}_m$ of order $m$ is the symmetry group of the regular $m$-gon, $m \geq 3$. Its standard action on $\mathbb{R}^2$ is generated by

$$\rho = \begin{pmatrix} \cos 2\pi/m & -\sin 2\pi/m \\ \sin 2\pi/m & \cos 2\pi/m \end{pmatrix}$$

$$\kappa = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$$

For $m$ even, the isotropy subgroups up to conjugacy are

$$\mathbb{D}_m, \quad \mathbb{Z}_2(\kappa), \quad \mathbb{Z}_2(\rho\kappa), \quad \mathbf{1}$$

where $\mathbb{Z}_j(g)$ denotes the cyclic group of order $j$ generated by $g$. The maximal isotropy subgroups $\Sigma = \mathbb{Z}_2(\kappa), \mathbb{Z}_2(\kappa\rho)$ are axial with $N(\Sigma)/\Sigma \cong \mathbb{Z}_2$. For $m$ odd, $\mathbb{Z}_2(\rho\kappa)$ is conjugate to $\mathbb{Z}_2(\kappa)$ leaving three conjugacy classes of isotropy subgroups, and $\Sigma = \mathbb{Z}_2(\kappa)$ is axial with $N(\Sigma)/\Sigma = \mathbf{1}$.

The space of commuting linear maps

$$\mathrm{Hom}_\Gamma(\mathbb{R}^n) = \{L : \mathbb{R}^n \to \mathbb{R}^n \text{ linear: } L\gamma = \gamma L \text{ for all } \gamma \in \Gamma\}$$

is completely described representation-theoretically. Recall that $\Gamma$ acts irreducibly on $\mathbb{R}^n$ if the only $\Gamma$-invariant subspaces of $\mathbb{R}^n$ are $\mathbb{R}^n$ and $\{0\}$. Then $\mathrm{Hom}_\Gamma(\mathbb{R}^n)$ is a real division ring (skew field) $\mathcal{D} \cong \mathbb{R}$, $\mathbb{C}$ or $\mathbb{H}$. The representation is called absolutely irreducible when $\mathcal{D} = \mathbb{R}$ and nonabsolutely irreducible when $\mathcal{D} = \mathbb{C}$ or $\mathbb{H}$.

If the action of $\Gamma$ is not irreducible, write $\mathbb{R}^n = V_1 \oplus \cdots \oplus V_k$ (nonuniquely) as a sum of irreducible subspaces. Summing together irreducible subspaces that are isomorphic to form isotypic components $W$ gives the (unique) isotypic decomposition $\mathbb{R}^n = W_1 \oplus \cdots \oplus W_\ell$. If $L \in \mathrm{Hom}_\Gamma(\mathbb{R}^n)$, then $L(W_j) \subset W_j$ for each $j$, hence $\mathrm{Hom}_\Gamma(\mathbb{R}^n) = \mathrm{Hom}_\Gamma(W_1) \oplus \cdots \oplus \mathrm{Hom}_\Gamma(W_\ell)$. Each $W_j$ consists of $k_j$ isomorphic copies of an irreducible representation with division ring $\mathcal{D}_j$. Let $M_k(\mathcal{D})$ denote the space of $k \times k$ matrices with entries in $\mathcal{D}$. Then

$$\mathrm{Hom}_\Gamma(\mathbb{R}^n) \cong M_{k_1}(\mathcal{D}_1) \oplus \cdots \oplus M_{k_\ell}(\mathcal{D}_\ell) \qquad [3]$$

Spectral properties of commuting linear maps can be recovered from the decomposition [3], paying due attention to multiplicity and complex conjugates of eigenvalues.

## Equivariant Dynamics

The dynamics of equivariant systems includes (relative) equilibria and periodic solutions, robust heteroclinic cycles/networks, and symmetric chaotic attractors.

### Equilibria

Consider the ODE [1] with $\Gamma$-equivariant vector field $f$ satisfying [2]. If $x(t) \equiv x_0$ is an equilibrium, $f(x_0) = 0$, then there is a group orbit $\Gamma x_0$ of equilibria.

Let $\Sigma = \Sigma_{x_0}$ be the isotropy subgroup of $x_0$. If $\dim \Sigma = \dim \Gamma$, then generically (for an open dense set of $\Gamma$-equivariant vector fields), the eigenvalues of $(df)_{x_0}$ have nonzero real part, hence $x_0$ is hyperbolic. If the eigenvalues all have negative real part, then $x_0$ is asymptotically stable. If at least one eigenvalue has positive real part, then $x_0$ is unstable. Hyperbolic equilibria are isolated and persist under perturbations of $f$; the perturbed equilibria continue to have isotropy $\Sigma$. Since $(df)_{x_0} \in \mathrm{Hom}_\Sigma(\mathbb{R}^n)$, decomposition [3] for the action of $\Sigma$ on $\mathbb{R}^n$ facilitates stability computations for $x_0$.

If $\dim \Sigma < \dim \Gamma$, then $\Gamma x_0$ is a continuous group orbit of equilibria. Generically, $\dim \ker (df)_{x_0} = \dim \Gamma - \dim \Sigma$ and $\ker (df)_0 = \{\xi x_0 : \xi \in L\Gamma\}$, where $L\Gamma$ is the Lie algebra of $\Gamma$. The remaining $k = n - \dim \Gamma + \dim \Sigma$ eigenvalues generically have nonzero real part so $\Gamma x_0$ is normally hyperbolic. If all $k$ eigenvalues have nonzero real part, then $\Gamma x_0$ is asymptotically stable. If at least one has positive real part, then $\Gamma x_0$ is unstable. When $N(\Sigma)/\Sigma$ is finite, generically $x_0$ is an isolated equilibrium in $\mathrm{Fix}\, \Sigma$ and persists as an equilibrium with isotropy $\Sigma$ under perturbation.

### Relative Equilibria and Skew Products

A point $x_0 \in \mathbb{R}^n$ (or the corresponding group orbit $\Gamma x_0$) is a relative equilibrium if $f(x_0) \in T_{x_0}\Gamma x_0 = L\Gamma x_0$. If $x_0$ has isotropy $\Sigma$, then $x_0$ is a relative equilibrium if $f(x_0) \in LD_\Sigma x_0$, where $D_\Sigma = (N(\Sigma)/\Sigma)^0$.

Write $f(x_0) = \xi x_0$, where $\xi \in LD_\Sigma$. The closure of the one-parameter subgroup $\exp(t\xi)$ is a maximal torus in $D_\Sigma$ for almost every $\xi$. All maximal tori are conjugate with common dimension $d = \mathrm{rank}\, D_\Sigma$. The solution $x(t) = \exp(t\xi)x_0$ is typically a $d$-dimensional quasiperiodic motion. "Typically" holds in both the topological and probabilistic sense and there is no phase-locking. When $d = 1$, $x(t)$ is periodic, often called a rotating wave.

Choose a $\Sigma$-invariant local cross section $X$ to the group orbit $\Gamma x_0$ at $x_0$. There is a $\Gamma$-invariant neighborhood of $\Gamma x_0$ that is $\Gamma$-equivariantly diffeomorphic to $(\Gamma \times X)/\Sigma$, where $\Sigma$ acts freely on $\Gamma \times X$ by

$$\sigma \cdot (\gamma, x) = (\gamma\sigma^{-1}, \sigma x)$$

and $\Gamma$ acts by left multiplication on the first factor. The $\Gamma$-equivariant ODE on $(\Gamma \times X)/\Sigma$ lifts to a $(\Gamma \times \Sigma)$-equivariant skew product on $\Gamma \times X$

$$\dot{\gamma} = \gamma\xi(x), \qquad \dot{x} = h(x) \qquad [4]$$

where $\xi : X \to L\Gamma$, $h : X \to X$ satisfy the $\Sigma$-equivariance conditions

$$\xi(\sigma x) = \mathrm{Ad}_\sigma \xi(x) = \sigma\xi(x)\sigma^{-1}$$
$$h(\sigma x) = \sigma h(x)$$

and $h(x_0) = 0$.

Thus, dynamics near the relative equilibrium $\Gamma x_0 \subset \mathbb{R}^n$ reduces to dynamics near the ordinary equilibrium $x_0 \in X$ for the $\Sigma$-equivariant vector $h : X \to X$, coupled with $\Gamma$ drifts. In particular, the stability of $\Gamma x_0$ is determined by $(dh)_{x_0}$.

### Periodic Solutions

A nonequilibrium solution $x(t)$ is periodic if $x(t + T) = x(t)$ for some $T > 0$. The least such $T$ is the (absolute) period. The spatial symmetry group $\Delta$ is the isotropy subgroup of $x(t)$ for some, and hence all, $t \in \mathbb{R}$. The periodic solution $P = \{x(t): 0 \le t < T\}$ lies inside $\mathrm{Fix}\, \Delta$. Define the spatiotemporal symmetry group $\Sigma = \{\gamma \in \Gamma : \gamma P = P\}$. Note that $\Delta$ is a normal subgroup of $\Sigma$ and either $\Sigma/\Delta \cong S^1$ ($P$ is a rotating wave) or $\Sigma/\Delta \cong \mathbb{Z}_q$ and $P$ is called a standing wave or a discrete rotating wave. For each $\sigma \in \Sigma$, there exists $T_\sigma \in [0, T)$ such that $\sigma x(t) = x(t + T_\sigma)$. The relative period of $x(t)$ is the least $T > 0$ such that $x(T) \in \Sigma x_0$.

If $\dim \Sigma = \dim \Gamma$, then generically $P$ is hyperbolic, hence isolated, the stability of $P$ is determined by its

Floquet exponents, and $P$ persists under perturbation as a periodic solution with spatial symmetry $\Delta$ and spatiotemporal symmetry $\Sigma$. For $\Gamma$ infinite and $N(\Delta)/\Delta$ finite, generically $P$ is isolated in $\mathrm{Fix}\,\Delta$ and the neutral Floquet exponent has multiplicity $\dim\Gamma - \dim\Sigma + 1$.

### Relative Periodic Solutions

A solution $x(t)$ is a relative periodic solution if it is not a relative equilibrium and $x(T) \in \Gamma x(0)$ for some $T > 0$. The least such $T$ is the relative period. The spatial symmetry group $\Delta = \Sigma_{x(t)}$ for some, hence all, $t$. The spatiotemporal symmetry group $\Sigma$ is the closed subgroup of $\Gamma$ generated by $\Delta$ and $\sigma$, where $x(T) = \sigma x(0)$, and generically $\Sigma/\Delta \cong \mathbb{T}^d \times \mathbb{Z}_q$ is a maximal topologically cyclic (Cartan) subgroup of $N(\Delta)/\Delta$ containing $\sigma\Delta$. Then $x(t)$ is a $(d+1)$-dimensional quasiperiodic motion.

The dynamics near the relative periodic solution is again governed by a skew product. There exists $n \geq 1$ such that $\sigma^n = \exp(n\xi)$, where $\xi \in LZ(\Sigma)$ and $Z(\Sigma) \subset \Gamma$ is the centralizer of $\Sigma$. Define $\alpha = \exp(-\xi)\sigma$. Form a semidirect product $\Delta \rtimes \mathbb{Z}_{2n}$ by adjoining to $\Delta$ an element $Q$ of order $2n$ such that $Q\delta Q^{-1} = \sigma\delta\sigma^{-1}$ for $\delta \in \Delta$.

In a comoving frame with velocity $\xi$, a neighborhood of the relative periodic orbit is $\Gamma$-equivariantly diffeomorphic to $(\Gamma \times X \times S^1)/\Delta \rtimes \mathbb{Z}_{2n}$, where $X$ is a $\Delta \rtimes \mathbb{Z}_{2n}$-invariant cross section, $S^1 = \mathbb{R}/2n\mathbb{Z}$ and $\Delta \rtimes \mathbb{Z}_{2n}$ acts on $\Gamma \times X \times S^1$ as

$$\delta \cdot (\gamma, x, \theta) = (\gamma\delta^{-1}, \delta x, \theta)$$
$$Q \cdot (\gamma, x, \theta) = (\gamma\alpha^{-1}, Qx, \theta + 1)$$

The $\Gamma$-equivariant ODE on $(\Gamma \times X \times S^1)/\Delta \rtimes \mathbb{Z}_{2n}$ lifts to a $\Gamma \times (\Delta \rtimes \mathbb{Z}_{2n})$-equivariant skew product

$$\dot{\gamma} = \gamma\xi(x, \theta), \quad \dot{x} = h(x, \theta), \quad \dot{\theta} = 1 \qquad [5]$$

where $\xi : X \times S^1 \to L\Gamma$, $h : X \times S^1 \to X$ satisfy appropriate $\Delta \rtimes \mathbb{Z}_{2n}$-equivariance conditions.

### Robust Heteroclinic Cycles

Heteroclinic cycles, degenerate in systems without symmetry, arise robustly in equivariant systems. Let $x_1, \ldots, x_m \in \mathbb{R}^n$ be saddles with $W^{\mathrm{u}}(x_i) - \{x_i\} \subset \Gamma W^{\mathrm{s}}(x_{i+1})$ (where $m + 1 = 1$). If $\Sigma_1, \ldots, \Sigma_m \subset \Gamma$ are isotropy subgroups, $W^{\mathrm{u}}(x_i) \subset \mathrm{Fix}\,\Sigma_i$, and $x_{i+1}$ is a sink in $\mathrm{Fix}\,\Sigma_i$, then saddle–sink connections from $x_i$ to $x_{i+1}$ persist for nearby $\Gamma$-equivariant flows. The union $\bigcup_{i=1}^{m} \Gamma W^{\mathrm{u}}(x_i)$ forms a robust heteroclinic cycle (see the subsection "Dynamics" for an example). Such cycles, when asymptotically stable, are a mechanism for intermittency or bursting, notably in rotating Rayleigh–Bénard convection (where rolls disappear and reorient themselves at approximately 60°), and provide a possible intrinsic explanation for irregular reversals of the Earth's magnetic field.

Asymmetric perturbations (deterministic or noisy) destroy the cycles, but the perturbed attractors inherit the bursting behavior.

Establishing the existence of heteroclinic connections is often straightforward when $\dim \mathrm{Fix}\,\Sigma_i = 2$ and nontrivial with $\dim \mathrm{Fix}\,\Sigma_i \geq 3$. Criteria for asymptotic stability of heteroclinic cycles are given in terms of real parts of eigenvalues of $(df)_{x_i}$, and depend on the geometry of the representation of $\Gamma$.

Robust cycles exist also between more complicated dynamical states such as periodic solutions or chaotic sets (cycling chaos). When $W^u(x_i)$ connects to two or more distinct states, the collection of unstable manifolds forms a heteroclinic network leading to competition between various subnetworks.

### Symmetric Attractors

Suppose that $\Gamma$ is a finite group acting linearly on $\mathbb{R}^n$. A closed subset $A \subset \mathbb{R}^n$ has symmetry groups $\Delta = \{\gamma \in \Gamma\colon \gamma x = x \text{ for all } x \in A\}, \Sigma = \{\gamma \in \Gamma\colon \gamma A = A\}$. Here, $\Delta$ is an isotropy subgroup and $\Delta \subset \Sigma \subset N(\Delta)$. In applications, $\Delta$ corresponds to instantaneous symmetry and $\Sigma$ to symmetry on average.

If $A$ is an attractor (a Lyapunov stable $\omega$-limit set) for a $\Gamma$-equivariant vector field $f : \mathbb{R}^n \to \mathbb{R}^n$, then $\Sigma$ fixes a connected component of $\mathrm{Fix}\,\Delta - L$, where $L$ is the union of proper fixed-point spaces in $\mathrm{Fix}\,\Delta$.

Provided $\dim \mathrm{Fix}\,\Delta \geq 3$, all pairs $\Delta, \Sigma$ satisfying the above restrictions arise as symmetry groups of a nonperiodic attractor $A$. If $\dim \mathrm{Fix}\,\Delta \geq 5$, then $A$ is realized by a uniformly hyperbolic (Axiom A) attractor.

If $\dim \mathrm{Fix}\,\Delta \geq 3$ and $\Sigma$ fixes a connected component of $\mathrm{Fix}\,\Delta - L$, then $A$ is realized by a periodic sink provided $\Sigma/\Delta$ is cyclic. If $\dim \mathrm{Fix}\,\Delta = 2$, then in addition either $\Sigma = \Delta$ or $\Sigma = N(\Delta)$.

Suppose $A$ is an attractor and $\gamma \in \Gamma - \Sigma$. Then $\gamma A \cap A = \emptyset$. Varying a parameter, $A$ may undergo a symmetry-increasing bifurcation: $A$ grows until it collides with $\gamma A$ producing a larger attractor with symmetry on average generated by $\Sigma$ and $\gamma$.

Determining symmetries of an attractor by inspection is often infeasible. A detective is a $\Gamma$-equivariant polynomial $\phi : \mathbb{R}^n \to V$ where every subgroup of $\Gamma$ is an isotropy subgroup for the action on $V$, and each component of $\phi$ is nonzero. Suppose that $A \subset \mathbb{R}^n$ is an attractor with physical (Sinai–Ruelle–Bowen) measure $\mu$. By ergodicity, the time average

$$\psi_A = \lim_{T \to \infty} \frac{1}{T} \int_0^T \phi(x(t))\mathrm{d}t \in V$$

is well defined for almost every trajectory $x(t)$ in $\operatorname{supp}\mu$. Generically, $\Sigma_{\psi_A} = \Sigma_A$ so computing the symmetry of $A$ reduces to computing the symmetry of a point.

If $\Gamma$ is an infinite compact Lie group, and $A$ is an $\omega$-limit set containing points of trivial isotropy, then $A$ cannot be uniformly hyperbolic. Hence partially hyperbolic flows arise naturally in systems with continuous symmetry. Consider the skew product [4] where $\Sigma = \mathbf{1}$ and $h: X \to X$ possesses a hyperbolic basic set $\Lambda \subset X$ with equilibrium measure $\mu$ (for a Hölder potential). Let $\nu$ denote Haar measure on $\Gamma$. Then $\Lambda \times \Gamma$ is partially hyperbolic, and $\mu \times \nu$ is ergodic (even Bernoulli) for an open dense set of equivariant flows. Such stably ergodic flows possess strong statistical properties (rapid decay of correlations, central-limit theorem); a possible explanation for hypermeander (Brownian-like motion) of spiral waves in planar excitable media.

### Forced Symmetry Breaking

In applications, symmetry is not perfect and account should be taken of $\Gamma'$-equivariant perturbations of [1] for $\Gamma'$ a subgroup of $\Gamma$ (including $\Gamma' = \mathbf{1}$). This topic is not discussed in this article, except in the subsections "Robust heteroclinic cycles" and "Branching patterns and finite determinacy."

## Equivariant Bifurcation Theory

Consider families of ODEs $\dot{x} = f(x, \lambda)$, with bifurcation parameter $\lambda \in \mathbb{R}$ and vector field $f: \mathbb{R}^n \times \mathbb{R} \to \mathbb{R}^n$ satisfying $f(0, 0) = 0$ and the $\Gamma$-equivariance condition

$$f(\gamma x, \lambda) = \gamma f(x, \lambda) \quad \text{for all } x \in \mathbb{R}^n, \ \lambda \in \mathbb{R}, \ \gamma \in \Gamma$$

A local bifurcation from the equilibrium $x = 0$ occurs if $(df)_{0,0}$ is nonhyperbolic. The center subspace $E^c$ is the sum of generalized eigenspaces corresponding to eigenvalues on the imaginary axis, and is $\Gamma$-invariant. By center manifold theory, local dynamics ($(x, \lambda)$ near $(0, 0)$) are captured by the center manifold $W^c$. After center manifold reduction (or Lyapunov–Schmidt reduction if the focus is on equilibria), it may be assumed that $\mathbb{R}^n = E^c$.

If $(df)_{0,0}$ possesses zero eigenvalues, then there is a steady-state bifurcation. Generically, $(df)_{0,0} = 0$ and $E^c$ is absolutely irreducible. There are two subcases.

If $\Gamma$ acts trivially on $\mathbb{R}^n$, then $n = 1$ and generically there is a saddle–node (or limit point) bifurcation where the zero sets of $f(x, \lambda)$ and $\pm x^2 \pm \lambda$ are diffeomorphic for $(x, \lambda)$ near $(0, 0)$. Higher-order degeneracies can be treated using singularity theory. The equilibria and their stability determines the local dynamics. All bifurcating equilibria have isotropy $\Gamma$, so there is no symmetry breaking.

From now on, consider the remaining subcase where $\Gamma$ acts absolutely irreducibly and nontrivially on $\mathbb{R}^n$. Then $\operatorname{Fix}\Gamma = \{0\}$, $f(0, \lambda) \equiv 0$, and $(df)_{0,\lambda} = c(\lambda) I_n$ where generically $c'(0) \neq 0$. Assume that $c'(0) > 0$, so the "trivial solution" $x = 0$ is asymptotically stable subcritically ($\lambda < 0$) and unstable supercritically ($\lambda > 0$). Bifurcating solutions lie outside $\operatorname{Fix}\Gamma$ and hence there is spontaneous symmetry breaking.

### Axial Isotropy Subgroups

The "equivariant branching lemma" guarantees branches of equilibria with isotropy $\Sigma$ for each axial isotropy subgroup. There are three associated branching patterns, see Figure 1.

If $N(\Sigma)/\Sigma = \mathbb{Z}_2$, then $f_\Sigma$ is odd. Generically, $\partial_x^3 f_\Sigma(0, 0) \neq 0$, since $(x_1^2 + \cdots + x_n^2)x$ is $\Gamma$-equivariant, and there are two branches of equilibria bifurcating supercritically or subcritically together, and lying on the same group orbit. The branches form a symmetric pitchfork whose direction of branching is determined by $\operatorname{sgn} \partial_x^3 f_\Sigma(0, 0)$.

If $N(\Sigma)/\Sigma \cong \mathbf{1}$, then generically $f_\Sigma$ is even. If all quadratic $\Gamma$-equivariant maps vanish on $\operatorname{Fix}\Sigma$, then the bifurcation is sub/supercritical depending on $\operatorname{sgn} \partial_x^3 f_\Sigma(0, 0)$ but the branches lie on distinct group orbits. This is an asymmetric pitchfork.

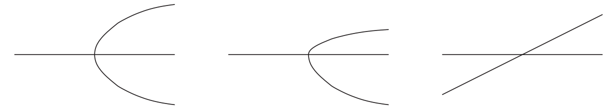
If $\partial_x^2 f_\Sigma(0, 0) \neq 0$, then the equilibria exist transcritically: for $\lambda < 0$ and $\lambda > 0$.

The natural actions of $\mathbb{D}_m$ on $\mathbb{R}^2$ are absolutely irreducible. The axial branches are symmetric pitchforks for $m \geq 4$ even, asymmetric pitchforks for $m \geq 5$ odd, and transcritical for $m = 3$.

The actions of $\mathbb{D}_m, m \geq 5$ odd, provide the simplest instances of hidden symmetries, where certain $N(\Sigma)/\Sigma$-equivariant mappings on $\operatorname{Fix}\Sigma$ do not extend to smooth $\Gamma$-equivariant mappings on $\mathbb{R}^n$.

### Nonaxial Maximal Isotropy Subgroups

For $\Sigma$ a real maximal isotropy subgroup, $\dim \operatorname{Fix}\Sigma$ odd, there exist branches of equilibria with isotropy



(a) (b) (c)

**Figure 1** Axial branches: (a) supercritical symmetric pitchfork, (b) supercritical asymmetric pitchfork, and (c) transcritical branches.

$\Sigma$. When $\dim \mathrm{Fix}\,\Sigma$ is even, there are examples where equilibria exist and examples where no equilibria exist. For $\Sigma$ complex or quaternionic, there exist branches of rotating waves with isotropy $\Sigma$. In the quaternionic case, the rotating waves foliate the SU(2) group orbits according to the Hopf fibration.

### Submaximal Isotropy Subgroups

It has been conjectured falsely that steady-state bifurcation leads generically to equilibria only with maximal isotropy. The simplest counterexample is the 24-element group $\Gamma = \mathbb{Z}_3\mathbb{Z}_2^3$ generated by

$$\rho = \begin{pmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{pmatrix}, \quad \kappa = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -1 \end{pmatrix}$$

(Alternatively, $\Gamma = \mathrm{T} \oplus \mathbb{Z}_2(-I_3)$, where $\mathrm{T} \subset \mathrm{SO}(3)$ is the tetrahedral group.)

The isotropy subgroup $\Sigma = \mathbb{Z}_2(\kappa)$ has two-dimensional fixed-point subspace $\mathrm{Fix}\,\Sigma = \{(x, y, 0)\}$. The only one-dimensional fixed-point spaces contained in $\mathrm{Fix}\,\Sigma$ are the $x$- and $y$-axes. The general $\Gamma$-equivariant vector field is

$$\begin{aligned} \dot{x} &= g(x^2, y^2, z^2, \lambda)x \\ \dot{y} &= g(y^2, z^2, x^2, \lambda)y \\ \dot{z} &= g(z^2, x^2, y^2, \lambda)z \end{aligned}$$

After scaling,

$$\begin{aligned} &g(x^2, y^2, z^2, \lambda) \\ &\quad = \lambda - x^2 - ay^2 - bz^2 + o(x^2, y^2, z^2, \lambda) \end{aligned} \qquad [6]$$

Restricting to $\mathrm{Fix}\,\Sigma$ and dividing out the axial solutions $x = 0$ and $y = 0$ yields at lowest order the equations $\lambda = x^2 + ay^2 = y^2 + bx^2$. Submaximal solutions exist provided $\mathrm{sgn}(a-1) = \mathrm{sgn}(b-1)$.

In general, the existence of equilibria with submaximal isotropy must be treated on a case-by-case basis (for each absolutely irreducible representation of $\Gamma$ and isotropy subgroup $\Sigma$).

### Asymptotic Stability

Subcritical and axial transcritical branches are automatically unstable. Moreover, the existence of a quadratic $\Gamma$-equivariant mapping $q : \mathbb{R}^n \to \mathbb{R}^n$ and $x \in \mathrm{Fix}\,\Sigma$ such that $(dq)_x$ has eigenvalues with nonzero real part guarantees that branches of equilibria with axial isotropy $\Sigma$ are generically unstable (even when $q|_{\mathrm{Fix}\Sigma} \equiv 0$).

There are no general results for asymptotic stability, and calculations must be done on a case-by-case basis. (The remarks in the subsection “Equilibria” are useful here.)

### Branching Patterns and Finite Determinacy

The following notion of finite determinacy is based on equivariant transversality theory. Assume $\Gamma$ acts absolutely irreducibly. Consider the set $\mathcal{F}$ of $\Gamma$-equivariant vector fields $f : \mathbb{R}^n \times \mathbb{R} \to \mathbb{R}^n$ satisfying $(df)_{0,0} = 0$. For an open dense subset of $\mathcal{F}$, branches of relative equilibria near $(0, 0)$ are normally hyperbolic. The collection of branches of relative equilibria, together with their isotropy type, direction of branching, and stability properties, is called a branching pattern. These persist under small perturbations and are finitely determined: there exist $q = q_\Gamma \geq 2$ and an open dense subset $\mathcal{U}(q) \subset \mathcal{F}$ such that the branching patterns of $f$ and $f + g$ are identical for $f \in \mathcal{U}(q)$, $g \in \mathcal{F}$, provided $g(x, \lambda) = o(\|x\|^q)$.

Furthermore, branching patterns are strongly finitely determined: there exist $d \geq 2$ and an open dense subset $\mathcal{S}(d) \subset \mathcal{F}$ such that the branching patterns of $f$ and $f + g$ are identical for $f \in \mathcal{S}(d)$ and all (not necessarily equivariant) $g$ satisfying $g(x, \lambda) = o(\|x\|^d)$.

For example, consider the hyperoctahedral group $S_n\mathbb{Z}_2^n$, $n \geq 1$. Here $S_n$ acts by permutations of the coordinates $(x_1, \ldots, x_n)$ and $\mathbb{Z}_2^n$ consists of diagonal matrices with entries $\pm 1$. Let $\Gamma = T\,\mathbb{Z}_2^n$, where $T \subset S_n$ is a transitive subgroup. Then $\Gamma$ acts absolutely irreducibly on $\mathbb{R}^n$ and is strongly 3-determined. Submaximal branches of equilibria exist except when $T = S_n$, $T = A_n$ and, if $n = 6$, $T = \mathrm{PGL}_2(\mathbb{F}_5)$.

### Dynamics

Absolutely irreducible representations have arbitrarily high dimension, so steady-state bifurcation leads to rich dynamics. The group $\Gamma = \mathbb{Z}_3\mathbb{Z}_2^3$ with $\mathrm{sgn}(a-1) \neq \mathrm{sgn}(b-1)$ and $a + b > 2$ in [6] yields asymptotically stable heteroclinic cycles with planar connections connecting equilibria in the $x$-, $y$- and $z$-axes (see Figure 2). In $\mathbb{R}^4$, there is the possibility of instant chaos where chaotic dynamics bifurcates directly from the equilibrium 0.

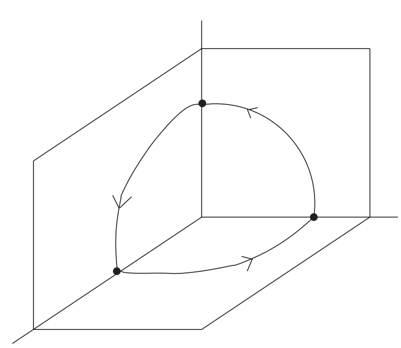


**Figure 2** Robust heteroclinic cycle for the group $\Gamma = \mathbb{Z}_3 \ltimes \mathbb{Z}_2^3$.

In the absence of quadratic equivariants, the invariant-sphere theorem gives an open set of equivariant vector fields for which an attracting normally hyperbolic flow-invariant $(n-1)$-dimensional sphere bifurcates supercritically. This simplifies computations of nontrivial dynamics.

## Hopf Bifurcation and Mode Interactions

### Equivariant Hopf Bifurcation

The setting is the same as in the last section, except that $L=(df)_{0,0}$ has imaginary eigenvalues $\pm i\omega$ of algebraic and geometric multiplicity $n/2$. Generically, $\mathbb{R}^n=E^c$ is Γ-simple: either the direct sum of two isomorphic absolutely irreducible subspaces, or nonabsolutely irreducible.

By Birkhoff normal-form theory (see below), for any $k\geq 1$ there is a Γ-equivariant change of coordinates after which $f(x,\lambda)=f_k(x,\lambda)+o(\|x\|^k)$, where $f_k$ is $(\Gamma\times S^1)$-equivariant. Here $S^1=\overline{\{\exp(tL)\colon t\in\mathbb{R}\}}$ acts freely on $\mathbb{R}^n$ and $\Gamma\times S^1$ acts complex irreducibly ($\mathcal{D}=\mathbb{C}$). Hence, $\dim \mathrm{Fix}\, J$ is even for each isotropy subgroup $J\subset\Gamma\times S^1$, and $N(J)/J\cong S^1$ when $J$ is maximal. The equivariant Hopf theorem guarantees, generically, branches of rotating waves with absolute period approximately $2\pi/\omega$ for each maximal isotropy subgroup $J$.

The notions of finite and strong finite determinacy extend to complex irreducible representations and the rotating waves persist as periodic solutions for the original Γ-equivariant vector field $f$. Define the spatial and spatiotemporal symmetry groups $\Delta\subset\Sigma\subset\Gamma$ as in the subsection "Periodic solutions." Then $J=\{(\sigma,\theta(\sigma))\colon \sigma\in\Sigma\}$ is a twisted subgroup, with $\theta:\Sigma\to S^1$ a homomorphism and $\Delta=J\cap\Gamma=\ker\theta$.

In the non-symmetry-breaking case, where Γ acts trivially on $\mathbb{R}^2$, phase–amplitude reduction leads to $\mathbb{Z}_2$-equivariant amplitude equations on $\mathbb{R}$ and higher-order degeneracies are amenable to $\mathbb{Z}_2$-equivariant singularity theory. Similar comments apply to O(2)-equivariant Hopf bifurcation where the amplitude equations are $\mathbb{D}_4$-equivariant. The technique fails for general groups Γ.

### Mode Interactions and Birkhoff Normal Form

Steady-state and Hopf bifurcations are codimension 1 and occur generically in one-parameter families of Γ-equivariant vector fields. Multiparameter families may undergo higher-codimension bifurcations called mode interactions. Suppressing parameters, steady-state/steady-state bifurcation occurs when $\mathbb{R}^n=E^c=V_1\oplus V_2$, where $V_1$ and $V_2$ are absolutely irreducible and $L=(df)_0$ has zero eigenvalues. If $V_1$ and $V_2$ are nonisomorphic then $L=0$, otherwise $L$ is nilpotent and there is an equivariant Takens–Bogdanov bifurcation. Similarly, there are codimension-2 steady-state/Hopf and Hopf/Hopf bifurcations.

Write $L=S+N$ (uniquely), where $S$ is semisimple, $N$ is nilpotent, and $SN=NS$. Then $\overline{\{\exp tS\colon t\in\mathbb{R}\}}$ is a torus $\mathbb{T}^p$, where $p\geq 0$ is the number of rationally independent eigenvalues for $L$.

For each $k\geq 1$, there is a Γ-equivariant degree-$k$ polynomial change of coordinates $P:\mathbb{R}^n\to\mathbb{R}^n$ satisfying $P(0)=0, (dP)_0=I$ transforming $f$ to Birkhoff normal form $f_k+o(\|x\|^k)$, where $f_k$ is $(\Gamma\times\mathbb{T}^p)$-equivariant.

If $N\neq 0$, then $\overline{\{\exp tN^T\colon t\in\mathbb{R}\}}\cong\mathbb{R}$ and $f_k$ can be chosen so that the nonlinear terms are $(\Gamma\times\mathbb{T}^p\times\mathbb{R})$-equivariant. The linear terms are not $\mathbb{R}$-equivariant.

The study of mode interactions proceeds by first analyzing $(\Gamma\times\mathbb{T}^p)$-equivariant normal forms, then considering exponentially small effects of the Γ-equivariant tail. Versions of the equivariant branching lemma and equivariant Hopf theorem establish existence of certain solutions. There are numerous examples of robust heteroclinic cycles connecting (relative) equilibria and periodic solutions, symmetric chaos, and symmetry-increasing bifurcations.

## Bifurcations from Relative Equilibria and Periodic Solutions

Using the skew product [4], bifurcations from a relative equilibrium with isotropy Σ for a Γ-equivariant vector field reduce to bifurcations from a fully symmetric equilibrium for a Σ-equivariant vector field $h$ coupled with Γ drifts. If $h$ possesses (relative) equilibria or periodic solutions, then the drift is determined generically as in the subsections "Relative equilibria and skew products" and "Relative periodic solutions." Nevertheless, solving the drift equation can be useful for understanding behavior in physical space. This is facilitated by making equivariant polynomial changes of coordinates $(\gamma Q(x),P(x))$ putting $h$ into Birkhoff normal form and simplifying $\xi$.

Bifurcations from (relative) periodic solutions also reduce, mainly, to bifurcations from equilibria (with enlarged symmetry group). Based on the discussion in the subsection "Relative periodic solutions," it suffices to consider bifurcations from isolated periodic solutions $P=\{x(t)\}$ with spatial symmetry Δ and spatiotemporal symmetry Σ. Write $x(T)=\sigma x(0)$, where $T$ is the relative period and $\sigma$ is chosen so that the automorphism $\delta\mapsto\sigma^{-1}\delta\sigma, \delta\in\Delta$, has finite order $k$. Form the semidirect product $\Delta\rtimes\mathbb{Z}_{2k}$ by adjoining to Δ an element τ of order

$2k$ such that $\tau^{-1}\delta\tau = \sigma^{-1}\delta\sigma$, for $\delta \in \Delta$. Codimension-1 bifurcations from $P$ are in one-to-one correspondence (modulo tail terms) with bifurcations from fully symmetric equilibria for a $(\Delta \rtimes \mathbb{Z}_{2k})$-equivariant vector field. In particular, period-preserving and period-doubling bifurcations from $P$ reduce to steady-state bifurcations, and Naimark–Sacker bifurcations reduce to Hopf bifurcations. This framework incorporates issues such as suppression of period doubling. Similar results hold for higher-codimension bifurcations.

The skew products [4] and [5] are valid for proper actions of certain noncompact Lie groups $\Gamma$ provided the spatial symmetries are compact, leading to explanations of spiral and scroll wave phenomena in excitable media.

When the spatial symmetry group is noncompact, $E^c$ may be infinite-dimensional and center manifold reduction may break down due to continuous-spectrum issues. For Euclidean symmetry, there is a theory of modulation or Ginzburg–Landau equations.

# Symmetry and Symplectic Reduction

**J-P Ortega**, Université de Franche-Comté, Besançon, France

**T S Ratiu**, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

## Introduction

The use of symmetries in the quantitative and qualitative study of dynamical systems has a long history that goes back to the founders of mechanics. In most cases, the symmetries of a system are used to implement a procedure generically known under the name of "reduction" that restricts the study of its dynamics to a system of smaller dimension. This procedure is also used in a purely geometric context to construct new nontrivial manifolds having various additional structures.

Most of the reduction methods can be seen as constructions that systematize the techniques of elimination of variables found in classical mechanics. These procedures consist basically of two steps. First, one restricts the dynamics to flow-invariant submanifolds of the system in question and, second, one projects the restricted dynamics onto the symmetry orbit quotients of the spaces constructed in the first step. Sometimes, the

flow-invariant manifolds appear as the level sets of a momentum map induced by the symmetry of the system.

## Symmetry Reduction

### The Symmetries of a System

The standard mathematical fashion to describe the symmetries of a dynamical system (*see* Dynamical Systems in Mathematical Physics: An Illustration from Water Waves) $X \in \mathfrak{X}(M)$ defined on a manifold $M(\mathfrak{X}(M)$ denotes the Lie algebra of smooth vector fields on $M$ endowed with the Jacobi–Lie bracket $[\cdot,\cdot])$ consists in studying its invariance properties with respect to a smooth Lie group $\Phi : G \times M \to M$ (continuous symmetries) or Lie algebra $\phi : \mathfrak{g} \to \mathfrak{X}(M)$ (infinitesimal symmetry) action. Recall that $\Phi$ is a (left) action if the map $g \in G \mapsto \Phi(g,\cdot) \in \mathrm{Diff}(M)$ is a group homomorphism, where $\mathrm{Diff}(M)$ denotes the group of smooth diffeomorphisms of the manifold $M$. The map $\phi$ is a (left) Lie algebra action if the map $\xi \in \mathfrak{g} \mapsto \phi(\xi) \in \mathfrak{X}(M)$ is a Lie algebra antihomomorphism and the map $(m,\xi) \in M \times \mathfrak{g} \mapsto \phi(\xi)(m) \in TM$ is smooth. The vector field $X$ is said to be $G$-symmetric whenever it is equivariant with respect to the $G$-action $\Phi$, that is, $X \circ \Phi_g = T\Phi_g \circ X$, for any $g \in G$. The space of $G$-symmetric vector fields on $M$ is denoted by $\mathfrak{X}(M)^G$. The flow $F_t$ of a $G$-symmetric vector field $X \in \mathfrak{X}(M)^G$ is $G$-equivariant, that is, $F_t \circ \Phi_g = \Phi_g \circ F_t$, for any $g \in G$. The vector field $X$ is said to be $\mathfrak{g}$-symmetric if $[\phi(\xi), X] = 0$, for any $\xi \in \mathfrak{g}$.

If $\mathfrak{g}$ is the Lie algebra of the Lie group $G$ (*see* Lie Groups: General Theory) then the infinitesimal generators $\xi_M \in \mathfrak{X}(M)$ of a smooth $G$-group action defined by

$$\xi_M(m) := \left.\frac{\mathrm{d}}{\mathrm{d}t}\right|_{t=0} \Phi(\exp t\xi, m), \quad \xi \in \mathfrak{g},\ m \in M$$

constitute a smooth Lie algebra $\mathfrak{g}$-action and we denote in this case $\phi(\xi) = \xi_M$.

If $m \in M$, the closed Lie subgroup $G_m := \{g \in G \mid \Phi(g,m) = m\}$ is called the isotropy or symmetry subgroup of $m$. Similarly, the Lie subalgebra $\mathfrak{g}_m := \{\xi \in \mathfrak{g} \mid \phi(\xi)(m) = 0\}$ is called the isotropy or symmetry subalgebra of $m$. If $\mathfrak{g}$ is the Lie algebra of $G$ and the Lie algebra action is given by the infinitesimal generators, then $\mathfrak{g}_m$ is the Lie algebra of $G_m$. The action is called free if $G_m = \{e\}$ for every $m \in M$ and locally free if $\mathfrak{g}_m = \{0\}$ for every $m \in M$. We will write interchangeably $\Phi(g,m) = \Phi_g(m) = \Phi^m(g) = g \cdot m$, for $m \in M$ and $g \in G$.

In this article we will focus mainly on continuous symmetries induced by proper Lie group actions. The action $\Phi$ is called proper whenever for any two convergent sequences $\{m_n\}_{n\in\mathbb{N}}$ and $\{g_n \cdot m_n := \Phi(g_n, m_n)\}_{n\in\mathbb{N}}$ in $M$, there exists a convergent subsequence $\{g_{n_k}\}_{k\in\mathbb{N}}$ in $G$. Compact group actions are obviously proper.

### Symmetry Reduction of Vector Fields

Let $M$ be a smooth manifold and $G$ a Lie group acting properly on $M$. Let $X \in \mathfrak{X}(M)^G$ and $F_t$ be its (necessarily equivariant) flow. For any isotropy subgroup $H$ of the $G$-action on $M$, the $H$-isotropy type submanifold $M_H := \{m \in M \mid G_m = H\}$ is preserved by the flow $F_t$. This property is known as the law of conservation of isotropy. The properness of the action guarantees that $G_m$ is compact and that the (connected components of) $M_H$ are embedded submanifolds of $M$ for any closed subgroup $H$ of $G$. The manifolds $M_H$ are, in general, not closed in $M$. Moreover, the quotient group $N(H)/H$ (where $N(H)$ denotes the normalizer of $H$ in $G$) acts freely and properly on $M_H$. Hence, if $\pi_H : M_H \to M_H/(N(H)/H)$ denotes the projection onto orbit space and $i_H : M_H \hookrightarrow M$ is the injection, the vector field $X$ induces a unique vector field $X^H$ on the quotient $M_H/(N(H)/H)$ defined by $X^H \circ \pi_H = T\pi_H \circ X \circ i_H$, whose flow $F_t^H$ is given by $F_t^H \circ \pi_H = \pi_H \circ F_t \circ i_H$. We will refer to $X^H \in \mathfrak{X}(M_H/(N(H)/H))$ as the $H$-isotropy type reduced vector field induced by $X$.

This reduction technique has been widely exploited in handling specific dynamical systems. When the symmetry group $G$ is compact and we are dealing with a linear action, the construction of the quotient $M_H/(N(H)/H)$ can be implemented in a very explicit and convenient manner by using the invariant polynomials of the action and the theorems of Hilbert and Schwarz–Mather.

## Symplectic Reduction

Symplectic or Marsden–Weinstein reduction is a procedure that implements symmetry reduction for the symmetric Hamiltonian systems defined on a symplectic manifold $(M,\omega)$. The particular case in which the symplectic manifold is a cotangent bundle is dealt with separately (*see* Cotangent Bundle Reduction). We recall that the Hamiltonian vector field $X_h \in \mathfrak{X}(M)$ associated to the Hamiltonian function $h \in C^\infty(M)$ is uniquely determined by the equality $\omega(X_h,\cdot) = \mathrm{d}h$. In this context, the symmetries $\Phi : G \times M \to M$ of interest are given by symplectic or canonical transformations, that is, $\Phi_g^*\omega = \omega$, for any $g \in G$. For canonical actions each $G$-invariant function $h \in C^\infty(M)^G$ has an associated $G$-symmetric Hamiltonian vector field $X_h$. A Lie

algebra action $\varphi$ is called symplectic or canonical if $\pounds_{\phi(\xi)}\omega = 0$ for all $\xi \in \mathfrak{g}$, where $\pounds$ denotes the Lie derivative operator. If the Lie algebra action is induced from a canonical Lie group action by taking its infinitesimal generators, then it is also canonical.

#### Momentum Maps

The symmetry reduction described in the previous section for general vector fields does not produce a well-adapted answer for symplectic manifolds $(M, \omega)$ in the sense that the reduced spaces $M_H/(N(H)/H)$ are, in general, not symplectic. To solve this problem one has to use the conservation laws associated to the canonical action, which often appear as momentum maps.

Let $G$ be a Lie group acting canonically on the symplectic manifold $(M, \omega)$. Suppose that for any $\xi \in \mathfrak{g}$, the vector field $\xi_M$ is Hamiltonian, with Hamiltonian function $\boldsymbol{J}^\xi \in C^\infty(M)$ and that $\xi \in \mathfrak{g} \mapsto \boldsymbol{J}^\xi \in C^\infty(M)$ is linear. The map $\boldsymbol{J} : M \to \mathfrak{g}^*$ defined by the relation $\langle \boldsymbol{J}(z), \xi \rangle = \boldsymbol{J}^\xi(z)$, for all $\xi \in \mathfrak{g}$ and $z \in M$, is called a momentum map of the $G$-action (*see* Hamiltonian Group Actions). Momentum maps, if they exist, are determined up to a constant in $\mathfrak{g}^*$ for any connected component of $M$.

**Examples 1**

(i) (*Linear momentum*) The phase space of an $N$-particle system is the cotangent space $T^*\mathbb{R}^{3N}$ endowed with its canonical symplectic structure. The additive group $\mathbb{R}^3$, whose Lie algebra is abelian and is also equal to $\mathbb{R}^3$, acts canonically on it by spatial translation on each factor: $\boldsymbol{v} \cdot (\boldsymbol{q}_i, \boldsymbol{p}^i) = (\boldsymbol{q}_i + \boldsymbol{v}, \boldsymbol{p}^i)$, with $i = 1, \ldots, N$. This action has an associated momentum map $\boldsymbol{J} : T^*\mathbb{R}^{3N} \to \mathbb{R}^3$, where we identified the dual of $\mathbb{R}^3$ with itself using the Euclidean inner product, which coincides with the classical linear momentum $\boldsymbol{J}(\boldsymbol{q}_i, \boldsymbol{p}^i) = \sum_{i=1}^N \boldsymbol{p}_i$.

(ii) (*Angular momentum*) Let SO(3) act on $\mathbb{R}^3$ and then, by lift, on $T^*\mathbb{R}^3$, that is, $A \cdot (\boldsymbol{q}, \boldsymbol{p}) = (A\boldsymbol{q}, A\boldsymbol{p})$. This action is canonical and has as associated momentum map $\boldsymbol{J} : T^*\mathbb{R}^3 \to \mathfrak{so}(3)^* \cong \mathbb{R}^3$, the classical angular momentum $\boldsymbol{J}(\boldsymbol{q}, \boldsymbol{p}) = \boldsymbol{q} \times \boldsymbol{p}$.

(iii) (*Lifted actions on cotangent bundles*) The previous two examples are particular cases of the following situation. Let $\Phi : G \times M \to M$ be a smooth Lie group action. The (left) cotangent lifted action of $G$ on $T^*Q$ is given by $g \cdot \alpha_q := T^*_{g \cdot q}\Phi_{g^{-1}}(\alpha_q)$ for $g \in G$ and $\alpha_q \in T^*Q$. Cotangent lifted actions preserve the canonical 1-form on $T^*Q$ and hence are canonical. They admit an associated momentum map $\boldsymbol{J} : T^*Q \to \mathfrak{g}^*$ given by $\langle \boldsymbol{J}(\alpha_q), \xi \rangle = \alpha_q(\xi_Q(q))$, for any $\alpha_q \in T^*Q$ and any $\xi \in \mathfrak{g}$.

(iv) (*Symplectic linear actions*) Let $(V, \omega)$ be a symplectic linear space and let $G$ be a subgroup of the linear symplectic group, acting naturally on $V$. By the choice of $G$ this action is canonical and has a momentum map given by $\langle \boldsymbol{J}(v), \xi \rangle = (1/2)\omega(\xi_V(v), v)$, for $\xi \in \mathfrak{g}$ and $v \in V$ arbitrary.

#### Properties of the Momentum Map

The main feature of the momentum map that makes it of interest for use in reduction is that it encodes conservation laws for $G$-symmetric Hamiltonian systems. Noether's theorem states that the momentum map is a constant of the motion for the Hamiltonian vector field $X_h$ associated to any $G$-invariant function $h \in C^\infty(M)^G$ (*see* Symmetries and Conservation Laws).

The derivative $T\boldsymbol{J}$ of the momentum map satisfies the following two properties: range $(T_m\boldsymbol{J}) = (\mathfrak{g}_m)^\circ$ and $\ker T_m\boldsymbol{J} = (\mathfrak{g} \cdot m)^\omega$, for any $m \in M$, where $(\mathfrak{g}_m)^\circ$ denotes the annihilator in $\mathfrak{g}^*$ of the isotropy subalgebra $\mathfrak{g}_m$ of $m$, $\mathfrak{g} \cdot m := T_m(G \cdot m) = \{\xi_M(m) | \xi \in \mathfrak{g}\}$ is the tangent space at $m$ to the $G$-orbit that contains this point, and $(\mathfrak{g} \cdot m)^\omega$ is the symplectic orthogonal space to $\mathfrak{g} \cdot m$ in the symplectic vector space $(T_mM, \omega(m))$. The first relation is sometimes called the bifurcation lemma since it establishes a link between the symmetry of a point and the rank of the momentum map at that point.

The existence of the momentum map for a given canonical action is not guaranteed. A momentum map exists if and only if the linear map $\rho : [\xi] \in \mathfrak{g}/[\mathfrak{g}, \mathfrak{g}] \mapsto [\omega(\xi_M, \cdot)] \in H^1(M, \mathbb{R})$ is identically zero. Thus, if $H^1(M, \mathbb{R}) = 0$ or $\mathfrak{g}/[\mathfrak{g}, \mathfrak{g}] = H^1(\mathfrak{g}, \mathbb{R}) = 0$ then $\rho \equiv 0$. In particular, if $\mathfrak{g}$ is semisimple, the "first Whitehead lemma" states that $H^1(\mathfrak{g}, \mathbb{R}) = 0$ and therefore a momentum map always exists for canonical semisimple Lie algebra actions.

A natural question to ask is when the map $(\mathfrak{g}, [\cdot, \cdot]) \to (C^\infty(M), \{\cdot, \cdot\})$ defined by $\xi \mapsto \boldsymbol{J}^\xi, \xi \in \mathfrak{g}$, is a Lie algebra homomorphism, that is, $\boldsymbol{J}^{[\xi,\eta]} = \{\boldsymbol{J}^\xi, \boldsymbol{J}^\eta\}$, $\xi, \eta \in \mathfrak{g}$. Here $\{\cdot, \cdot\} : C^\infty(M) \times C^\infty(M) \to C^\infty(M)$ denotes the Poisson bracket associated to the symplectic form $\omega$ of $M$ defined by $\{f, h\} := \omega(X_f, X_h), f, h \in C^\infty(M)$. This is the case if and only if $T_z\boldsymbol{J}(\xi_M(z)) = -\mathrm{ad}^*_\xi \boldsymbol{J}(z)$, for any $\xi \in \mathfrak{g}$, $z \in M$, where $\mathrm{ad}^*$ is the dual of the adjoint representation $\mathrm{ad} : (\xi, \eta) \in \mathfrak{g} \times \mathfrak{g} \mapsto [\xi, \eta] \in \mathfrak{g}$ of $\mathfrak{g}$ on itself. A momentum map that satisfies this relation in called infinitesimally equivariant. The reason behind this terminology is that this is the infinitesimal version of global or coadjoint equivariance: $\boldsymbol{J}$ is $G$-equivariant if $\mathrm{Ad}^*_{g^{-1}} \circ \boldsymbol{J} = \boldsymbol{J} \circ \Phi_g$ or, equivalently,

$J_g^{\mathrm{Ad}}\xi(g \cdot z) = J^{\xi}(z)$, for all $g \in G$, $\xi \in \mathfrak{g}$, and $z \in M$; $\mathrm{Ad}^*$ denotes the dual of the adjoint representation Ad of $G$ on $\mathfrak{g}$. Actions admitting infinitesimally equivariant momentum maps are called Hamiltonian actions and Lie group actions with coadjoint equivariant momentum maps are called globally Hamiltonian actions. If the symmetry group $G$ is connected then global and infinitesimal equivariance of the momentum map are equivalent concepts. If $\mathfrak{g}$ acts canonically on $(M, \omega)$ and $H^1(\mathfrak{g}, \mathbb{R}) = \{0\}$ then this action admits at most one infinitesimally equivariant momentum map.

Since momentum maps are not uniquely defined, one may ask whether one can choose them to be equivariant. It turns out that if the momentum map is associated to the action of a compact Lie group, this can always be done. Momentum maps of cotangent lifted actions are also equivariant as are momentum maps defined by symplectic linear actions. Canonical actions of semisimple Lie algebras on symplectic manifolds admit infinitesimally equivariant momentum maps, since the "second Whitehead lemma" states that $H^2(\mathfrak{g}, \mathbb{R}) = 0$ if $\mathfrak{g}$ is semisimple. We shall identify below a specific element of $H^2(\mathfrak{g}, \mathbb{R})$ which is the obstruction to the equivariance of a momentum map (assuming it exists).

Even though, in general, it is not possible to choose a coadjoint equivariant momentum map, it turns out that when the symplectic manifold is connected there is an affine action on the dual of the Lie algebra with respect to which the momentum map is equivariant. Define the nonequivariance 1-cocycle associated to $J$ as the map $\sigma : G \longrightarrow \mathfrak{g}^*$ given by $g \mapsto J(\Phi_g(z)) - \mathrm{Ad}^*_{g^{-1}}(J(z))$. The connectivity of $M$ implies that the right-hand side of this equality is independent of the point $z \in M$. In addition, $\sigma$ is a (left) $\mathfrak{g}^*$-valued 1-cocycle on $G$ with respect to the coadjoint representation of $G$ on $\mathfrak{g}^*$, that is, $\sigma(gh) = \sigma(g) + \mathrm{Ad}^*_{g^{-1}}\sigma(h)$ for all $g, h \in G$. Relative to the affine action $\Theta : G \times \mathfrak{g}^* \longrightarrow \mathfrak{g}^*$ given by $(g, \mu) \longmapsto \mathrm{Ad}^*_{g^{-1}}\mu + \sigma(g)$, the momentum map $J$ is equivariant. The "reduction lemma," the main technical ingredient in the proof of the reduction theorem, states that for any $m \in M$ we have

$$\mathfrak{g}_{J(m)} \cdot m = \mathfrak{g} \cdot m \cap \ker T_m J = \mathfrak{g} \cdot m \cap (\mathfrak{g} \cdot m)^{\omega}$$

where $\mathfrak{g}_{J(m)}$ is the Lie algebra of the isotropy group $G_{J(m)}$ of $J(m) \in \mathfrak{g}^*$ with respect to the affine action of $G$ on $\mathfrak{g}^*$ induced by the nonequivariance 1-cocycle of $J$.

## The Symplectic Reduction Theorem

The symplectic reduction procedure that we now present consists of constructing a new symplectic manifold out of a given symmetric one in which the conservation laws encoded in the form of a momentum map and the degeneracies associated to the symmetry have been eliminated. This strategy allows the reduction of a symmetric Hamiltonian dynamical system to a dimensionally smaller one. This reduction procedure preserves the symplectic category, that is, if we start with a Hamiltonian system on a symplectic manifold, the reduced system is also a Hamiltonian system on a symplectic manifold. The reduced symplectic manifold is usually referred to as the symplectic or Marsden–Weinstein reduced space.

**Theorem 2** *Let $\Phi : G \times M \to M$ be a free proper canonical action of the Lie group $G$ on the connected symplectic manifold $(M, \omega)$. Suppose that this action has an associated momentum map $J : M \to \mathfrak{g}^*$, with nonequivariance 1-cocycle $\sigma : G \to \mathfrak{g}^*$. Let $\mu \in \mathfrak{g}^*$ be a value of $J$ and denote by $G_\mu$ the isotropy of $\mu$ under the affine action of $G$ on $\mathfrak{g}^*$. Then:*

(i) *The space $M_\mu := J^{-1}(\mu)/G_\mu$ is a regular quotient manifold and, moreover, it is a symplectic manifold with symplectic form $\omega_\mu$ uniquely characterized by the relation*

$$\pi_\mu^* \omega_\mu = i_\mu^* \omega$$

*The maps $i_\mu : J^{-1}(\mu) \hookrightarrow M$ and $\pi_\mu : J^{-1}(\mu) \to J^{-1}(\mu)/G_\mu$ denote the inclusion and the projection, respectively. The pair $(M_\mu, \omega_\mu)$ is called the symplectic point reduced space.*

(ii) *Let $h \in C^\infty(M)^G$ be a $G$-invariant Hamiltonian. The flow $F_t$ of the Hamiltonian vector field $X_h$ leaves the connected components of $J^{-1}(\mu)$ invariant and commutes with the $G$-action, so it induces a flow $F_t^\mu$ on $M_\mu$ defined by $\pi_\mu \circ F_t \circ i_\mu = F_t^\mu \circ \pi_\mu$.*

(iii) *The vector field generated by the flow $F_t^\mu$ on $(M_\mu, \omega_\mu)$ is Hamiltonian with associated reduced Hamiltonian function $h_\mu \in C^\infty(M_\mu)$ defined by $h_\mu \circ \pi_\mu = h \circ i_\mu$. The vector fields $X_h$ and $X_{h_\mu}$ are $\pi_\mu$-related. The triple $(M_\mu, \omega_\mu, h_\mu)$ is called the reduced Hamiltonian system.*

(iv) *Let $k \in C^\infty(M)^G$ be another $G$-invariant function. Then $\{h, k\}$ is also $G$-invariant and $\{h, k\}_\mu = \{h_\mu, k_\mu\}_{M_\mu}$, where $\{\cdot, \cdot\}_{M_\mu}$ denotes the Poisson bracket associated to the symplectic form $\omega_\mu$ on $M_\mu$.*

## Reconstruction of Dynamics

We pose now the question converse to the reduction of a Hamiltonian system. Assume that an integral curve $c_\mu(t)$ of the reduced Hamiltonian system $X_{h_\mu}$

on $(M_\mu, \omega_\mu)$ is known. Let $m_0 \in \mathbf{J}^{-1}(\mu)$ be given. One can determine from this data the integral curve of the Hamiltonian system $X_h$ with initial condition $m_0$. In other words, one can reconstruct the solution of the given system knowing the corresponding reduced solution. The general method of reconstruction is the following. Pick a smooth curve $d(t)$ in $\mathbf{J}^{-1}(\mu)$ such that $d(0)=m_0$ and $\pi_\mu(d(t))=c_\mu(t)$. Then, if $c(t)$ denotes the integral curve of $X_h$ with $c(0)=m_0$, we can write $c(t)=g(t)\cdot d(t)$ for some smooth curve $g(t)$ in $G_\mu$ that is obtained in two steps. First, one finds a smooth curve $\xi(t)$ in $\mathfrak{g}_\mu$ such that $\xi(t)_M(d(t))=X_h(d(t))-\dot{d}(t)$. With the $\xi(t)\in\mathfrak{g}_\mu$ just obtained, one solves the nonautonomous differential equation $\dot{g}(t)=T_eL_{g(t)}\xi(t)$ on $G_\mu$ with $g(0)=e$.

### The Orbit Formulation of the Symplectic Reduction Theorem

There is an alternative approach to the reduction theorem which consists of choosing as numerator of the symplectic reduced space the group invariant saturation of the level sets of the momentum map. This option produces as a result a space that is symplectomorphic to the Marsden–Weinstein quotient but presents the advantage of being more appropriate in the context of quantization problems. Additionally, this approach makes easier the comparison of the symplectic reduced spaces corresponding to different values of the momentum map which is important in the context of Poisson reduction (*see* Poisson Reduction). In carrying out this construction, one needs to use the natural symplectic structures that one can define on the orbits of the affine action of a group on the dual of its Lie algebra and that we now quickly review.

Let $G$ be a Lie group, $\sigma: G\to\mathfrak{g}^*$ a coadjoint 1-cocycle, and $\mu\in\mathfrak{g}^*$. Let $\mathcal{O}_\mu$ be the orbit through $\mu$ of the affine $G$-action on $\mathfrak{g}^*$ associated to $\sigma$. If $\Sigma:\mathfrak{g}\times\mathfrak{g}\to\mathbb{R}$ defined by

$$\sum(\xi,\eta):=\left.\frac{\mathrm{d}}{\mathrm{d}t}\right|_{t=0}\langle\sigma(\exp(t\xi),\eta\rangle$$

is a real-valued Lie algebra 2-cocycle (which is always the case if $\sigma$ is the derivative of a smooth real-valued group 2-cocycle or if $\sigma$ is the nonequivariance 1-cocycle of a momentum map), that is, $\Sigma:\mathfrak{g}\times\mathfrak{g}\to\mathbb{R}$ is skew-symmetric and $\Sigma([\xi,\eta],\zeta)+\Sigma([\eta,\zeta],\xi)+\Sigma([\zeta,\xi],\eta)=0$ for all $\xi,\eta,\zeta\in\mathfrak{g}$, then the affine orbit $\mathcal{O}_\mu$ is a symplectic manifold with $G$-invariant symplectic structure $\omega^\pm_{\mathcal{O}_\mu}$ given by

$$\omega^\pm_{\mathcal{O}_\mu}(\nu)(\xi_{\mathfrak{g}^*}(\nu),\eta_{\mathfrak{g}^*}(\nu))=\pm\langle\nu,[\xi,\eta]\rangle\mp\Sigma(\xi,\eta) \qquad [1]$$

for arbitrary $\nu\in\mathcal{O}_\mu$, and $\xi,\eta\in\mathfrak{g}$. The symbol $\xi_{\mathfrak{g}^*}(\nu):=-\mathrm{ad}^*_\xi\nu+\Sigma(\xi,\cdot)$ denotes the infinitesimal generator of the affine action on $\mathfrak{g}^*$ associated to $\xi\in\mathfrak{g}$. The symplectic structures $\omega_{\mathcal{O}}\mu^\pm$ on $\mathcal{O}_\mu$ are called the $(\pm)$-orbit or Kostant–Kirillov–Souriau (KKS) symplectic forms.

This symplectic form can be obtained from Theorem 2 by considering the symplectic reduction of the cotangent bundle $T^*G$ endowed with the magnetic symplectic structure $\overline{\omega_\Sigma}:=\omega_{\mathrm{can}}-\pi^*B_\Sigma$, where $\omega_{\mathrm{can}}$ is the canonical symplectic form on $T^*G,\pi:T^*G\to G$ is the projection onto the base, and $B_\Sigma\in\Omega^2(G)^G$ is a left-invariant 2-form on $G$ whose value at the identity is the Lie algebra 2-cocycle $\Sigma:\mathfrak{g}\times\mathfrak{g}\to\mathbb{R}$. Since $\Sigma$ is a cocycle, it follows that $B_\Sigma$ is closed and hence $\overline{\omega_\Sigma}$ is a symplectic form. Moreover, the lifting of the left translations on $G$ provides a canonical $G$-action on $T^*G$ that has a momentum map given by $\mathbf{J}(g,\mu)=\Theta(g,\mu),(g,\mu)\in G\times\mathfrak{g}^*\simeq T^*G$, where the trivialization $G\times\mathfrak{g}^*\simeq T^*G$ is obtained via left translations. Symplectic reduction using these ingredients yields symplectic reduced spaces that are naturally symplectically diffeomorphic to the affine orbits $\mathcal{O}_\mu$ with the symplectic form [1].

**Theorem 3** (Symplectic orbit reduction). *Let $\Phi:G\times M\to M$ be a free proper canonical action of the Lie group $G$ on the connected symplectic manifold $(M,\omega)$. Suppose that this action has an associated momentum map $\mathbf{J}:M\to\mathfrak{g}^*$, with nonequivariance 1-cocycle $\sigma:G\to\mathfrak{g}^*$. Let $\mathcal{O}_\mu:=G\cdot\mu\subset\mathfrak{g}^*$ be the G-orbit of the point $\mu\in\mathfrak{g}^*$ with respect to the affine action of G on $\mathfrak{g}^*$ associated to $\sigma$. Then the set $M_{\mathcal{O}_\mu}:=\mathbf{J}^{-1}(\mathcal{O}_\mu)/G$ is a regular quotient symplectic manifold with the symplectic form $\omega_{\mathcal{O}_\mu}$ uniquely characterized by the relation $i^*_{\mathcal{O}_\mu}\omega=\pi^*_{\mathcal{O}_\mu}\omega_{\mathcal{O}_\mu}+\mathbf{J}^*_{\mathcal{O}_\mu}\omega^+_{\mathcal{O}_\mu}$, where $\mathbf{J}_{\mathcal{O}_\mu}$ is the restriction of $\mathbf{J}$ to $\mathbf{J}^{-1}(\mathcal{O}_\mu)$ and $\omega^+_{\mathcal{O}_\mu}$ is the $(+)$–symplectic structure on the affine orbit $\mathcal{O}_\mu$. The maps $i_{\mathcal{O}_\mu}:\mathbf{J}^{-1}(\mathcal{O}_\mu)\hookrightarrow M$ and $\pi_{\mathcal{O}_\mu}:\mathbf{J}^{-1}(\mathcal{O}_\mu)\to M_{\mathcal{O}_\mu}$ are natural injection and the projection, respectively. The pair $(M_{\mathcal{O}_\mu},\omega_{\mathcal{O}_\mu})$ is called the symplectic orbit reduced space. Statements similar to (ii)–(iv) in Theorem 2 can be formulated for the orbit reduced spaces $(M_{\mathcal{O}_\mu},\omega_{\mathcal{O}_\mu})$.*

We emphasize that given a momentum value $\mu\in\mathfrak{g}^*$, the reduced spaces $M_\mu$ and $M_{\mathcal{O}_\mu}$ are symplectically diffeomorphic via the projection to the quotients of the inclusion $\mathbf{J}^{-1}(\mu)\hookrightarrow\mathbf{J}^{-1}(\mathcal{O}_\mu)$.

Reduction at a general point can be replaced by reduction at zero at the expense of enlarging the manifold by the affine orbit. Consider the canonical diagonal action of $G$ on the symplectic difference $M\ominus\mathcal{O}^+_\mu$, which is the manifold $M\times\mathcal{O}_\mu$ with the symplectic form $\pi_1^*\omega-\pi_2^*\omega_{\mathcal{O}^+_\mu}$, where $\pi_1:M\times\mathcal{O}_\mu\to M$ and $\pi_2:M\times\mathcal{O}_\mu\to\mathcal{O}_\mu$ are the projections.

A momentum map for this action is given by $\boldsymbol{J} \circ \pi_1 - \pi_2 : M \ominus \mathcal{O}_\mu^+ \to \mathfrak{g}^*$. Let $(M \ominus \mathcal{O}_\mu^+)_0 := ((\boldsymbol{J} \circ \pi_1 - \pi_2)^{-1}(0)/G, (\omega \ominus \omega_{\mathcal{O}_\mu}^+)_0)$ be the symplectic point reduced space at zero.

**Theorem 4** (Shifting theorem). *Under the hypotheses of the symplectic orbit reduction theorem (Theorem 3), the symplectic orbit reduced space $M_{\mathcal{O}_\mu}$, the point reduced spaces $M_\mu$, and $(M \ominus \mathcal{O}_\mu^+)_0$ are symplectically diffeomorphic.*

## Singular Reduction

In the previous section we carried out symplectic reduction for free and proper actions. The freeness guarantees via the bifurcation lemma that the momentum map $\boldsymbol{J}$ is a submersion and hence the level sets $\boldsymbol{J}^{-1}(\mu)$ are smooth manifolds. Freeness and properness ensure that the orbit spaces $M_\mu := \boldsymbol{J}^{-1}(\mu)/G_\mu$ are regular quotient manifolds. The theory of singular reduction studies the properties of the orbit space $M_\mu$ when the hypothesis on the freeness of the action is dropped. The main result in this situation shows that these quotients are symplectic Whitney stratified spaces, in the sense that the strata are symplectic manifolds in a very natural way; moreover, the local properties of this Whitney stratification make it into what is called a cone space. This statement is referred to as the "symplectic stratification theorem" and adapts to the symplectic symmetric context the stratification theorem of the orbit space of a proper Lie group action by using its orbit type manifolds. In order to present this result, we review the necessary definitions and results on stratified spaces (*see* Singularity and Bifurcation Theory for more information on singularity theory).

### Stratified Spaces

Let $\mathcal{Z}$ be a locally finite partition of the topological space $P$ into smooth manifolds $S_i \subset P, i \in I$. We assume that the manifolds $S_i \subset P, i \in I$, with their manifold topology are locally closed topological subspaces of $P$. The pair $(P, \mathcal{Z})$ is a decomposition of $P$ with pieces in $\mathcal{Z}$ when the following condition is satisfied:

**Condition (DS)** If $R, S \in \mathcal{Z}$ are such that $R \cap \bar{S} \neq \emptyset$, then $R \subset \bar{S}$. In this case we write $R \preceq S$. If, in addition, $R \neq S$ we say that $R$ is incident to $S$ or that it is a boundary piece of $S$ and write $R \prec S$.

The above condition is called the frontier condition and the pair $(P, \mathcal{Z})$ is called a decomposed space. The dimension of $P$ is defined as $\dim P = \sup\{\dim S_i \mid S_i \in \mathcal{Z}\}$. If $k \in \mathbb{N}$, the $k$-skeleton $P^k$ of $P$ is the union of all the pieces of dimension smaller than or equal to $k$; its topology is the relative topology induced by $P$. The depth $\mathrm{dp}(z)$ of any $z \in (P, \mathcal{Z})$ is defined as

$$\mathrm{dp}(z) := \sup\{k \in \mathbb{N} \mid \exists S_0, S_1, \ldots, S_k \in \mathcal{Z} \text{ with } z \in S_0 \prec S_1 \prec \cdots \prec S_k\}$$

Since for any two elements $x, y \in \mathcal{S}$ in the same piece $\mathcal{S} \in P$ we have $\mathrm{dp}(x) = \mathrm{dp}(y)$, the depth $\mathrm{dp}(S)$ of the piece $S$ is well defined by $\mathrm{dp}(S) := \mathrm{dp}(x), x \in \mathcal{S}$. Finally, the depth $\mathrm{dp}(P)$ of $(P, \mathcal{Z})$ is defined by $\mathrm{dp}(P) := \sup\{\mathrm{dp}(S) \mid S \in \mathcal{Z}\}$.

A continuous mapping $f : P \to Q$ between the decomposed spaces $(P, \mathcal{Z})$ and $(Q, \mathcal{Y})$ is a morphism of decomposed spaces if, for every piece $S \in \mathcal{Z}$, there is a piece $T \in \mathcal{Y}$ such that $f(S) \subset T$ and the restriction $f|_S : S \to T$ is smooth. If $(P, \mathcal{Z})$ and $(P, \mathcal{T})$ are two decompositions of the same topological space we say that $\mathcal{Z}$ is coarser than $\mathcal{T}$ or that $\mathcal{T}$ is finer than $\mathcal{Z}$ if the identity mapping $(P, \mathcal{T}) \to (P, \mathcal{Z})$ is a morphism of decomposed spaces. A topological subspace $Q \subset P$ is a decomposed subspace of $(P, \mathcal{Z})$ if, for all pieces $S \in \mathcal{Z}$, the intersection $S \cap Q$ is a submanifold of $S$ and the corresponding partition $\mathcal{Z} \cap Q$ forms a decomposition of $Q$.

Let $P$ be a topological space and $z \in P$. Two subsets $A$ and $B$ of $P$ are said to be equivalent at $z$ if there is an open neighborhood $U$ of $z$ such that $A \cap U = B \cap U$. This relation constitutes an equivalence relation on the power set of $P$. The class of all sets equivalent to a given subset $A$ at $z$ will be denoted by $[A]_z$ and called the set germ of $A$ at $z$. If $A \subset B \subset P$, we say that $[A]_z$ is a subgerm of $[B]_z$, and denote $[A]_z \subset [B]_z$.

A stratification of the topological space $P$ is a map $\mathcal{S}$ that associates to any $z \in P$ the set germ $\mathcal{S}(z)$ of a closed subset of $P$ such that the following condition is satisfied:

**Condition (ST)** For every $z \in P$ there is a neighborhood $U$ of $z$ and a decomposition $\mathcal{Z}$ of $U$ such that for all $y \in U$ the germ $\mathcal{S}(y)$ coincides with the set germ of the piece of $\mathcal{Z}$ that contains $y$.

The pair $(P, \mathcal{S})$ is called a stratified space. Any decomposition of $P$ defines a stratification of $P$ by associating to each of its points the set germ of the piece in which it is contained. The converse is, by definition, locally true.

### The Strata

Two decompositions $\mathcal{Z}_1$ and $\mathcal{Z}_2$ of $P$ are said to be equivalent if they induce the same stratification of $P$. If $\mathcal{Z}_1$ and $\mathcal{Z}_2$ are equivalent decompositions of $P$ then, for all $z \in P$, we have that $\mathrm{dp}_{\mathcal{Z}_1}(z) = \mathrm{dp}_{\mathcal{Z}_2}(z)$. Any stratified space $(P, \mathcal{S})$ has a unique decomposition $\mathcal{Z}_\mathcal{S}$ associated with the following maximality property: for any open subset $U \subset P$ and any

decomposition $\mathcal{Z}$ of $P$ inducing $\mathcal{S}$ over $U$, the restriction of $\mathcal{Z}_{\mathcal{S}}$ to $U$ is coarser than the restriction of $\mathcal{Z}$ to $U$. The decomposition $\mathcal{Z}_{\mathcal{S}}$ is called the canonical decomposition associated to the stratification $(P, \mathcal{S})$. It is often denoted by $\mathcal{S}$ and its pieces are called the strata of $P$. The local finiteness of the decomposition $\mathcal{Z}_{\mathcal{S}}$ implies that for any stratum $S$ of $(P, \mathcal{S})$ there are only finitely many strata $R$ with $S \prec R$. Henceforth, the symbol $\mathcal{S}$ in the stratification $(P, \mathcal{S})$ will denote both the map that associates to each point a set germ and the set of pieces associated to the canonical decomposition induced by the stratification of $P$.

### Stratified Spaces with Smooth Structure

Let $(P, \mathcal{S})$ be a stratified space. A singular or stratified chart of $P$ is a homeomorphism $\phi : U \to \phi(U) \subset \mathbb{R}^n$ from an open set $U \subset P$ to a subset of $\mathbb{R}^n$ such that for every stratum $S \in \mathcal{S}$ the image $\phi(U \cap S)$ is a submanifold of $\mathbb{R}^n$ and the restriction $\phi|_{U\cap S} : U \cap S \to \phi(U \cap S)$ is a diffeomorphism. Two singular charts $\phi : U \to \phi(U) \subset \mathbb{R}^n$ and $\varphi : V \to \varphi(V) \subset \mathbb{R}^m$ are compatible if for any $z \in U \cap V$ there exist an open neighborhood $W \subset U \cap V$ of $z$, a natural number $N \geq \max\{n, m\}$, open neighborhoods $O, O' \subset \mathbb{R}^N$ of $\phi(U) \times \{0\}$ and $\varphi(V) \times \{0\}$, respectively, and a diffeomorphism $\psi : O \to O'$ such that $i_m \circ \varphi|_W = \psi \circ i_n \circ \phi|_W$, where $i_n$ and $i_m$ denote the natural embeddings of $\mathbb{R}^n$ and $\mathbb{R}^m$ into $\mathbb{R}^N$ by using the first $n$ and $m$ coordinates, respectively. The notion of singular or stratified atlas is the natural generalization for stratifications of the concept of atlas existing for smooth manifolds. Analogously, we can talk of compatible and maximal stratified atlases. If the stratified space $(P, \mathcal{S})$ has a well-defined maximal atlas, then we say that this atlas determines a smooth or differentiable structure on $P$. We will refer to $(P, \mathcal{S})$ as a smooth stratified space.

### The Whitney Conditions

Let $M$ be a manifold and $R, S \subset M$ two submanifolds. We say that the pair $(R, S)$ satisfies the Whitney condition (A) at the point $z \in R$ if the following condition is satisfied:

**Condition (A)** For any sequence of points $\{z_n\}_{n\in\mathbb{N}}$ in $S$ converging to $z \in R$ for which the sequence of tangent spaces $\{T_{z_n}S\}_{n\in\mathbb{N}}$ converges in the Grassmann bundle of $\dim S$–dimensional subspaces of $TM$ to $\tau \subset T_zM$, we have that $T_zR \subset \tau$.

Let $\phi : U \to \mathbb{R}^n$ be a smooth chart of $M$ around the point $z$. The Whitney condition (B) at the point $z \in R$ with respect to the chart $(U, \phi)$ is given by the following statement:

**Condition (B)** Let $\{x_n\}_{n\in\mathbb{N}} \subset R \cap U$ and $\{y_n\}_{n\in\mathbb{N}} \subset S \cap U$ be two sequences with the same limit

$$z = \lim_{n\to\infty} x_n = \lim_{n\to\infty} y_n$$

and such that $x_n \neq y_n$, for all $n \in \mathbb{N}$. Suppose that the set of connecting lines $\overline{\phi(x_n)\phi(y_n)} \subset \mathbb{R}^n$ converges in projective space to a line $L$ and that the sequence of tangent spaces $\{T_{y_n}S\}_{n\in\mathbb{N}}$ converges in the Grassmann bundle of $(\dim S)$-dimensional subspaces of $TM$ to $\tau \subset T_zM$. Then, $(T_z\phi)^{-1}(L) \subset \tau$.

If the condition (A) (respectively (B)) is verified for every point $z \in R$, the pair $(R, S)$ is said to satisfy the Whitney condition (A) (respectively (B)). It can be verified that Whitney's condition (B) does not depend on the chart used to formulate it. A stratified space with smooth structure such that, for every pair of strata, Whitney's condition (B) is satisfied is called a Whitney space.

### Cone Spaces and Local Triviality

Let $P$ be a topological space. Consider the equivalence relation $\sim$ in the product $P \times [0, \infty)$ given by $(z, a) \sim (z', a')$ if and only if $a = a' = 0$. We define the cone $CP$ on $P$ as the quotient topological space $P \times [0, \infty)/\sim$. If $P$ is a smooth manifold then the cone $CP$ is a decomposed space with two pieces, namely, $P \times (0, \infty)$ and the vertex which is the class corresponding to any element of the form $(z, 0)$, $z \in P$, that is, $P \times \{0\}$. Analogously, if $(P, \mathcal{Z})$ is a decomposed (stratified) space then the associated cone $CP$ is also a decomposed (stratified) space whose pieces (strata) are the vertex and the sets of the form $S \times (0, \infty)$, with $S \in \mathcal{Z}$. This implies, in particular, that $\dim CP = \dim P + 1$ and $\mathrm{dp}(CP) = \mathrm{dp}(P) + 1$.

A stratified space $(P, \mathcal{S})$ is said to be locally trivial if for any $z \in P$ there exist a neighborhood $U$ of $z$, a stratified space $(F, \mathcal{S}^F)$, a distinguished point $\mathbf{0} \in F$, and an isomorphism of stratified spaces

$$\psi : U \to (S \cap U) \times F$$

where $S$ is the stratum that contains $z$ and $\psi$ satisfies $\psi^{-1}(y, 0) = y$, for all $y \in S \cap U$. When $F$ is given by a cone $CL$ over a compact stratified space $L$ then $L$ is called the link of $z$.

An important corollary of "Thom's first isotopy lemma" guarantees that every Whitney stratified space is locally trivial. A converse to this implication needs the introduction of cone spaces. Their definition is given by recursion on the depth of the space.

**Definition 5** Let $m \in \mathbb{N} \cup \{\infty, \omega\}$. A cone space of class $C^m$ and depth 0 is the union of countably many $C^m$ manifolds together with the stratification whose strata are the unions of the connected components of equal dimension. A cone space of class $C^m$ and depth $d+1, d \in \mathbb{N}$, is a stratified space $(P, \mathcal{S})$ with a $C^m$ differentiable structure such that for any $z \in P$ there exists a connected neighborhood $U$ of $z$, a compact cone space $L$ of class $C^m$ and depth $d$ called the link, and a stratified isomorphism

$$\psi : U \to (S \cap U) \times CL$$

where $S$ is the stratum that contains the point $z$, the map $\psi$ satisfies $\psi^{-1}(y, 0) = y$, for all $y \in S \cap U$, and $0$ is the vertex of the cone $CL$.

If $m \neq 0$ then $L$ is required to be embedded into a sphere via a fixed smooth global singular chart $\varphi : L \to S^l$ that determines the smooth structure of $CL$. More specifically, the smooth structure of $CL$ is generated by the global chart $\tau : [z, t] \in CL \longmapsto t\varphi(z) \in \mathbb{R}^{l+1}$. The maps $\psi : U \to (S \cap U) \times CL$ and $\varphi : L \to S^l$ are referred to as a cone chart and a link chart, respectively. Moreover, if $m \neq 0$ then $\psi$ and $\psi^{-1}$ are required to be differentiable of class $C^m$ as maps between stratified spaces with a smooth structure.

### The Symplectic Stratification Theorem

Let $(M, \omega)$ be a connected symplectic manifold acted canonically and properly upon by a Lie group $G$. Suppose that this action has an associated momentum map $\mathbf{J} : M \to \mathfrak{g}^*$ with nonequivariance 1–cocycle $\sigma : G \to \mathfrak{g}^*$. Let $\mu \in \mathfrak{g}^*$ be a value of $\mathbf{J}, G_\mu$ the isotropy subgroup of $\mu$ with respect to the affine action $\Theta : G \times \mathfrak{g}^* \to \mathfrak{g}^*$ determined by $\sigma$, and let $H \subset G$ be an isotropy subgroup of the $G$-action on $M$. Let $M_H^z$ be the connected component of the $H$-isotropy type manifold that contains a given element $z \in M$ such that $\mathbf{J}(z) = \mu$ and let $G_\mu M_H^z$ be its $G_\mu$-saturation. Then the following hold:

1. The set $\mathbf{J}^{-1}(\mu) \cap G_\mu M_H^z$ is a submanifold of $M$.
2. The set $M_\mu^{(H)} := [\mathbf{J}^{-1}(\mu) \cap G_\mu M_H^z]/G_\mu$ has a unique quotient differentiable structure such that the canonical projection $\pi_\mu^{(H)} : \mathbf{J}^{-1}(\mu) \cap G_\mu M_H^z \longrightarrow M_\mu^{(H)}$ is a surjective submersion.
3. There is a unique symplectic structure $\omega_\mu^{(H)}$ on $M_\mu^{(H)}$ characterized by
$$i_\mu^{(H)*}\omega = \pi_\mu^{(H)*}\omega_\mu^{(H)}$$
where $i_\mu^{(H)} : \mathbf{J}^{-1}(\mu) \cap G_\mu M_H^z \hookrightarrow M$ is the natural inclusion. The pairs $(M_\mu^{(H)}, \omega_\mu^{(H)})$ will be called singular symplectic point strata.
4. Let $h \in C^\infty(M)^G$ be a $G$-invariant Hamiltonian. Then the flow $F_t$ of $X_h$ leaves the connected components of $\mathbf{J}^{-1}(\mu) \cap G_\mu M_H^z$ invariant and commutes with the $G_\mu$-action, so it induces a flow $F_t^\mu$ on $M_\mu^{(H)}$ that is characterized by $\pi_\mu^{(H)} \circ F_t \circ i_\mu^{(H)} = F_t^\mu \circ \pi_\mu^{(H)}$.
5. The flow $F_t^\mu$ is Hamiltonian on $M_\mu^{(H)}$, with reduced Hamiltonian function $h_\mu^{(H)} : M_\mu^{(H)} \to \mathbb{R}$ defined by $h_\mu^{(H)} \circ \pi_\mu^{(H)} = h \circ i_\mu^{(H)}$. The vector fields $X_h$ and $X_{h_\mu^{(H)}}$ are $\pi_\mu^{(H)}$-related.
6. Let $k : M \to \mathbb{R}$ be another $G$-invariant function. Then $\{h, k\}$ is also $G$-invariant and $\{h, k\}_\mu^{(H)} = \{h_\mu^{(H)}, k_\mu^{(H)}\}_{M_\mu^{(H)}}$, where $\{\,,\}_{M_\mu^{(H)}}$ denotes the Poisson bracket induced by the symplectic structure on $M_\mu^{(H)}$.

**Theorem 6** (Symplectic stratification theorem). *The quotient $M_\mu := \mathbf{J}^{-1}(\mu)/G_\mu$ is a cone space when considered as a stratified space with strata $M_\mu^{(H)}$.*

As was the case for regular reduction, this theorem can also be formulated from the orbit reduction point of view. Using that approach one can conclude that the orbit reduced spaces $M_{\mathcal{O}_\mu}$ are cone spaces symplectically stratified by the manifolds $M_{\mathcal{O}_\mu}^{(H)} := G \cdot (\mathbf{J}^{-1}(\mu) \cap M_H^z)/G$ that have symplectic structure uniquely determined by the expression

$$i_{\mathcal{O}_\mu}^{(H)*}\omega = \pi_{\mathcal{O}_\mu}^{(H)*}\omega_{\mathcal{O}_\mu}^{(H)} + \mathbf{J}_{\mathcal{O}_\mu}^{(H)*}\omega_{\mathcal{O}_\mu}^{+}$$

where $i_{\mathcal{O}_\mu}^{(H)} : G \cdot (\mathbf{J}^{-1}(\mu) \cap M_H^z) \hookrightarrow M$ is the inclusion, $\mathbf{J}_{\mathcal{O}_\mu}^{(H)} : G \cdot (\mathbf{J}^{-1}(\mu) \cap M_H^z) \to \mathcal{O}_\mu$ is obtained by restriction of the momentum map $\mathbf{J}$, and $\omega_{\mathcal{O}_\mu}^{+}$ is the $(+)$–symplectic form on $\mathcal{O}_\mu$. Analogous statements to (7)–(6) above with obvious modifications are valid.

# Symmetry Breaking in Field Theory

**T W B Kibble**, Imperial College, London, UK

## Introduction

Spontaneous symmetry breaking in its simplest form occurs when there is a symmetry of a dynamical system that is not manifest in its ground state or equilibrium state. It is a common feature of many classical and quantum systems. In quantum field theories, in the infinite-volume limit, there are new features, the appearance of unitarily inequivalent representations of the canonical commutation relations, and the possibility of a true phase transition – a point in the phase space where the thermodynamic free energy is nonanalytic. The spontaneous breaking of a continuous global symmetry implies the existence of massless particles, the Goldstone bosons, while in the local-symmetry case some or all of these may be eliminated by the Higgs mechanism. Spontaneous symmetry breaking in gauge theories is however a more elusive concept.

## Breaking of Global Symmetries

In a quantum-mechanical system a (time-independent) symmetry is represented by a unitary operator $\hat{U}$ acting on the Hilbert space of quantum states which commutes with the Hamiltonian $\hat{H}$. If the ground state $|0\rangle$ of the system in not invariant under $\hat{U}$, then $|0'\rangle = \hat{U}|0\rangle \neq c|0\rangle$ is also a ground state. In other words, the ground state is degenerate.

For a system with a finite number of degrees of freedom, whose states are represented by vectors in a separable Hilbert space $\mathcal{H}$, symmetry breaking of an abelian symmetry group $G$ is impossible, unless there are additional accidental symmetries. Consider, for example, a particle in a double-well potential

$$V = \frac{m\omega^2}{4a^2}(x^2 - a^2)^2 \qquad [1]$$

which has the discrete symmetry group $G = \mathbb{Z}_2$; the inversion symmetry operator $\hat{U}$ satisfies $\hat{U}^2 = \hat{1}$. There are then two approximate ground states $|0\rangle$ and $|0'\rangle = \hat{U}|0\rangle$, with wave functions proportional to $\exp[-(1/2)\, m\omega(x \mp a)^2]$. However, there is an overlap between these, and the off-diagonal matrix element $\langle 0|\hat{H}|0'\rangle$ is nonzero, although exponentially small, so the true energy eigenstates are, approximately, $|0_\pm\rangle = (1/\sqrt{2})(|0\rangle \pm |0'\rangle)$. (More accurate energy eigenfunctions and eigenvalues may be found by using the WKB approximation.)

Of course, if the symmetry group is nonabelian, and the ground state belongs to a nontrivial representation, then degeneracy is unavoidable. For example, if $G$ is the rotation group SO(3) (or SU(2))

and the ground state has angular momentum $j \neq 0$, then it is $(2j+1)$-fold degenerate.

The situation is different, however, in a quantum field theory. In the infinite-volume limit, even abelian symmetries can be spontaneously broken. Take, for example, a real scalar field with Lagrangian

$$\mathcal{L} = \tfrac{1}{2}\partial_\mu\phi\partial^\mu\phi - V = \tfrac{1}{2}\dot{\phi}^2 - \tfrac{1}{2}(\nabla\phi)^2 - V \qquad [2]$$

(where we set $c = \hbar = 1$), again with a double-well potential

$$V = \tfrac{1}{8}\lambda(\phi^2 - \eta^2)^2 \qquad [3]$$

exhibiting a $\mathbb{Z}_2$ symmetry under which $\phi(x) \mapsto -\phi(x)$.

At least in the semiclassical or tree approximation, there are two degenerate vacuum states $|0\rangle$ and $|0'\rangle$, with

$$\langle 0|\hat{\phi}(x)|0\rangle \approx \eta \quad \text{and} \quad \langle 0'|\hat{\phi}(x)|0'\rangle \approx -\eta \qquad [4]$$

If we quantize the system in a box of finite volume $\mathcal{V}$, then, as earlier, there is an off-diagonal matrix element of the Hamiltonian connecting the two states, so the true ground state is (approximately) $(1/\sqrt{2})(|0\rangle + |0'\rangle)$. However, this matrix element goes to zero exponentially as $\mathcal{V} \to 0$. Even for large but finite volume, the rate of transitions from $|0\rangle$ to $|0'\rangle$ is exponentially slow.

Similarly, we can consider a complex scalar field theory with a sombrero potential:

$$\begin{aligned} \mathcal{L} &= |\dot{\phi}|^2 - |\nabla\phi|^2 - V \\ V &= \tfrac{1}{2}\lambda\left(|\phi|^2 - \tfrac{1}{2}\eta^2\right)^2 \end{aligned} \qquad [5]$$

This model is invariant under the U(1) group of phase transformations, $\phi(x) \mapsto \phi(x)e^{i\alpha}$, so we now have a continuously infinite set of degenerate vacuum states $|0_\alpha\rangle$ labeled by an angle $\alpha$, and satisfying

$$\langle 0_\alpha|\hat{\phi}(x)|0_\alpha\rangle \approx \frac{1}{\sqrt{2}}\eta e^{i\alpha} \qquad [6]$$

Once again, one finds that in the infinite-volume limit there are no matrix elements connecting the different vacuum states. Moreover, in this limit no polynomial formed from the field operators $\hat{\phi}(x)$ in a finite volume can have nonzero matrix elements between $|0_\alpha\rangle$ and $|0_\beta\rangle$ for $\alpha \neq \beta$. Applying the operators $\hat{\phi}(x)$ to any one of these vacuum states $|0_\alpha\rangle$, we can construct a Fock space $\mathcal{H}_\alpha$, and the representations of the canonical commutation relations on these separate Hilbert spaces are unitarily inequivalent. Formally, we can introduce operators $\hat{U}_\alpha$ that perform the symmetry transformations:

$$\hat{U}_\alpha\hat{\phi}(x)\hat{U}_\alpha^{-1} = \hat{\phi}(x)e^{i\alpha} \qquad [7]$$

However, these are not unitary operators on the spaces $\mathcal{H}_\beta$, but rather maps from one space to another: $\hat{U}_\alpha : \mathcal{H}_\beta \to \mathcal{H}_{\alpha+\beta}$ – or, alternatively, operators on the nonseparable Hilbert space $\mathcal{H} = \bigoplus_\alpha \mathcal{H}_\alpha$.

So far, our discussion has been restricted to the tree approximation. For a full quantum treatment, $V(\phi)$ must be replaced by the effective potential $V_{\text{eff}}(\phi)$, which may be defined as the minimum value of the mean energy density in all states in which the field $\hat{\phi}$ has the uniform expectation value $\langle\hat{\phi}(x)\rangle = \phi$. $V_{\text{eff}}$ may be computed by summing vacuum loop diagrams.

A point to note is that although the degenerate vacua $|0_\alpha\rangle$ are mathematically distinct, in the absence of any external definition of phase, they are physically identical. There is no internal observational test that will distinguish them.

## Symmetry-Breaking Phase Transitions

Spontaneous symmetry breaking often occurs in the context of a phase transition. At high temperature, $T \gg \eta$, there are large fluctuations in $\phi$ and the central hump of the potential is unimportant. Then the equilibrium state is symmetric, with $\langle\hat{\phi}\rangle = 0$. However, as the temperature falls, it becomes less probable that the field will fluctuate over the top of the hump. It will tend to fall into the trough, and acquire a nonzero average value $\langle\hat{\phi}\rangle$ – the order parameter for the phase transition – thus breaking the symmetry. The direction of symmetry breaking (e.g., the phase of $\phi$ in the U(1) model) is random, determined in practice by small preexisting fluctuations or interactions with the environment.

One way of studying this process is to compute the temperature-dependent effective potential $V_{\text{eff}}(\phi, T)$. In the one-loop approximation, at high temperature, the leading corrections to the zero-temperature effective potential $V_{\text{eff}}(\phi, T)$ are of the form

$$\begin{aligned} V_{\text{eff}}(\phi, T) = V_{\text{eff}}(\phi, 0) &- \frac{\pi^2}{90}N_* T^4 \\ &+ \frac{1}{24}M_*^2(\phi)T^2 + \mathcal{O}(T) \end{aligned} \qquad [8]$$

where $N_*$ is the total number of helicity states of light particles (those with masses $\ll T$), and $M_*^2$, which depends on $\phi$, is the sum of their squared masses. (Fermions if present contribute to $N_*$ with a factor of 7/8 and to $M_*^2$ with a factor of 1/2.) In the simplest case, where we have only a multiplet $\boldsymbol{\phi} = (\phi_a)_{a=1,\ldots,N}$ of real scalar fields, $N_* = N$ and $M_*^2 = M_{aa}^2$

(summation over $a$ implied), where the mass-squared matrix is

$$M_{ab}^2 = \frac{\partial^2 V}{\partial\phi_a \partial\phi_b} \quad [9]$$

For example, in an O($N$) theory, with $V = (1/8)\lambda(\boldsymbol{\phi}^2 - \eta^2)^2$, where $\boldsymbol{\phi}^2 = \phi_a\phi_a$, one has

$$M_{ab}^2 = \tfrac{1}{2}\lambda(\boldsymbol{\phi}^2 - \eta^2)\delta_{ab} + \lambda\phi_a\phi_b \quad [10]$$

whence

$$V_{\rm eff}(\boldsymbol{\phi}, T) \approx \frac{1}{8}\lambda(\boldsymbol{\phi}^2 - \eta^2)^2 - \frac{\pi^2}{90}NT^4 + \frac{1}{48}\lambda T^2[(N+2)\boldsymbol{\phi}^2 - N\eta^2] \quad [11]$$

It is then easy to see that the minimum occurs at $\boldsymbol{\phi} = 0$ for $T > T_{\rm c}$, where in this approximation ${T_{\rm c}}^2 = 12\eta^2/(N+2)$, while below the critical temperature the minimum is at

$$\boldsymbol{\phi}^2 = \phi_{\rm eq}^2(T) \approx \eta^2 - \frac{N+2}{12}T^2 \quad [12]$$

As $T \to 0$, the equilibrium state approaches one of the vacuum states $|0_{\boldsymbol{n}}\rangle$, labeled by an $N$-dimensional unit vector $\boldsymbol{n}$, such that $\langle 0_{\boldsymbol{n}}|\hat{\boldsymbol{\phi}}|0_{\boldsymbol{n}}\rangle = \eta\boldsymbol{n}$.

It is often convenient to introduce a classical symmetry-breaking potential. For example, in the O($N$) model, we may take $V_{\rm sb} = -\boldsymbol{j}\cdot\boldsymbol{\phi}(x)$, where $\boldsymbol{j}$ is a constant $N$-vector. This has the effect of tilting the potential, thus removing the degeneracy. A characteristic of spontaneous symmetry breaking is that the limits $\boldsymbol{j} \to \boldsymbol{0}$ and $\mathcal{V} \to \infty$ do not commute. If (for $T < T_{\rm c}$) we take the infinite-volume limit first, and then let $\boldsymbol{j} \to 0$, we get different equilibrium states, depending on the direction from which $\boldsymbol{j}$ approaches zero; if we fix $\boldsymbol{n}$ and let $\boldsymbol{j} = j\boldsymbol{n}$, $j \to 0$, then we find

$$\lim_{j\to 0}\lim_{\mathcal{V}\to\infty}\langle\hat{\boldsymbol{\phi}}(x)\rangle_{j\boldsymbol{n}} = \phi_{\rm eq}(T)\boldsymbol{n} \quad [13]$$

We may also regard $\boldsymbol{j}$ as representing an interaction with the external environment (e.g., other fields). If such a term is present during the cooling of the system through the phase transition, it will constrain the direction of the spontaneous symmetry breaking. Note that one always arrives in this way at one of the degenerate vacua $|0_{\boldsymbol{n}}\rangle$, not a linear combination of them.

## Goldstone Bosons

The Goldstone theorem states that spontaneous breaking of any continuous global symmetry leads inevitably (except, as we discuss later, in the presence of long-range forces) to the appearance of massless modes – the Goldstone bosons.

The proof is straightforward. Associated with any continuous symmetry there is a Noether current satisfying the continuity equation $\partial_\mu\hat{j}^\mu = 0$ and such that infinitesimal symmetry transformations are generated by the spatial integral of $\hat{j}^0$. The fact that the symmetry is broken means that there is some scalar field $\hat{\phi}(x)$ whose vacuum expectation value $\langle 0|\hat{\phi}(0)|0\rangle$ is not invariant under the symmetry transformation. Hence,

$$\lim_{\mathcal{V}\to 0} {\rm i}\int_{\mathcal{V}} {\rm d}^3x\langle 0|[\hat{j}^0(x), \hat{\phi}(0)]|0\rangle|_{x^0=0} \neq 0 \quad [14]$$

Moreover, the time derivative of this integral is

$$\lim_{\mathcal{V}\to 0} {\rm i}\int_{\mathcal{V}} {\rm d}^3x\langle 0|[\partial_0\hat{j}^0(x), \hat{\phi}(0)]|0\rangle|_{x^0=0} = -\lim_{\mathcal{V}\to 0} {\rm i}\int_{\partial\mathcal{V}} {\rm d}S_k\langle 0|[\hat{j}^k(x), \hat{\phi}(0)]|0\rangle|_{x^0=0} = 0 \quad [15]$$

where $\partial\mathcal{V}$ is the bounding surface of $\mathcal{V}$. This vanishes because the surface integral is zero – in a relativistic theory, because the commutator vanishes at space-like separation, and more generally in the absence of long-range interactions because it tends rapidly to zero at large spatial separation.

Now, inserting a complete set of momentum eigenstates $|n, \boldsymbol{p}\rangle$ in [14], we can see that there must exist states such that $\langle n, \boldsymbol{p}|\hat{\phi}(0)|0\rangle \neq 0$, with $p^0 \to 0$ in the limit $|\boldsymbol{p}| \to 0$, that is, massless modes.

One can see this more directly in the U(1) model above. Consider a vacuum state $|0\rangle$ such that $\langle 0|\hat{\phi}|0\rangle = \eta/\sqrt{2}$ is real. Then it is useful to shift the origin of $\phi$ by writing

$$\phi(x) = \frac{1}{\sqrt{2}}[\eta + \varphi_1(x) + {\rm i}\varphi_2(x)] \quad [16]$$

where $\varphi_1$ and $\varphi_2$ are real. Then the Lagrangian becomes

$$\mathcal{L} = \tfrac{1}{2}\Big[\dot{\varphi}_1^2 - (\nabla\varphi_1)^2 + \dot{\varphi}_2^2 - (\nabla\varphi_2)^2 - \lambda\eta^2\varphi_1^2 - \lambda\eta\varphi_1(\varphi_1^2 + \varphi_2^2) - \tfrac{1}{4}\lambda(\varphi_1^2 + \varphi_2^2)^2\Big] \quad [17]$$

Evidently, the field $\varphi_1$, corresponding to radial oscillations in $\phi$, is massive, with mass $\sqrt{\lambda}\eta$. But there is no term in $\varphi_2^2$, so $\varphi_2$ is massless.

In the case of spontaneous symmetry breaking of nonabelian symmetries, there may be several Goldstone bosons, one for each broken component of the continuous symmetry. In our theory with symmetry group $G = {\rm O}(N)$, the possible values of the vacuum expectation value at $T = 0$ are $\langle 0_{\boldsymbol{n}}|\hat{\phi}(0)|0_{\boldsymbol{n}}\rangle \approx \eta\boldsymbol{n}$,

where $\boldsymbol{n}$ is an arbitrary unit vector. In this case, for given $\boldsymbol{n}$, there is an unbroken symmetry subgroup

$$H = \{R \in \mathrm{O}(N) : R\boldsymbol{n} = \boldsymbol{n}\} = \mathrm{O}(N-1) \qquad [18]$$

and the number of broken symmetries is

$$\dim G - \dim H = N - 1 \qquad [19]$$

Thus, the radial component of $\phi$ is massive, and there are $N-1$ Goldstone bosons, the $N-1$ transverse components.

## Spontaneously Broken Gauge Theories

As we shall see, symmetry breaking in gauge theories is a more problematic concept but, for the moment, these complications are ignored and the present discussion will continue with an approach similar to that used above.

The simplest local gauge symmetry theory is a U(1) Higgs model, a model of a complex scalar field $\phi(x)$ interacting with a gauge potential $A_\mu(x)$, described by the Lagrangian

$$\mathcal{L} = D_\mu\phi^* D^\mu\phi - \tfrac{1}{4}F_{\mu\nu}F^{\mu\nu} - V(|\phi|) \qquad [20]$$

where $V$ is a sombrero potential as in [5], while the covariant derivative $D_\mu\phi$ and gauge field $F_{\mu\nu}$ are given by

$$D_\mu\phi = \partial_\mu\phi + \mathrm{i}eA_\mu\phi, \qquad F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu \qquad [21]$$

The model is invariant under the local U(1) gauge transformations

$$\begin{aligned}\phi(x) &\mapsto \phi(x)\mathrm{e}^{\mathrm{i}\alpha(x)} \\ A_\mu(x) &\mapsto A_\mu(x) - \frac{1}{e}\partial_\mu\alpha(x)\end{aligned} \qquad [22]$$

The Goldstone theorem does not apply to local-symmetry theories. The problem is that to have a Hilbert space containing only physical states one must eliminate the gauge freedom by choosing a gauge condition (e.g., in the U(1) case the Coulomb gauge $\partial_k A^k(x) = 0$, which has the effect of restricting the number of polarization states of photons to two). This necessarily breaks manifest Lorentz invariance, although the theory is, of course, still fully Lorentz invariant. The proof of the theorem fails because the current is no longer local; the long-range Coulomb interaction makes the commutator fall off only like $1/r^2$, so the surface integral no longer vanishes in the infinite-volume limit. (The theorem also fails for nonrelativistic models with long-range forces.)

Again, consider a vacuum state $|0\rangle$ in which $\langle 0|\hat{\phi}|0\rangle = \eta/\sqrt{2}$, and make the same decomposition, [16]. Then, if we set

$$A'_\mu = A_\mu + \frac{1}{e\eta}\partial_\mu\varphi_2 \qquad [23]$$

we find that the kinetic term for $\varphi_2$ has been absorbed into a mass term $(1/2)e^2\eta^2 A'_\mu A'^\mu$ for the vector field. We have a model with only massive fields: the "Higgs field" $\varphi_1$ with mass $\sqrt{\lambda}\eta$ and the gauge field $A'_\mu$ with mass $e\eta$. The Goldstone bosons have been "eaten up" by the vector field to provide its longitudinal mode. This is the Higgs mechanism, first noted by Anderson in the context of the photon in a plasma becoming a massive plasmon.

A more elegant way of seeing this is to note that we can always make a gauge transformation to ensure that $\phi$ is real (at least so long as $\phi \neq 0$; where it is zero, there may be problems). This means that $\phi(x) = (1/\sqrt{2})(\eta + \varphi_1)$; $\varphi_2$ disappears altogether, and its kinetic term reduces to $(1/2)e^2 A_\mu A^\mu(\eta + \varphi_1)^2$, which includes the mass term for $A_\mu$ as well as cubic and quartic interaction terms.

As before, the discussion can be generalized to nonabelian theories, although there are additional problems to be discussed later. If we have a local symmetry group $G$ that breaks spontaneously to leave an unbroken subgroup $H$, then the gauge fields associated with $H$ remain massless. Each of the (dim $G$ – dim $H$) complementary fields "eats up" one of the Goldstone bosons, becoming massive in the process. We are left only with other, "radial" components of $\boldsymbol{\phi}$, the massive Higgs fields.

Consider, for example, a local SO(3) model, with scalar fields $\boldsymbol{\phi} = (\phi_a)_{a=1,2,3}$ and gauge potentials $\boldsymbol{A}_\mu = (A_{a\mu})$. The infinitesimal gauge transformations are

$$\delta\boldsymbol{\phi} = \boldsymbol{\delta\omega} \times \boldsymbol{\phi}, \qquad \delta\boldsymbol{A}_\mu = \boldsymbol{\delta\omega} \times \boldsymbol{A} - \frac{1}{e}\partial_\mu\boldsymbol{\delta\omega} \qquad [24]$$

where $\boldsymbol{\delta\omega}$ is the gauge parameter. The Lagrangian is

$$\mathcal{L} = \tfrac{1}{2}D_\mu\boldsymbol{\phi}\cdot D^\mu\boldsymbol{\phi} - \tfrac{1}{4}\boldsymbol{F}_{\mu\nu}\cdot\boldsymbol{F}^{\mu\nu} - \tfrac{1}{8}\lambda(\boldsymbol{\phi}^2 - \eta^2)^2 \qquad [25]$$

where the covariant derivative and gauge field are

$$\begin{aligned}D_\mu\boldsymbol{\phi} &= \partial_\mu\boldsymbol{\phi} + e\boldsymbol{A}_\mu \times \boldsymbol{\phi} \\ \boldsymbol{F}_{\mu\nu} &= \partial_\mu\boldsymbol{A}_\nu - \partial_\nu\boldsymbol{A}_\mu + e\boldsymbol{A}_\mu \times \boldsymbol{A}_\nu\end{aligned} \qquad [26]$$

If we take $\langle\hat{\boldsymbol{\phi}}\rangle$ in the 3-direction, the fields $A_{1\mu}$ and $A_{2\mu}$ absorb the Goldstone fields $\phi_1$, $\phi_2$ to become massive. As in the abelian case, we can use the local SO(3) invariance to rotate $\boldsymbol{\phi}$ everywhere to the 3-direction, and write $\boldsymbol{\phi} = (0, 0, \eta + \varphi_3)$. In this gauge the kinetic term $(1/2)(e\boldsymbol{A}_\mu \times \boldsymbol{\phi})^2$ gives a mass $e\eta$ to the fields $A_{1\mu}, A_{2\mu}$ while $A_{3\mu}$ remains massless, and the Higgs field $\varphi_3$ again has mass $\sqrt{\lambda}\eta$.

## Elitzur's Theorem; the Role of Gauge Fixing

The concept of spontaneous symmetry breaking in the context of a local symmetry requires further discussion, in particular because of Elitzur's theorem, proved in 1975, which states in essence that "spontaneous breaking of a local symmetry is impossible." In the light of this theorem, it may seem that a "spontaneously broken gauge theory" is an oxymoron. In fact, it means something rather different, although even that is not unproblematic.

The theorem was proved in the context of lattice gauge theory, where the spatial continuum is replaced by a discrete lattice. The scalar field is then represented by values $\boldsymbol{\phi}_x$ at each lattice site, and the gauge potential by values $\boldsymbol{A}_{x,\mu}$ on the links of the lattice. This is significant because on the lattice one can use a manifestly gauge-invariant formalism. Expectation values of gauge-invariant physical variables can be found, for example, by a Monte Carlo algorithm that effectively averages over all possible gauges. In this context, it is possible to show that the expectation value of any gauge-noninvariant operator (such as $\hat{\boldsymbol{\phi}}_x$) necessarily vanishes identically.

To be more specific, suppose we incorporate a symmetry-breaking term of the form $-\boldsymbol{j}\cdot\sum_x \boldsymbol{\phi}_x$, and consider the limits $\mathcal{V}\to\infty$ followed by $\boldsymbol{j}\to\boldsymbol{0}$. In the global-symmetry case, as we noted earlier, this yields the nonzero result [13]. However, in the case of a local gauge symmetry, one can show rigorously that

$$\lim_{j\to 0}\lim_{\mathcal{V}\to\infty}\langle\hat{\boldsymbol{\phi}}_x\rangle_{jn} = \boldsymbol{0} \qquad [27]$$

The essential reason for this is that we can make a gauge transformation in the neighborhood of the point $x$ to make $\boldsymbol{\phi}_x$ have any value we like without changing the energy by more than a very small amount that goes to zero as $j\to 0$. Within this manifestly gauge-invariant formalism, it is clear that the expectation value of a gauge-noninvariant operator such as $\hat{\boldsymbol{\phi}}$ is not an appropriate order parameter. One must instead look for a gauge-invariant order parameter.

It is important to note, however, that this result applies only in the context of a manifestly gauge-invariant formalism. But, in general, gauge theories cannot be quantized in a manifestly gauge-invariant way. In a path-integral formalism, the action functional, which appears in the exponent, is constant along the orbits of the gauge-group action. Consequently, the integral contains an infinite factor, the volume of the (infinite-dimensional) gauge group. There are corresponding divergences in the perturbation series. As is well known, this problem can be dealt with by introducing a gauge-fixing term, which explicitly breaks the gauge symmetry, and renders Elitzur's theorem inapplicable. But this procedure leaves a global symmetry unbroken, and it is in fact that global symmetry that is broken spontaneously.

One example is the Landau–Ginzburg model of a superconductor, which is essentially just the non-relativistic limit of the abelian Higgs model, although there is one significant difference: here the field $\hat{\phi}$ annihilates a Cooper pair, a bound pair of electrons with equal and opposite momenta and spins, so $e$ above is replaced by the charge $2e$ of a Cooper pair. The appearance of a condensate of Cooper pairs in the low-temperature superconducting phase corresponds to a state in which $\langle\hat{\phi}\rangle$ is nonzero. This would not be possible without fixing a gauge. In the nonrelativistic context, the obvious gauge to choose is the Coulomb gauge, defined by the condition $\partial_k A^k = 0$. This gauge-fixing condition breaks the local symmetry explicitly, but it leaves unbroken the global symmetry $\phi(x)\to\phi(x)\mathrm{e}^{\mathrm{i}\alpha}$ with constant $\alpha$. It is that global symmetry that is spontaneously broken when $\langle\hat{\phi}\rangle\neq 0$.

For a model with nonabelian local symmetry the standard procedure used to derive a perturbation expansion is that of Faddeev and Popov. Consider, for example, the SO(3) gauge theory discussed in the preceding section. To fix the gauge, we can choose a set of functions $\boldsymbol{F}=(F_a)$ of the fields, and introduce into the path integral a gauge-fixing term of the form

$$\mathcal{L}_{\mathrm{gf}} = -\frac{1}{2\xi}\boldsymbol{F}^2 \qquad [28]$$

where $\xi$ is an arbitrary real constant. However, to ensure that this does not bias the integral, so that the gauge-fixed theory is at least formally equivalent to the original gauge-invariant theory, one must also include the determinant of the Jacobian matrix

$$J_{ab}(x,y) = \frac{\delta F_a(x)}{\delta\omega_b(y)} \qquad [29]$$

The easiest way to do this is to introduce Faddeev–Popov ghost fields $\bar{\mathbf{C}},\mathbf{C}$, which are scalar Grassmann variables, and an appropriate term in the Lagrangian

$$\mathcal{L}_{\mathrm{FP}} = \bar{\boldsymbol{C}}\cdot\boldsymbol{J}\cdot\boldsymbol{C} \qquad [30]$$

For the SO(3) model, a convenient choice of gauge is the $R_\xi$ gauge defined by

$$\boldsymbol{F} = \partial_\mu\boldsymbol{A}^\mu - \xi e\eta\,\boldsymbol{n}\times\boldsymbol{\phi} \qquad [31]$$

where $\boldsymbol{n}$ is an arbitrarily chosen unit vector. It is clear that the full Lagrangian $\mathcal{L} + \mathcal{L}_{\text{gf}} + \mathcal{L}_{\text{FP}}$ is no longer invariant under the full SO(3) gauge group, although there is a residual U(1) gauge invariance corresponding to rotations about $\boldsymbol{n}$. In this gauge, the arbitrary choice of $\boldsymbol{n}$ means that the global SO(3) symmetry is also broken. However, for other choices, such as the Lorentz gauge $\boldsymbol{F} = \partial_\mu \boldsymbol{A}^\mu$ or axial gauge $\boldsymbol{F} = \boldsymbol{A}_3$, the Lagrangian *is* invariant under global SO(3) rotations of all the fields. This global symmetry is then spontaneously broken, with $\hat{\boldsymbol{\phi}}$ acquiring as before a nonzero expectation value of the form $\langle \hat{\boldsymbol{\phi}}(x) \rangle = \eta \boldsymbol{n}$.

It is interesting to look again at the particle content of this model. By setting $\boldsymbol{\phi}(x) = \eta \boldsymbol{n} + \boldsymbol{\varphi}(x)$ with $\boldsymbol{n} = (0, 0, 1)$, one finds that in the quadratic part of the Lagrangian, the cross-terms between $\boldsymbol{A}_\mu$ and $\boldsymbol{\varphi}$ combine to form a total divergence which can be dropped. As before, $\varphi_3$ is the Higgs field, with $m^2 = \lambda\eta^2$, $A_{3\mu}$ is the massless gauge field corresponding to the unbroken gauge symmetry, and the three transverse components of $A_{1\mu}$ and $A_{2\mu}$ represent the massive vector fields, with $m^2 = e^2\eta^2$. There are, however, also unphysical fields with $\xi$-dependent masses: $\varphi_{1,2}, C_{1,2}, \bar{C}_{1,2}$, and the longitudinal components $\partial_\mu A^\mu_{1,2}$ all have $m^2 = \xi e^2 \eta^2$. We can now compute the effective potential $V_{\text{eff}}(T, \boldsymbol{\varphi})$. One point that should be noted in performing this calculation is that the ghost fields $\boldsymbol{C}, \bar{\boldsymbol{C}}$ contribute negatively. Obviously, $V_{\text{eff}}$, being $\xi$-dependent, is not itself physically meaningful. Nevertheless, it can be shown that the stationary points of $V_{\text{eff}}$ are physical, and correspond to the possible equilibrium states of the theory. Moreover, the extremal values of $V_{\text{eff}}$ are independent of $\xi$ and give correctly the thermodynamic potential in the corresponding equilibrium states. The negative contributions from the ghost fields to $N_*$ and $M_*^2$ ensure that the $\xi$ dependence cancels out, and we find as expected $N_* = 9$ and $M_*^2 = (\lambda + 6e^2)\eta^2$.

## Phase Transitions and Crossovers

Our discussion so far has for the most part been restricted to a semiclassical or mean-field approximation. It is important to bear in mind, however, that this approximation does not suffice to determine whether a phase transition (where the thermodynamic free energy is nonanalytic) exists, or what its nature is. Determining the detailed characteristics of phase transitions requires other methods, such as the renormalization group or lattice simulations. In many cases, it is far from trivial to establish the order of the transition, or even whether a true phase transition actually exists.

Gauge theories pose particular problems because of the infrared divergences in the thermal field theory at high temperature, and because in asymptotically free nonabelian theories the coupling becomes large at very low energy. Even when they appear to exhibit spontaneous symmetry breaking, they do not necessarily undergo a true phase transition. Lattice gauge theory calculations have led to the conclusion that in nonabelian gauge theories with the Higgs field in the fundamental representation, there are values of the coupling constants for which there is no phase transition, only a rapid but smooth crossover from one type of behavior to another, so that the high- and low-temperature phases are analytically connected. If the coupling constant is small, there is a first-order phase transition, and for moderate values the theory exhibits a very rapid crossover that looks quite similar to a symmetry-breaking phase transition. Nevertheless, the analytic connection between the two phases implies that there cannot exist an order parameter that is strictly zero above the transition and nonzero below it.

In particular, it appears that for physical values of the Higgs mass, the electroweak theory does not undergo in fact undergo a true phase transition. It is somewhat ironic that the most famous example of a spontaneously broken gauge theory probably does not, strictly speaking, exhibit a symmetry-breaking phase transition!

## Conclusions

We have discussed the main features of spontaneous symmetry breaking in both the global- and local-symmetry cases, especially the appearance of Goldstone bosons when a continuous global symmetry breaks, and their elimination in the local-symmetry case by the Higgs mechanism, as well as the problems attaching to the concept of spontaneous symmetry breaking in gauge theories.

# Symmetry Classes in Random Matrix Theory

**M R Zirnbauer**, Universität Köln, Köln, Germany

## Introduction

A classification of random matrix ensembles by symmetries was first established by Dyson, in an influential 1962 paper with the title "the threefold way: algebraic structure of symmetry groups and ensembles in quantum mechanics." Dyson's threefold way has since become fundamental to various areas of theoretical physics, including the statistical theory of complex many-body systems, mesoscopic physics, disordered electron systems, and the field of quantum chaos.

Over the last decade, a number of random matrix ensembles beyond Dyson's classification have come to the fore in physics and mathematics. On the physics side, these emerged from work on the low-energy Dirac spectrum of quantum chromodynamics (QCD) and from the mesoscopic physics of low-energy quasiparticles in disordered superconductors. In the mathematical research area of number theory, the study of statistical correlations in the values of Riemann zeta and similar functions has prompted some of the same generalizations.

In this article, Dyson's fundamental result will be reviewed from a modern perspective, and the recent extension of Dyson's threefold way will be motivated and described. In particular, it will be explained why symmetry classes are associated with large families of symmetric spaces.

## The Framework

Random matrices have their physical origin in the quantum world, more precisely in the statistical theory of strongly interacting many-body systems such as atomic nuclei. Although random matrix theory is nowadays understood to be of relevance to numerous areas of physics – *see* Random Matrix Theory in Physics – quantum mechanics is still where many of its applications lie. Quantum mechanics also provides a natural framework in which to classify random matrix ensembles.

Following Dyson, the mathematical setting for classification consists of two pieces of data:

- A finite-dimensional complex vector space $V$ with a Hermitian scalar product $\langle \cdot, \cdot \rangle$, called a "unitary structure" for short. (In physics applications, $V$ will usually be the truncated Hilbert space of a family of quantum Hamiltonian systems.)
- On $V$ there acts a group $G$ of unitary and antiunitary operators (the joint symmetry group of the multiparameter family of quantum systems).

Given this setup, one is interested in the linear space of self-adjoint operators on $V$ – the Hamiltonians $H$ – with the property that they commute with the $G$-action. Such a space is reducible in general, that is, the matrix of $H$ decomposes into blocks. The goal of classification is to list all of the irreducible blocks that occur.

### Symmetry Groups

Basic to classification is the notion of a symmetry group in quantum Hamiltonian systems, a notion that will now be explained.

In classical mechanics, the symmetry group $G_0$ of a Hamiltonian system is understood to be the group of canonical transformations that commute with the phase flow of the system. An important example is the rotation group for systems in a central field.

In passing from classical to quantum mechanics, one replaces the classical phase space by a quantum-mechanical Hilbert space $V$ and assigns to the symmetry group $G_0$ a (projective) representation by unitary $\mathbb{C}$-linear operators on $V$. Besides the one-parameter continuous subgroups, whose significance is highlighted by Noether's theorem, the components of $G_0$ not connected with the identity play an

important role. A prominent example is provided by the operator for space reflection. Its eigenspaces are the subspaces of states with positive and negative parity; these reduce the matrix of any reflection-invariant Hamiltonian to two blocks.

Not all symmetries of a quantum-mechanical system are of the canonical, unitary kind: the prime counterexample is the operation of inverting the time direction, called time reversal for short. In classical mechanics, this operation reverses the sign of the symplectic structure of phase space; in quantum mechanics, its algebraic properties reflect the fact that inverting the time direction, $t \mapsto -t$, amounts to sending $\mathrm{i} = \sqrt{-1}$ to $-\mathrm{i}$. Indeed, time $t$ enters in the Dirac, Pauli, or Schrödinger equation as $\mathrm{i}\hbar\mathrm{d}/\mathrm{d}t$. Therefore, time reversal is represented in the quantum theory by an antiunitary operator $T$, which is to say that $T$ is complex antilinear:

$$T(zv) = \bar{z}Tv \quad (z \in \mathbb{C}, v \in V)$$

and preserves the Hermitian scalar product or unitary structure up to complex conjugation:

$$\langle Tv_1 \, , Tv_2 \rangle = \overline{\langle v_1 \, , v_2 \rangle} = \langle v_2 \, , v_1 \rangle$$

Another operation of this kind is charge conjugation in relativistic theories such as the Dirac equation.

By the symmetry group $G$ of a quantum-mechanical system with Hamiltonian $H$, one then means the group of all unitary and antiunitary transformations $g$ of $V$ that leave the Hamiltonian invariant: $gHg^{-1} = H$. We denote the unitary subgroup of $G$ by $G_0$, and the set of antiunitary operators in $G$ by $G_1$ (not a group). If $V$ carries extra structure, as will be the case for some extensions of Dyson's basic scheme, the action of $G$ on $V$ has to be compatible with that structure.

The set $G_1$ may be empty. When it is not, the composition of any two elements of $G_1$ is unitary, so every $g \in G_1$ can be obtained from a fixed element of $G_1$, say $T$, by right multiplication with some $U \in G_0$: $g = TU$. In other words, when $G_1$ is nonempty the coset space $G/G_0$ consists of exactly two elements, $G_0$ and $T \cdot G_0 = G_1$. We shall assume that $T$ represents some inversion symmetry such as time reversal or charge conjugation. $T$ must then be a (projective) involution, that is, $T^2 = z \times \mathrm{Id}$ with $z$ a complex number of unit modulus, so that conjugation by $T^2$ is the identity operation. Since $T$ is complex antilinear, the associative law $T^2 \cdot T = T \cdot T^2$ forces $z$ to be real, and hence $T^2 = \pm\mathrm{Id}$.

Finding the total symmetry group of a Hamiltonian system need not always be straightforward, but this complication will not be an issue here: we take the symmetry group $G$ and its action on the Hilbert space $V$ as fundamental and given, and then ask what are the corresponding symmetry classes, meaning the irreducible spaces of Hamiltonians on $V$ that commute with $G$.

For technical reasons, we assume the group $G_0$ to be compact; this is an assumption that covers most (if not all) of the cases of interest in physics. The noncompact group of space translations can be incorporated, if necessary, by wrapping the system around a torus, whereby translations are turned into compact torus rotations.

While the primary objects to classify are the spaces of Hamiltonians $H$, we shall focus for convenience on the spaces of time evolutions $U_t = \mathrm{e}^{-\mathrm{i}tH/\hbar}$ instead. This change of focus results in no loss, as the Hamiltonians can always be retrieved by linearizing in $t$ at $t = 0$.

### Symmetric Spaces

We appropriate a few basic facts from the theory of symmetric spaces.

Let $M$ be a connected $m$-dimensional Riemannian manifold and $p$ a point of $M$. In some open subset $N_p$ of a neighborhood of $p$ there exists a map $s_p : N_p \to N_p$, the geodesic inversion with respect to $p$, which sends a point $x \in N_p$ with normal coordinates $(x_1, \ldots, x_m)$ to the point with normal coordinates $(-x_1, \ldots, -x_m)$. The Riemannian manifold $M$ is called locally symmetric if the geodesic inversion is an isometry, and is called globally symmetric if $s_p$ extends to an isometry $s_p : M \to M$, for all $p \in M$. A globally symmetric Riemannian manifold is called a symmetric space for short.

The Riemann curvature tensor of a symmetric space is covariantly constant, which leads one to distinguish between three cases: the scalar curvature can be positive, zero, or negative, and the symmetric space is said to be of compact type, Euclidean type, or noncompact type, respectively. (In mesoscopic physics, each type plays a role: the first provides us with the scattering matrices and time evolutions, the second with the Hamiltonians, and the third with the transfer matrices.) The focus in the current article will be on compact type, as it is this type that houses the unitary time evolution operators of quantum mechanics. The compact symmetric spaces are subdivided into two major subtypes, both of which occur naturally in the present context, as follows.

### Type II

Consider first the case where the antiunitary component $G_1$ of the symmetry group is empty, so the data are $(V, G)$ with $G = G_0$. Let $\mathscr{U}(V)$ denote the group of all complex linear transformations that

leave the structure of the vector space $V$ invariant. Thus, $\mathscr{U}(V)$ is a group of unitary transformations if $V$ carries no more than the usual Hermitian scalar product; and is some subgroup of the unitary group if $V$ does have extra structure (as is the case for the Nambu space of quasiparticle excitations in a superconductor). The symmetry group $G_0$, by acting on $V$ and preserving its structure, is contained as a subgroup in $\mathscr{U}(V)$.

Let now $H$ be any Hamiltonian with the prescribed symmetries. Then the time evolution $t \mapsto U_t = e^{-itH/\hbar}$ generated by $H$ is a one-parameter subgroup of $\mathscr{U}(V)$ which commutes with the $G_0$-action. The total set of transformations $U_t$ that arise in this way is called the (connected part of the) "centralizer" of $G_0$ in $\mathscr{U}(V)$, and is denoted by $Z$. This is the "good" set of unitary time evolutions – the set compatible with the given symmetries of an ensemble of quantum systems.

The centralizer $Z$ is obviously a group: if $U$ and $U'$ belong to $Z$, then so do their inverses and their product. What can one say about the structure of the group $Z$?

Since $G_0$ is compact by assumption, its group action on $V$ is completely reducible and $V$ is guaranteed to have an orthogonal decomposition

$$V = \bigoplus_{\lambda} V_\lambda$$

where the sum runs over isomorphism classes of irreducible $G_0$-representations $\lambda$, and the vector spaces $V_\lambda$ are called the $G_0$-*isotypic* components of $V$. For example, if $G_0$ is the rotation group $SO_3$, the $G_0$-isotypic component $V_\lambda$ of $V$ is the subspace spanned by all the states with total angular momentum $\lambda$.

Consider now any $U \in Z$. Since $U$ commutes with the $G_0$-action, it does not connect different $G_0$-isotypic components. (Indeed, in the example of $SO_3$-invariant dynamics, angular momentum is conserved and transitions between different angular momentum sectors are forbidden.) Thus, every $G_0$-isotypic component $V_\lambda$ is an invariant subspace for the action of $Z$ on $V$, and $Z$ decomposes as $Z = \prod_\lambda Z_\lambda$ with blocks $Z_\lambda = Z|_{V_\lambda}$.

To say more, fix a standard irreducible $G_0$-module $R_\lambda$ of isomorphism class $\lambda$ and consider

$$L_\lambda := \mathrm{Hom}_{G_0}(R_\lambda, V_\lambda)$$

the linear space of $\mathbb{C}$-linear maps $l : R_\lambda \to V_\lambda$ that intertwine the $G_0$-actions on $R_\lambda$ and $V_\lambda$. An element of $L_\lambda$ is called a $G_0$-*equivariant homomorphism*. By Schur's lemma, $L_\lambda \cong \mathbb{C}$ if $V_\lambda$ is $G_0$-irreducible. More generally, $\dim L_\lambda =: m_\lambda$ counts the multiplicity of occurrence of $R_\lambda$ in $V_\lambda$; for example, in the case of $G_0 = SO_3$ we take $R_\lambda$ to be the standard irreducible module of dimension $2\lambda + 1$; and $m_\lambda$ then is the number of times a multiplet of states with total angular momentum $\lambda$ occurs in $V_\lambda$.

The natural mapping $L_\lambda \otimes R_\lambda \to V_\lambda$ by $l \otimes r \mapsto l(r)$ is an isomorphism,

$$V_\lambda \cong L_\lambda \otimes R_\lambda$$

and using it we can transfer the entire discussion from $V_\lambda$ to $L_\lambda \otimes R_\lambda$. The group $G_0$ acts trivially on $L_\lambda \cong \mathbb{C}^{m_\lambda}$ and irreducibly on $R_\lambda$. Therefore, the component $Z_\lambda$ of the centralizer $Z$ is the unitary group

$$Z_\lambda \cong \mathrm{U}(L_\lambda) \cong \mathrm{U}_{m_\lambda}$$

if $V$ is a unitary vector space with no extra structure. In the presence of extra structure (which, by compatibility with the $G_0$-action, restricts to every subspace $V_\lambda$), the factor $Z_\lambda$ is some subgroup of $\mathrm{U}_{m_\lambda}$. In all cases, $Z$ is a direct product of connected compact Lie groups $Z_\lambda$.

To make the connection with symmetric spaces, write $M := Z_\lambda$. Since $M$ is a group, the operation of taking the inverse, $U \mapsto U^{-1}$, makes sense for all $U \in M$. Moreover, being a compact Lie group, the manifold $M$ admits a left- and right-invariant Riemannian structure in which the inversion $U \mapsto U^{-1}$ is an isometry. By translation, one gets an isometry $s_{U_1} : U \mapsto U_1 U^{-1} U_1$ for every $U_1 \in M$. All of these maps $s_{U_1}$ are globally defined, and the restriction of $s_{U_1}$ to some neighborhood of $U_1$ coincides with the geodesic inversion with respect to $U_1$. Thus, $M$ is a symmetric space by the definition given above. Symmetric spaces of this kind are called type II.

### Type I

Consider next the case of $G_1 \neq \emptyset$, where some antiunitary symmetry $T$ is present. As before, let $Z$ be the connected component of the centralizer of $G_0$ in $\mathscr{U}(V)$. Conjugation by $T$,

$$U \mapsto \tau(U) := TUT^{-1}$$

is an automorphism of $\mathscr{U}(V)$ and, owing to $T^2 = \pm \mathrm{Id}$, $\tau$ is involutive. Because $G_0 \subset G$ is a normal subgroup, $\tau$ restricts to an involutive automorphism (still denoted by $\tau$) of $Z$. Now recall that $T$ is complex antilinear and the good Hamiltonians are subject to $THT^{-1} = H$. The good time evolutions $U_t = e^{-itH/\hbar}$ clearly satisfy $\tau(U_t) = U_{-t} = U_t^{-1}$. Thus, the good set to consider is $\mathscr{M} := \{U \in Z \mid U = \tau(U)^{-1}\}$. The set $\mathscr{M}$ is a manifold, but in general is not a Lie group.

Further details depend on what $\tau$ does with the factorization $Z = \prod_\lambda Z_\lambda$. If $V_\lambda$ is a $G_0$-isotypic

component of $V$, then so is $TV_\lambda$, since $T$ normalizes $G_0$. Thus, either $V_\lambda \cap TV_\lambda = 0$, or $TV_\lambda = V_\lambda$. In the former case, the involutive automorphism $\tau$ just relates $U \in Z_\lambda$ with $\tau(U) \in Z_{TV_\lambda}$, whence no intrinsic constraint on $Z_\lambda$ results, and the time evolutions $(U, \tau(U)^{-1}) \in Z_\lambda \times Z_{TV_\lambda}$ constitute a type-II symmetric space, as before.

A novel situation occurs when $TV_\lambda = V_\lambda$, in which case $\tau$ restricts to an automorphism of $Z_\lambda$. Let therefore $TV_\lambda = V_\lambda$, put $K \equiv Z_\lambda$ for short, and consider

$$M := \{U \in K | U = \tau(U)^{-1}\}$$

Note that if two elements $p, p_0$ of $K$ are in $M$, then so is the product $p_0 p^{-1} p_0$. The group $K$ acts on $M \subset K$ by

$$k \cdot U = kU\tau(k)^{-1} \quad (k \in K)$$

and this group action is transitive, that is, every $U \in M$ can be written as $U = k\tau(k)^{-1}$ with some $k \in K$. (Finding $k$ for a given $U$ is like taking a square root, which is possible since $\exp : \mathrm{Lie}\, K \to K$ is surjective.) There exists such a $K$-invariant Riemannian structure for $M$ that for all $p_0 \in M$ the mapping $s_{p_0} : M \to M$ defined by

$$s_{p_0}(p) = p_0 p^{-1} p_0$$

is the geodesic inversion with respect to $p_0 \in M$. Thus, in this natural geometry $M$ is a globally symmetric Riemannian manifold and hence a symmetric space. The present kind of symmetric space is called type I. If $K_\tau$ is the set of fixed points of $\tau$ in $K$, the symmetric space $M$ is analytically diffeomorphic to the coset space $K/K_\tau$ by

$$K/K_\tau \to M \subset K, \qquad UK_\tau \mapsto U\tau(U)^{-1}$$

which we call the "Cartan embedding" of $K/K_\tau$ into $K$.

In summary, the solution to the problem of finding the set of unitary time evolution operators that are compatible with a given symmetry group $G$ and structure of Hilbert space $V$ is always a symmetric space. This is a valuable insight, as symmetric spaces are rigid objects and have been completely classified by Cartan.

If the dimension of $V$ is kept variable, the irreducible symmetric spaces that occur belong to one of the large families listed in Table 1.

**Table 1** The large families of symmetric spaces. The form of $H$ in the header applies to the last seven families

| *Family* | *Symmetric space* | *Form of* $H = \begin{pmatrix} W & Z \\ Z^\dagger & -\bar{W} \end{pmatrix}$ |
|---|---|---|
| $A$ | $\mathrm{U}_N$ | Complex Hermitian |
| $A$I | $\mathrm{U}_N/\mathrm{O}_N$ | Real symmetric |
| $A$II | $\mathrm{U}_{2N}/\mathrm{USp}_{2N}$ | Quaternion self-adjoint |
| $C$ | $\mathrm{USp}_{2N}$ | $Z$ complex symmetric, $W = W^\dagger$ |
| $C$I | $\mathrm{USp}_{2N}/\mathrm{U}_N$ | $Z$ complex symmetric, $W = 0$ |
| $D$ | $\mathrm{SO}_{2N}$ | $Z$ complex skew, $W = W^\dagger$ |
| $D$III | $\mathrm{SO}_{2N}/\mathrm{U}_N$ | $Z$ complex skew, $W = 0$ |
| $A$III | $\mathrm{U}_{p+q}/\mathrm{U}_p \times \mathrm{U}_q$ | $Z$ complex $p \times q$, $W = 0$ |
| $BD$I | $\mathrm{SO}_{p+q}/\mathrm{SO}_p \times \mathrm{SO}_q$ | $Z$ real $p \times q$, $W = 0$ |
| $C$II | $\mathrm{USp}_{2p+2q}/\mathrm{USp}_{2p} \times \mathrm{USp}_{2q}$ | $Z$ quaternion $2p \times 2q$, $W = 0$ |

## Dyson's Threefold Way

Recall the goal: given a Hilbert space $V$ and a symmetry group $G$ acting on it, one wants to classify the (irreducible) spaces of time evolution operators $U$ that are "compatible" with $G$, meaning

$$U = g_0 U g_0^{-1} = g_1 U^{-1} g_1^{-1} \quad (\text{for all } g_\sigma \in G_\sigma)$$

As we have seen, the spaces that arise in this way are symmetric spaces of type I or II depending on the nature of the time reversal (or other antiunitary symmetry) $T$.

An even stronger statement can be made when more information about the Hilbert space $V$ is specified. In Dyson's classification, the Hermitian scalar product of $V$ is assumed to be the only invariant structure that exists on $V$. With that assumption, only three large families of symmetric spaces arise; these correspond to what we call the "Wigner–Dyson symmetry classes."

### Class *A*

Recall that in Dyson's case, the connected part of the centralizer of $G_0$ in $\mathscr{U}(V)$ is a direct product of unitary groups, each factor being associated with one $G_0$-isotypic component $V_\lambda$ of $V$. The type-II situation occurs when the set $G_1$ of antiunitary symmetries is either empty or else exchanges different $V_\lambda$. In both cases, the set of good time evolution operators restricted to one $G_0$-isotypic component $V_\lambda$ is a unitary group $\mathrm{U}_{m_\lambda}$, with $m_\lambda$ being the multiplicity of the irreducible $G_0$-representation $\lambda$ in $V_\lambda$.

The unitary groups $\mathrm{U}_{N=m_\lambda}$ or, to be precise, their simple parts $\mathrm{SU}_N$, are called type-II symmetric spaces of the $A$ family or $A$ series – hence the name class $A$. The Hamiltonians $H$, the generators of time evolutions $U_t = \mathrm{e}^{-itH/\hbar}$, in this class are represented by

complex Hermitian $N \times N$ matrices. By putting a $U_N$-invariant Gaussian probability measure

$$\exp\left(-\mathrm{tr}H^2/2\sigma^2\right) \mathrm{d}H \quad (\sigma \in \mathbb{R})$$

on that space, one gets what is called the GUE – the Gaussian unitary ensemble – which defines the Wigner–Dyson universality class of unitary symmetry.

### Classes *A*I and *A*II

Consider next the case $G_1 \neq \emptyset$, with antiunitary generator $T$. Let $V_\lambda = TV_\lambda$ be any $G_0$-isotypic component of $V$ invariant under $T$ (the type-I situation). The mapping $U \mapsto TUT^{-1} = \tau(U)$ then is an automorphism of the groups $U(V_\lambda), G_0$ and $K = Z_\lambda \cong U_{m_\lambda}$. If $K_\tau$ is the subgroup of fixed points of $\tau$ in $K$, the space of good time evolutions can be identified with the symmetric space $K/K_\tau$ by the Cartan embedding. Our task is to determine $K_\tau$.

To simplify the notation let us write $V_\lambda \equiv V, R_\lambda \equiv R$, and $L_\lambda \equiv L$. We now ask what happens with $T: V \to V$ in the process of transfer to $L \otimes R \cong V$. The answer, so we claim, is that $T$ transfers to a *pure* tensor made from antiunitary maps $\alpha: L \to L$ and $\beta: R \to R$,

$$T = \alpha \otimes \beta$$

To prove this claim, let $C$ be the antilinear map from $V$ to the *dual* vector space $V^*$ by $v \mapsto \langle v, \cdot \rangle$. Because the elements of $G_0$ are represented by unitaries, the $\mathbb{C}$-linear operator $CT: V \to V^*$ intertwines $G_0$-actions:

$$CT\, a(g) = g^{-1^*} CT \quad (g \in G_0)$$

where $a$ is the automorphism $a(g) = T^{-1}gT$. From the irreducibility of $R$ it follows that the space of intertwiners $R \to R^*$ is one dimensional here (Schur's lemma). Therefore, $CT: L \otimes R \to L^* \otimes R^*$ must be a pure tensor (as opposed to a sum of such tensors), and since $C$ is clearly a pure tensor, so is $T$. This completes the proof.

By the involutive property $T^2 = \varepsilon_T \mathrm{Id}_V\, (\varepsilon_T = \pm 1)$, the two antiunitary factors of $T = \alpha \otimes \beta$ cannot but square to $\alpha^2 = \varepsilon_\alpha \mathrm{Id}_L$ and $\beta^2 = \varepsilon_\beta \mathrm{Id}_R$ where $\varepsilon_\alpha, \varepsilon_\beta = \pm 1$ are related by $\varepsilon_\alpha \varepsilon_\beta = \varepsilon_T$. The factor $\alpha$ determines a nondegenerate complex bilinear form $Q: L \times L \to \mathbb{C}$ by

$$Q(l_1, l_2) = \langle \alpha l_1, l_2 \rangle_L \quad (l_1, l_2 \in L)$$

Since $\alpha$ is antiunitary one has the exchange symmetry

$$Q(l_1, l_2) = \overline{\langle \alpha^2 l_1, \alpha l_2 \rangle}_L = \varepsilon_\alpha\, Q(l_2, l_1)$$

Thus, the complex bilinear form (or pairing) $Q$ is symmetric for $\varepsilon_\alpha = +1$ and alternating for $\varepsilon_\alpha = -1$.

Knowing the sign of $\varepsilon_\alpha = \pm 1$ we know the group $K_\tau$. Indeed, an element $k \in K_\tau$ commutes with $T$ and after transfer from $V$ to $L$ still commutes with $\alpha$. But since $K_\tau$ is a subgroup of $K = U_{m_\lambda}$, this means that $k \in K_\tau$ preserves $Q$. In the case of $\varepsilon_\alpha = +1$, what is preserved is a symmetric pairing, and therefore $K_\tau \cong O_{m_\lambda}$. For $\varepsilon_\alpha = -1$, the multiplicity $m_\lambda$ must be even and $K_\tau$ preserves an alternating pairing (or symplectic structure); in that case $K_\tau \cong \mathrm{USp}_{m_\lambda}$, the unitary symplectic group.

Thus, there is a dichotomy for the sets of good time evolutions $M \cong K/K_\tau$:

$$\text{Class } A\text{I}: \quad K/K_\tau \cong U_N/O_N \qquad (N = m_\lambda)$$
$$\text{Class } A\text{II}: \quad K/K_\tau \cong U_{2N}/\mathrm{USp}_{2N} \quad (2N = m_\lambda)$$

Again we are referring to symmetric spaces by the names they – or rather their simple parts $SU_N/SO_N$ and $SU_{2N}/\mathrm{USp}_{2N}$ – have in the Cartan classification.

In general, there is no immediate means of predicting the parity $\varepsilon_\alpha$, and one has no choice but to go through the steps of constructing $\alpha$. If $\beta: R \to R$ happens to be $G_0$-invariant, however, the situation simplifies. In that case $\beta$ determines a $G_0$-invariant pairing $R \times R \to \mathbb{C}$ (in the same way as $\alpha$ determines $Q: L \times L \to \mathbb{C}$ above). On general grounds, an irreducible $G_0$-representation space admits at most one such pairing. If that pairing is symmetric, then, as we have seen, $\varepsilon_\beta = 1$; if it is alternating, then $\varepsilon_\beta = -1$. The parity $\varepsilon_\alpha$ is given by $\varepsilon_\alpha \varepsilon_\beta = \varepsilon_T$.

**Example** Consider any physical system with spin-rotation symmetry ($G_0 = SU_2$) and time-reversal symmetry. The physical operation of time reversal, $T$, commutes with spin rotations and, hence, here is a case where the factor $\beta$ in $T = \alpha \otimes \beta$ is $G_0$-invariant. On fundamental physics grounds one has $T^2 = (-1)^{2S}$ on states with spin $S$. The spin-$S$ representation of $SU_2$ is known to carry an invariant pairing which is symmetric or skew depending on whether the integer $2S$ is even or odd. Therefore, $\varepsilon_T = \varepsilon_\beta$ and $\varepsilon_\alpha = +1$ in all cases.

Thus, $T$-invariant systems with no symmetries other than energy and spin invariably are class $A$I. By breaking spin-rotation symmetry ($G_0 = \{\mathrm{Id}\}$, $\varepsilon_\beta = +1$) while maintaining $T$-symmetry for states with half-integer spin (say single electrons, which carry spin $S = 1/2$), one gets $\varepsilon_\alpha = -1$, thereby realizing class $A$II.

**The Hamiltonians** By passing to the tangent space of $K/K_\tau$ at unity one obtains Hermitian matrices with entries that are real numbers (class $A$I) or real quaternions (class $A$II). When $K_\tau$-invariant Gaussian

probability measures (called GOE resp., GSE) are put on these spaces, one gets the Wigner–Dyson universality classes of orthogonal resp., symplectic symmetry. In mesoscopic physics, these are realized in disordered metals with time-reversal invariance (absence of magnetic fields and magnetic impurities). Spin-rotation symmetry is broken by strong spin–orbit scatterers such as gold impurities.

### Warning

The word "symmetry class" is not synonymous with "universality class." Indeed, inside a symmetry class many different types of physical behavior are possible. For example, random matrix models for disordered metallic grains with time-reversal symmetry belong to the symmetry class of the example above (class *A*I), and so do Anderson tight-binding models with real hopping. The former are known to exhibit energy level statistics of universal GOE type, whereas the latter have localized eigenfunctions and hence level statistics which is expected to approach the Poisson limit when the system size goes to infinity.

## Disordered Superconductors

When Dirac first wrote down his famous equation in 1928, he assumed that he was writing an equation for the wave function of the electron. Later, because of the instability caused by negative-energy solutions, the Dirac equation was reinterpreted (via second quantization) as an equation for the fermionic field operators of a quantum field theory. A similar change of viewpoint is carried out in reverse in the Hartree–Fock–Bogoliubov mean-field description of quasiparticle excitations in superconductors. There, one starts from the equations of motion for linear superpositions of the electron creation and annihilation operators, and reinterprets them as a unitary quantum dynamics for what might be called the quasiparticle "wave function."

In both cases – the Dirac equation and the quasiparticle dynamics of a superconductor – there enters a structure not present in the standard quantum mechanics underlying Dyson's classification: the field operators for fermionic particles are subject to a set of relations called the "canonical anticommutation relations," and these are preserved by the quantum dynamics. Therefore, whenever second quantization is undone (assuming it can be undone) to return from field operators to wave functions, the wave-function dynamics is required to preserve some extra structure. This puts a linear constraint on the good Hamiltonians $H$. For our purposes, the best viewpoint to take is to attribute the extra invariant structure to the Hilbert space $V$, thereby turning it into a Nambu space.

### Nambu Space

Adopting the standard physics conventions of second quantization, consider some set of single-particle creation and annihilation operators $c_i^\dagger$ and $c_i$, where $i = 1, 2, \ldots$ labels an orthonormal system of single-particle states. Such operators are subject to the canonical anticommutation relations (CARs)

$$\begin{aligned} c_i^\dagger c_j + c_j c_i^\dagger &= \delta_{ij} \\ c_i^\dagger c_j^\dagger + c_j^\dagger c_i^\dagger &= 0 = c_i c_j + c_j c_i \end{aligned} \qquad [1]$$

When written in terms of $c_j + c_j^\dagger$ and $\mathrm{i}(c_j - c_j^\dagger)$, these become the standard defining relations of a Clifford algebra over $\mathbb{R}$. Field operators are linear combinations $\boldsymbol{\psi} = \sum_i (u_i c_i + f_i c_i^\dagger)$ with complex coefficients $u_i$ and $f_i$.

Now take $H$ to be some Hamiltonian which is quadratic in the creation and annihilation operators:

$$H = \sum_{i,j} W_{ij} c_i^\dagger c_j + \frac{1}{2} \sum_{i,j} \left( Z_{ij} c_i^\dagger c_j^\dagger + \bar{Z}_{ij} c_j c_i \right)$$

and let $H$ act on field operators $\boldsymbol{\psi}$ by the commutator: $H \cdot \boldsymbol{\psi} \equiv [H, \boldsymbol{\psi}]$. The time evolution of $\boldsymbol{\psi}$ is then determined by the Heisenberg equation of motion

$$-\mathrm{i}\hbar \frac{\mathrm{d}\boldsymbol{\psi}}{\mathrm{d}t} = H \cdot \boldsymbol{\psi} \qquad [2]$$

which integrates to $\boldsymbol{\psi}(t) = \mathrm{e}^{\mathrm{i}tH/\hbar} \cdot \boldsymbol{\psi}(0)$, and is easily verified to preserve the CARs [1].

The dynamical equation [2] is equivalent to a system of linear differential equations for the amplitudes $u_i$ and $f_i$. If these are assembled into vectors, and the $W_{ij}$ and $Z_{ij}$ into matrices, eqn [2] becomes

$$-\mathrm{i}\hbar \frac{\mathrm{d}}{\mathrm{d}t} \begin{pmatrix} \boldsymbol{f} \\ \boldsymbol{u} \end{pmatrix} = \begin{pmatrix} W & Z \\ Z^\dagger & -\bar{W} \end{pmatrix} \begin{pmatrix} \boldsymbol{f} \\ \boldsymbol{u} \end{pmatrix}$$

The Hamiltonian matrix on the right-hand side has some special properties due to $Z_{ij} = -Z_{ji}$ (from $c_i c_j = -c_j c_i$) and $W_{ij} = \bar{W}_{ji}$ (from $H$ being self-adjoint as an operator in Fock space). To keep track of these properties while imposing some unitary and antiunitary symmetries, it is best to put everything in invariant form.

So, let $U$ be the unitary vector space of annihilation operators $u = \sum_i u_i c_i$, and view the creation operators $f = \sum_i f_i c_i^\dagger$ as lying in the dual vector space $U^*$. The field operators $\boldsymbol{\psi} = u + f$ then are elements of the direct sum $U \oplus U^* =: V$, called "Nambu

space." On $V$ there exists a canonical unitary structure expressed by

$$\langle \boldsymbol{\psi}, \tilde{\boldsymbol{\psi}} \rangle = \sum_i (\bar{u}_i \tilde{u}_i + \bar{f}_i \tilde{f}_i)$$

A second canonical structure on $V = U \oplus U^*$ is given by the symmetric complex bilinear form

$$\{\boldsymbol{\psi}, \tilde{\boldsymbol{\psi}}\} = \sum_i (\tilde{f}_i u_i + f_i \tilde{u}_i) = \tilde{f}(u) + f(\tilde{u})$$

where the last expression uses the meaning of $f$ as a linear function $f : U \to \mathbb{C}$. Note that $\{\boldsymbol{\psi}, \tilde{\boldsymbol{\psi}}\}$ agrees with the anticommutator of the field operators, $\boldsymbol{\psi}\tilde{\boldsymbol{\psi}} + \tilde{\boldsymbol{\psi}}\boldsymbol{\psi}$.

Now recall that the quantum dynamics is determined by a Hamiltonian $H$ that acts on $\boldsymbol{\psi}$ by the commutator $H \cdot \boldsymbol{\psi} = [H, \boldsymbol{\psi}]$. The one-parameter groups $t \mapsto e^{itH/\hbar}$ generated by this action (the time evolutions) preserve the symmetric pairing:

$$\{\boldsymbol{\psi}, \tilde{\boldsymbol{\psi}}\} = \{e^{itH/\hbar}\boldsymbol{\psi}, e^{itH/\hbar}\tilde{\boldsymbol{\psi}}\}$$

since the anticommutation relations [1] do not change with time. They also preserve the unitary structure,

$$\langle \boldsymbol{\psi}, \tilde{\boldsymbol{\psi}} \rangle = \left\langle e^{itH/\hbar}\boldsymbol{\psi}, e^{itH/\hbar}\tilde{\boldsymbol{\psi}} \right\rangle$$

because probability in Nambu space is conserved. (Physically speaking, this holds true as long as $H$ is quadratic, i.e., many-body interactions are negligible.)

One can now pose Dyson's question again: given Nambu space $V$ and a symmetry group $G$ acting on it, what is the set of time evolution operators that preserve the structure of $V$ and are compatible with $G$? From the section "The framework," we know the answer to be some symmetric space, but which are the symmetric spaces that occur?

### Class *D*

Consider a superconductor with no symmetries in its quasiparticle dynamics, so $G = \{\mathrm{Id}\}$. (A concrete example would be a disordered spin-triplet superconductor in the vortex phase.) The time evolutions $U_t = e^{itH/\hbar}$ are then constrained only by invariance of the unitary structure and the symmetric pairing $\{,\}$ of Nambu space. These two structures are consistent; they are related by particle–hole conjugation $C$:

$$\{\boldsymbol{\psi}, \tilde{\boldsymbol{\psi}}\} = \langle C\boldsymbol{\psi}, \tilde{\boldsymbol{\psi}} \rangle$$

which is an antiunitary operator with square $C^2 = +\mathrm{Id}$. Let $V_\mathbb{R} \subset V$ denote the real vector space of fixed points of $C$. (The field operators in $V_\mathbb{R}$ are called of "Majorana" type in physics.) The condition $\{\boldsymbol{\psi}, \tilde{\boldsymbol{\psi}}\} = \{U_t\boldsymbol{\psi}, U_t\tilde{\boldsymbol{\psi}}\}$ selects a complex orthogonal group $\mathrm{SO}(V)$, and imposing unitarity yields a real orthogonal subgroup $\mathrm{SO}(V_\mathbb{R})$ with $\dim V_\mathbb{R} \in 2\mathbb{N}$ – a symmetric space of the $D$ family.

When expressed in some basis of Majorana fermions (meaning a basis of $V_\mathbb{R}$), the matrix of the time evolution generator $iH \in \mathfrak{so}(V_\mathbb{R})$ is real skew, and that of $H$ imaginary skew. The simplest random matrix model for class $D$, the SO-invariant Gaussian ensemble of imaginary skew matrices, is analyzed in the second edition of Mehta's (1991) book. From the expressions given by Mehta it is seen that the level correlation functions at high energy coincide with those of the Wigner–Dyson universality class of unitary symmetry. The level correlations at low energy, however, show different behavior defining a separate universality class. This universal behavior at low energies has immediate physical relevance, as it is precisely the low-energy quasiparticles that determine the thermal transport properties of the superconductor at low temperatures.

### Class *D*III

Let now magnetic fields and magnetic impurities be absent, so that time reversal $T$ is a symmetry of the quasiparticle system: $G = \{\mathrm{Id}, T\}$. Following the section "The framework," the set of good time evolutions is $M \cong K/K_\tau$ with $K = \mathrm{SO}(V_\mathbb{R})$ and $K_\tau$ the set of fixed points of $U \mapsto \tau(U) = TUT^{-1}$ in $K$. What is $K_\tau$?

The square of the time-reversal operator is $T^2 = -\mathrm{Id}$ (for particles with spin 1/2), and commutes with particle–hole conjugation $C$, which makes $P := iCT$ a useful operator to consider. Since $C$ by definition commutes with the action of $K$, and hence also with that of $K_\tau$, the subgroup $K_\tau$ has an equivalent description as

$$K_\tau = \{k \in \mathrm{U}(V) \mid k = PkP^{-1} = \tau(k)\}$$

The operator $P$ is easily seen to have the following properties: (1) $P$ is unitary, (2) $P^2 = \mathrm{Id}$, and (3) $\mathrm{tr}_V P = 0$. Consequently, $P$ possesses two eigenspaces $V_\pm$ of equal dimension, and the condition $k = PkP^{-1}$ fixes a subgroup $\mathrm{U}(V_+) \times \mathrm{U}(V_-)$ of $\mathrm{U}(V)$. Since $P$ contains a factor $i = \sqrt{-1}$ in its definition, it anticommutes with the antilinear operator $T$. Therefore, the automorphism $\tau$ exchanges $\mathrm{U}(V_+)$ with $\mathrm{U}(V_-)$, and the fixed-point set $K_\tau$ is the same as $\mathrm{U}(V_+) \cong \mathrm{U}_{2N}$. Thus,

$$M = K/K_\tau \cong \mathrm{SO}_{4N}/\mathrm{U}_{2N} \quad (\dim V_+ = 2N)$$

a symmetric space in the $D$III family. Note that for particles with spin 1/2 the dimension of $V_+$ has to be even.

By realizing the algebra of involutions $C, T$ as $C\boldsymbol{\psi} = (1_{2N} \otimes i\sigma_x)\bar{\boldsymbol{\psi}}$ and $T\boldsymbol{\psi} = (1_{2N} \otimes i\sigma_y)\bar{\boldsymbol{\psi}}$, the Hamiltonians $H$ in class $D$III are brought into the standard form

$$H = \begin{pmatrix} 0 & Z \\ -\bar{Z} & 0 \end{pmatrix}$$

where the $2N \times 2N$ matrix $Z$ is complex and skew.

### Class *C*

Next let the spin of the quasiparticles be conserved, as is the case for a spin-singlet superconductor with no spin–orbit scatterers present, and let time-reversal invariance be broken by a magnetic field. The symmetry group of the quasiparticle system then is the spin-rotation group: $G = G_0 = \mathrm{Spin}_3 = \mathrm{SU}_2$.

Nambu space $V$ can be arranged to be a tensor product $V = L \otimes R$ so that $G_0$ acts trivially on $L$ and by the spinor representation on the spinor space $R \equiv \mathbb{C}^2$. Since two spinors combine to give a scalar, the latter comes with an alternating bilinear form $a : R \times R \to \mathbb{C}$. In a suitable basis, the anticommutation relations [1] factor on particle–hole and spin indices. The symmetric bilinear form {,} of $V$ correspondingly factors under the tensor product decomposition $V = L \otimes R$ as

$$\{l_1 \otimes r_1, l_2 \otimes r_2\} = [l_1, l_2] \times a(r_1, r_2)$$

where [ , ] is an alternating form on $L$, giving $L$ the structure of a complex symplectic vector space.

The good set $M$ now consists of the time evolutions that, in addition to preserving the structure of Nambu space, commute with the spin-rotation group $\mathrm{SU}_2$:

$$M = \{U \in \mathrm{U}(V) | UC = CU, \forall g \in \mathrm{SU}_2 : gU = Ug\}$$

By the last condition, all time evolutions act trivially on the factor $R$. The condition $UC = CU$, which expresses invariance of the symmetric form of $V$, then implies that time evolutions preserve the alternating form of $L$. Time evolutions therefore are unitary symplectic transformations of $L$, hence $M = \mathrm{USp}(L) \cong \mathrm{USp}_{2N}$ – a symmetric space of the $C$ family. The Hamiltonian matrices in class $C$ have the standard form

$$H = \begin{pmatrix} W & Z \\ Z^\dagger & -\bar{W} \end{pmatrix}$$

with $W$ being Hermitian and $Z$ complex and symmetric.

### Class *C*I

The next class is obtained by taking the time reversal $T$ as well as the spin rotations $g \in \mathrm{SU}_2$ to be symmetries of the quasiparticle system.

By arguments that should be familiar by now, the set of good time evolutions is a symmetric space $M \cong K/K_\tau$ with $K = \mathrm{USp}(L)$ and $K_\tau$ the set of fixed points of $\tau$ in $K$. Once again, the question to be answered is: what is $K_\tau$? The situation here is very similar to the one for class $D$III, with $L$ and $\mathrm{USp}(L)$ taking the roles of $V$ and $\mathrm{SO}(V_\mathbb{R})$. By adapting the previous argument to the present case, one shows that $K_\tau$ is the same as $\mathrm{U}(L_+) \cong \mathrm{U}_N$, where $L_+$ is the positive eigenspace of $P = iCT$ viewed as a unitary operator on $L$. Thus,

$$M = K/K_\tau \cong \mathrm{USp}_{2N}/\mathrm{U}_N$$

## Dirac Fermions: The Chiral Classes

Three large families of symmetric spaces remain to be implemented. Although these, too, occur in mesoscopic physics, their most natural realization is by 4D Dirac fermions in a random gauge field background.

Consider the Lagrangian $\mathscr{L}$ for the Euclidean spacetime version of QCD with $N_c \geq 3$ colors of quarks coupled to an $\mathrm{SU}_{N_c}$ gauge field $A_\mu$:

$$\mathscr{L} = i\bar{\boldsymbol{\psi}}\gamma^\mu(\partial_\mu - A_\mu)\boldsymbol{\psi} + im\bar{\boldsymbol{\psi}}\boldsymbol{\psi}$$

The massless Dirac operator $D = i\gamma^\mu(\partial_\mu - A_\mu)$ anticommutes with $\gamma_5 = \gamma^0\gamma^1\gamma^2\gamma^3$. Therefore, in a basis of eigenstates of $\gamma_5$ the matrix of $D$ takes the form

$$D = \begin{pmatrix} 0 & Z \\ Z^\dagger & 0 \end{pmatrix} \quad [3]$$

If the gauge field carries topological charge $\nu \in \mathbb{Z}$, the Dirac operator $D$ has at least $|\nu|$ zero modes by the index theorem. To make a simple model of the challenging situation where $A_\mu$ is distributed according to Yang–Mills measure, one takes the matrices $Z$ to be complex rectangular, of size $p \times q$ with $p - q = \nu$, and puts a Gaussian probability measure on that space. This random matrix model for $D$ captures the universal features of the QCD Dirac spectrum in the massless limit.

The exponential of the truncated Dirac operator, $e^{itD}$ (where $t$ is not the time), lies in a space equivalent to $\mathrm{U}_{p+q}/\mathrm{U}_p \times \mathrm{U}_q$ – a symmetric space of the $A$III family. We therefore say that the universal behavior of the QCD Dirac spectrum is that of symmetry class $A$III.

But hold on! Why are we entitled to speak of a symmetry class here? By definition, symmetries

always *commute* with the Hamiltonian, never do they anticommute! (The relation $D = -\gamma_5 D \gamma_5$ is not a symmetry in the sense of Dyson, nor is it a symmetry in our sense.)

### Class *A*III

To incorporate the massless QCD Dirac operator into the present classification scheme, we adapt it to the Nambu space setting. This is done by reorganizing the four-component Dirac spinor $\boldsymbol{\psi}, \bar{\boldsymbol{\psi}}$ as an eight-component Majorana spinor $\Psi$, to write

$$\mathscr{L}_{m=0} = \frac{\mathrm{i}}{2}\Psi\Gamma^{\mu}(\partial_{\mu} - \mathscr{A}_{\mu})\Psi$$

The $8 \times 8$ matrices $\Gamma^{\mu}$ are real symmetric besides satisfying the Clifford relations $\Gamma^{\mu}\Gamma^{\nu} + \Gamma^{\nu}\Gamma^{\mu} = 2\delta^{\mu\nu}$. A possible tensor product realization is

$$\Gamma^0 = 1 \otimes \sigma_z \otimes 1, \quad \Gamma^1 = \sigma_x \otimes \sigma_y \otimes \sigma_y$$
$$\Gamma^2 = \sigma_y \otimes \sigma_y \otimes 1, \quad \Gamma^3 = \sigma_z \otimes \sigma_y \otimes \sigma_y$$

The gauge field in this Majorana representation is $\mathcal{A}_{\mu} = 1 \otimes 1 \otimes (A_{\mu}^{(-)} - A_{\mu}^{(+)}\sigma_y)$ where $A_{\mu}^{(\pm)} = (1/2)(A_{\mu} \pm A_{\mu}^{\mathrm{t}})$ are the symmetric and skew parts of $A_{\mu} \in \mathfrak{su}(N_c)$.

The operator $H = \mathrm{i}\Gamma^{\mu}(\partial_{\mu} - \mathscr{A}_{\mu})$ is imaginary skew, therefore $\mathrm{e}^{\mathrm{i}tH}$ is real orthogonal. This means that there exists a Nambu space $V$ with unitary structure $\langle , \rangle$ and symmetric pairing $\{ , \}$, both of which are preserved by the action of $\mathrm{e}^{\mathrm{i}tH}$. No change of physical meaning or interpretation is implied by the identical rewriting from Dirac $D$ to Majorana $H$. The fact that Dirac fermions are not truly Majorana is encoded in a $U_1$-symmetry $H\mathrm{e}^{\mathrm{i}\theta Q} = \mathrm{e}^{\mathrm{i}\theta Q}H$ generated by $Q = 1 \otimes 1 \otimes \sigma_y$.

Now comes the essential point: since $H$ obeys $\bar{H} = -H$, the chiral "symmetry" $H = -\Gamma_5 H \Gamma_5$ with $\Gamma_5 = 1 \otimes \sigma_x \otimes 1$ can be recast as a true symmetry:

$$H = +\Gamma_5 \bar{H} \Gamma_5 = THT^{-1}$$

with antilinear $T : \Psi \mapsto \Gamma_5 \bar{\Psi}$. Thus, the massless QCD Dirac operator is indeed associated with a symmetry class in the present, post-Dyson sense: that is class *A*III, realized by self-adjoint operators on Nambu space with Dirac $U_1$-symmetry and an antiunitary symmetry $T$.

### Classes *BD*I and CII

Consider Hamiltonians $D$ still of the form [3] but now with matrix entries taken from either the real numbers or the real quaternions. Their one-parameter groups $\mathrm{e}^{\mathrm{i}tD}$ belong to two further families of symmetric spaces, namely the classes *BD*I and CII of Table 1. These large families are known to be realized as symmetry classes by the massless Dirac operator with gauge group $SU_2$ (for *BD*I), or with fermions in the adjoint representation (for CII). For the details we must refer to Verbaarschot's (1994) paper and the recent article by Heinzner *et al.* (2005).

# Synchronization of Chaos

**M A Aziz-Alaoui**, Université du Havre, Le Havre, France

## Introduction: Chaotic Systems Can Synchronize

Synchronization is a ubiquitous phenomenon characteristic of many processes in natural systems and (nonlinear) science. It has permanently remained an objective of intensive research and is today considered as one of the basic nonlinear phenomena studied in mathematics, physics, engineering, or life science. This word has a Greek root, *syn* = common and *chronos* = time, which means to share the common time or to occur at the same time, that is, correlation or agreement in time of different processes (Boccaletti *et al.* 2002). Thus, synchronization of two dynamical systems generally means that one system somehow traces the motion of another. Indeed, it is well known that many coupled oscillators have the ability to adjust some common relation that they have between them due to weak interaction, which yields to a situation in which a synchronization-like phenomenon takes place.

The original work on synchronization involved periodic oscillators. Indeed, observations of (periodic) synchronization phenomena in physics go back at least as far as C Huygens (1673), who, during his experiments on the development of improved pendulum clocks, discovered that two very weakly coupled pendulum clocks become synchronized in phase: two clocks hanging from a common support (on the same beam of his room) were found to oscillate with exactly the same frequency and opposite phase due to the (weak) coupling in terms of the almost imperceptible oscillations of the beam generated by the clocks.

Since this discovery, periodic synchronization has found numerous applications in various domains, for instance, in biological systems and living nature where synchronization is encountered on different levels. Examples range from the modeling of the heart to the investigation of the circadian rhythm, phase locking of respiration with a mechanical ventilator, synchronization of oscillations of human insulin secretion and glucose infusion, neuronal information processing within a brain area and communication between different brain areas. Also, synchronization plays an important role in several neurological diseases such as epilepsies and pathological tremors, or in different forms of cooperative behavior of insects, animals, or humans (Pikovsky *et al.* 2001).

This process may also be encountered in celestial mechanics, where it explains the locking of revolution period of planets and satellites.

Its view was strongly broadened with the developments in radio engineering and acoustics, due to the work of Eccles and Vincent, 1920, who found synchronization of a triode generator. Appleton, Van der Pol, and Van der Mark, 1922–27, have, experimentally and theoretically, extended it and worked on radio tube oscillators, where they observed entrainment when driving such oscillators sinusoidally, that is, the frequency of a generator can be synchronized by a weak external signal of a slightly different frequency.

But, even though original notion and theory of synchronization implies periodicity of oscillators, during the last decades, the notion of synchronization has been generalized to the case of interacting chaotic oscillators. Indeed, the discovery of deterministic chaos introduced new types of oscillating systems, namely the chaotic generators.

Chaotic oscillators are found in many dynamical systems of various origins; the behavior of such systems is characterized by instability and, as a result, limited predictability in time.

Roughly speaking, a system is chaotic if it is deterministic, has a long-term aperiodic behavior, and exhibits sensitive dependence on initial conditions on a closed invariant set (the chaos theory is discussed in more detail elsewhere in this encyclopedia) (*see* Chaos and Attractors).

Consequently, for a chaotic system, trajectories starting arbitrarily close to each other diverge exponentially with time, and quickly become uncorrelated. It follows that two identical chaotic systems cannot synchronize. This means that they cannot produce identical chaotic signals, unless they are initialized at exactly the same point, which is in general physically impossible. Thus, at first sight, synchronization of chaotic systems seems to be rather surprising because one may intuitively (and naively) expect that the sensitive dependence on initial conditions would lead to an immediate breakdown of any synchronization of coupled chaotic systems. This scenario in fact led to the belief that chaos is uncontrollable and thus unusable. Despite this, in the last decades, the search for synchronization has moved to chaotic systems. Significant research has been done and, as a result, Yamada and Fujisaka (1983), Afraimovich *et al.* (1986), and Pecora and Carroll (1990) showed that

two chaotic systems could be synchronized by coupling them: synchronization of chaos is actual and chaos could then be exploitable. Ever since, many researchers have discussed the theory and the design or applications of synchronized motion in coupled chaotic systems. A broad variety of applications has emerged, for example, to increase the power of lasers, to synchronize the output of electronic circuits, to control oscillations in chemical reactions, or to encode electronic messages for secure communications.

The publication of the seminal paper of Pecora and Caroll (1990) had a very strong impact in the domain of chaos theory and chaos synchronization, and their applications. It had stimulated very intense research activities and the related studies continue to attract great attention. Many authors have contributed to developing this domain, theoretically or experimentally (Boccaletti *et al.* 2002, Pecorra *et al.* 1997, references therein).

However, the special features of chaotic systems make it impossible to directly apply the methods developed for synchronization of periodic oscillators. Moreover, in the topics of coupled chaotic systems, many different phenomena, which are usually referred to as synchronization, exist and have been studied now for over a decade. Thus, more precise descriptions of such systems are indeed desirable.

Several different regimes of synchronization have been investigated. In the following, the focus will be on explaining the essentials on this large topic, subdivided into four basic types of synchronization of coupled or forced chaotic systems which have been found and have received much attention, while emphasizing on the first three:

- identical (or complete) synchronization (IS), which is defined as the coincidence of states of interacting systems;
- generalized synchronization (GS), which extends the IS phenomenon and implies the presence of some functional relation between two coupled systems; if this relationship is the identity, we recover the IS;
- phase synchronization (PS), which means entrainment of phases of chaotic oscillators, whereas their amplitudes remain uncorrelated; and
- lag synchronization (LS), which appears as a coincidence of time-shifted states of two systems.

Other regimes exist, some of them will be briefly pointed out at the end of this article; we also will briefly discuss the very relevant issue of the stability of synchronous motions.

Our discussion and examples given here are based on unidirectionally continuous systems, most of the exposed ideas can be easily extended to discrete systems.

Let us also emphasize that the same year, 1990, saw the publication of another seminal paper, by Ott, Grebogi, and Yorke (OGY) on the control of chaos (Ott *et al.* 1990). Recently, it has been realized that synchronization and control of chaos share a common root in nonlinear control theory. Both topics were presented by many authors in a unified framework. However, synchronization of chaos has evolved in its own right, even if it is nowadays known as a part of the nonlinear control theory.

## Synchronization and Stability

For the basic master–slave configuration, where an autonomous chaotic system (the master)

$$\frac{dX}{dt} = F(X), \quad X \in \mathbb{R}^n \qquad [1]$$

drives another system (the slave),

$$\frac{dY}{dt} = G(X, Y), \quad Y \in \mathbb{R}^m \qquad [2]$$

synchronization takes place when $Y$ asymptotically copies, in a certain manner, a subset $X_p$ of $X$. That is, there exists a relation between the two coupled systems, which could be a smooth invertible function $\psi$, which transforms the trajectories on the attractor of a first system into those on the attractor of a second system. In other words, if we know, after a transient regime, the state of the first system, it allows us to predict the state of the second: $Y(t) = \psi(X(t))$. Generally, it is assumed that $n \geq m$; however, for the sake of easy readability (even if this is not a necessary restriction) the case $n = m$ will only be considered; thus, $X_p = X$. Henceforth, if we denote the difference $Y - \psi(X)$ by $X_\perp$, in order to arrive at a synchronized motion, it is expected that

$$||X_\perp|| \longrightarrow 0, \quad \text{as } t \longrightarrow +\infty \qquad [3]$$

If $\psi$ is the identity function, the process is called IS.

**Definition of IS** System [2] synchronizes with system [1], if the set $M = \{(X, Y) \in \mathbb{R}^n \times \mathbb{R}^n, Y = X\}$ is an attracting set with a basin of attraction $B(M \subset B)$ such that $\lim_{t \to \infty} \|X(t) - Y(t)\| = 0$, for all $(X(0), Y(0)) \in B$.

Thus, this regime corresponds to the situation where all the variables of two (or more) coupled chaotic systems converge.

If $\psi$ is not the identity function, the phenomenon is more general and is referred to as GS.

**Definition of GS** System [2] synchronizes with system [1], in the generalized sense, if there exists a transformation $\psi : \mathbb{R}^n \longrightarrow \mathbb{R}^m$, a manifold $M = \{(X, Y) \in \mathbb{R}^{n+m}, Y = \psi(X)\}$ and a subset $B$ $(M \subset B)$, such that for all $(X_0, Y_0) \in B$, the trajectory based on the initial conditions $(X_0, Y_0)$ approaches $M$ as time goes to infinity. This is explained further in the following.

Henceforth, in the case of IS, eqn [3] above means that a certain hyperplane $M$, called synchronization manifold, within $\mathbb{R}^{2n}$, is asymptotically stable. Consequently, for the sake of synchrony motion, we have to prove that the origin of the transverse system $X_\perp = Y - X$ is asymptotically stable. That is, to prove that the motion transversal to the synchronization manifold dies out.

However, significant progress has been made by mathematicians and physicists in studying the stability of synchronous motions. Two main tools are used in the literature for this aim: conditional Lyapunov exponents and asymptotic stability. In the examples given below, we will essentially formulate conditions for synchronization in terms of Lyapunov exponents, which play a central role in chaos theory. These quantities measure the sensitive dependence on initial conditions for a dynamical system and also quantify synchronization of chaos.

The Lyapunov exponents associated with the variational equation corresponding to the transverse system $X_\perp$:

$$\frac{\mathrm{d}X_\perp}{\mathrm{d}t} = DF(X)X_\perp \qquad [4]$$

where $DF(X)$ is the Jacobian of the vector field evaluated onto the driving trajectory $X$, are referred to as transverse or conditional Lyapunov exponents (CLEs).

In the case of IS, it appears that the condition $L^\perp_{\max} < 0$ is sufficient to insure synchronization, where $L^\perp_{\max}$ is the largest CLE. Indeed, eqn [4] gives the dynamics of the motion transverse to the synchronization manifold; therefore, CLEs indicate if this motion dies out or not, and hence, whether the synchronization state is stable or not. Consequently, if $L^\perp_{\max}$ is negative, it insures the stability of the synchronized state. This will be best explained using two examples below.

Even if there exist other approaches for studying synchronization, one may ask if this condition on $L^\perp_{\max}$ is true in general. To answer this question, mathematicians have recently formulated it in terms of properties of manifolds (or synchronization hyperplanes). Some rigorous results on (generalized) synchronization, when the system is smooth, are given by Josic (2000). This approach relies on the Fenichel theory of normally hyperbolic invariant manifolds and quantities that resemble Lyapunov exponents, and is referred to as differentiable GS. However, many situations correspond to the case where, in some region of values of parameters coupling, the function $\psi$ is only continuous but not smooth, that is, the graph of $\psi$ is a complicated geometrical object. This kind of synchronization is called nonsmooth GS (Afraimovich *et al.* 2001).

Furthermore, the mathematical theory of IS often assumes the coupled oscillators to be identical, even if, in practice, no two oscillators are exact copies of each other. This leads to small differences in system parameters and then to synchronization errors. These errors have been studied by many authors (see, e.g., Illing (2002), and references therein).

## Identical Synchronization

Perhaps the best way to explain synchronization of chaos is through IS, also referred to as conventional or complete synchronization (Boccaletti *et al.* 2002). It is the simplest form of chaos synchronization and generalizes to the complete replacement which is explained below. It is also the most typical form of chaotic synchronization often observable in two identical systems.

There are various processes leading to synchronization; depending on the particular coupling configuration used these processes could be very different. So, one has to distinguish between the following two main situations, even if they are, in some sense, similar: the unidirectional and the bidirectional coupling. Indeed, synchronization of chaotic systems is often studied for schemes of the form

$$\begin{aligned} \frac{\mathrm{d}X}{\mathrm{d}t} &= F(X) + kN(X - Y) \\ \frac{\mathrm{d}Y}{\mathrm{d}t} &= G(Y) + kM(X - Y) \end{aligned} \qquad [5]$$

where $F$ and $G$ act in $\mathbb{R}^n, (X, Y) \in (\mathbb{R}^n)^2$, is a scalar, and $M$ and $N$ are coupling matrices belonging to $\mathbb{R}^{n\times n}$. If $F = G$ the two subsystems $X$ and $Y$ are identical. Moreover, when both matrices are nonzero then the coupling is called bidirectional, while it is referred to as unidirectional if one is the zero matrix, and the other nonzero.

### Constructing Pairs of Synchronized Systems: Complete Replacement

Pecora and Carroll (1990) proposed the use of stable subsystems of given chaotic systems to

construct pairs of unidirectionally coupled synchronizing systems. Since then generalizations of this approach have been developed and various methods now exist to synchronize systems (Wu 2002, Hasler 1998).

One way to build a couple of synchronized systems is then to use the basic construction method introduced by Pecora and Carroll, who made an important observation. They found that, when they make a replica of part of a chaotic system and send a system variable from the original system (transmitter) to drive this replica (receiver), sometimes the replica subsystem and the original chaotic one lock in their steps and evolve together chaotically in synchrony. This method can be described as follows. Consider the autonomous $n$-dimensional dynamical system,

$$\frac{\mathrm{d}u}{\mathrm{d}t} = F(u) \qquad [6]$$

divide this system into two subsystems ($u = (v, w)$),

$$\begin{aligned} \frac{\mathrm{d}v}{\mathrm{d}t} &= G(v, w) \\ \frac{\mathrm{d}w}{\mathrm{d}t} &= H(v, w) \end{aligned} \qquad [7]$$

where $v = (u_1, \ldots, u_m)$, $w = (u_{m+1}, \ldots, u_n)$, $G = (F_1, \ldots, F_m)$, and $H = (F_{m+1}, \ldots, F_n)$. Next, create a new subsystem $w'$ identical to the $w$-subsystem. This yields a $(2n - m)$-dimensional system:

$$\begin{aligned} \frac{\mathrm{d}v}{\mathrm{d}t} &= G(v, w) \\ \frac{\mathrm{d}w}{\mathrm{d}t} &= H(v, w) \\ \frac{\mathrm{d}w'}{\mathrm{d}t} &= H(v, w') \end{aligned} \qquad [8]$$

The first state-variable component $v(t)$ of the $(v, w)$ system is then used as the input to the $w'$-system. The coupling is unidirectional and the $(v, w)$ subsystem is referred to as the driving (or master) system, the $w'$-subsystem as the response (or slave) system. In this context, the following notions and results are useful.

**Definition** If $\lim_{t \to +\infty} \|w'(t) - w(t)\| = 0$ and $w'(t)$ continues to remain in step with $w(t)$ in the course of the time, the two subsystems are said to be synchronized.

**Definition** The Lyapunov exponents of the response subsystem $(w')$ for a particular driven trajectory $v(t)$ are called CLEs.

Let $w(t)$ be a chaotic trajectory with initial condition $w(0)$, and $w'(t)$ be a trajectory started at a nearly point $w'(0)$. The basic idea of the Pecora–Carroll approach is to establish the asymptotic stability of the solutions of $w'$-subsystem by means of CLEs. They have shown the following result (Pecora and Carroll 1990):

**Theorem** *A necessary and sufficient condition for the two subsystems, $w$ and$w'$, to be synchronized is that all of the CLEs be negative.*

Note that only a finite number of possible decompositions (or couplings) $v$–$w$ exist; this is bounded by the number of different possible subsystems, namely $N(N-1)/2$. (For a description and mathematical analysis of various coupling schemes see Wu (2002).) Furthermore, by splitting the main system [6] in a different way, (complete) synchronization could not exist. Indeed, in general, only a few of the possible response subsystems possess negative CLEs, and may thus be used to implement synchronizing systems using the Pecora–Caroll method. In fact, it has been pointed out in the literature that in some cases, the CLE criterion is not as practical as some other criteria.

For simplicity, the idea will now be developed on the following three-dimensional simple autonomous system, which belongs to the class of dynamical systems called generalized Lorenz systems (see Derivière and Aziz-Alaoui (2003), and references therein):

$$\begin{aligned} \dot{x} &= -9x - 9y \\ \dot{y} &= -17x - y - xz \\ \dot{z} &= -z + xy \end{aligned} \qquad [9]$$

(This should be compared with the well-known Lorenz system:

$$\begin{aligned} \dot{x} &= -10x + 10y \\ \dot{y} &= 28x - y - xz \\ \dot{z} &= -\tfrac{8}{3}z + xy \end{aligned}$$

which differs in the signs of various terms and the values of coefficients.) From previous observations, it was shown that system [9] oscillates chaotically; its Lyapunov exponents are +0.601, 0.000, and –16.470; it exhibits the chaotic attractor of Figure 1, with a three-dimensional feature very similar to that of Lorenz attractor (in fact, it satisfies the condition $z < 0$, but in our context it does not matter).

Let us divide system [9] into two subsystems $v = x_1$ and $w = (y_1, z_1)$. By creating a copy

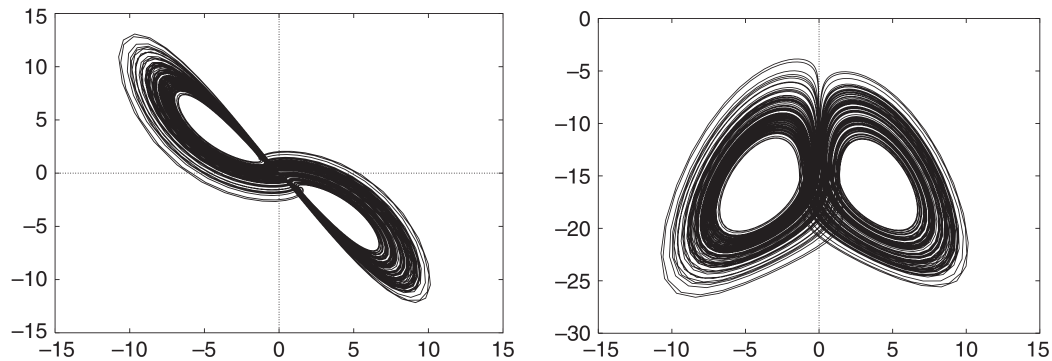

**Figure 1** The chaotic attractor of system [9]: $x$–$y$ and $x$–$z$ plane projections.

$w' = (y_2, z_2)$ of the $w$-subsystem, we obtain the following five-dimensional dynamical system:

$$\begin{aligned} \dot{x}_1 &= -9x_1 - 9y_1 \\ \dot{y}_1 &= -17x_1 - y_1 - x_1 z_1 \\ \dot{z}_1 &= -z_1 + x_1 y_1 \\ \dot{y}_2 &= -17x_1 - y_2 - x_1 z_2 \\ \dot{z}_2 &= -z_2 + x_1 y_2 \end{aligned} \qquad [10]$$

In numerical experiments, it was observed that the motion quickly results in the two equalities, $\lim_{t\to+\infty} |y_2 - y_1| = 0$ and $\lim_{t\to+\infty} |z_2 - z_1| = 0$, to be satisfied, that is, $\lim_{t\to+\infty} \|w' - w\| = 0$. These equalities persist as the system evolves. Hence, the two subsystems $w$ and $w'$ are synchronized. Figure 2 illustrates this phenomenon.

It is also easy to verify that the synchronization persists even if a slight change in the parameters of the system is made. The CLEs of the linearization of the system around the synchronous state, the negativity of which determines the stability of the synchronized solution, are also computed easily.

Pecora–Carroll similarly built the system [10] by using the following steps. Starting with two copies of system [9], a signal $x(t)$ is transmitted from the first to the second: in the second system all $x$-components are replaced with the signal from the first system, that is, $x_2$ is replaced by $x_1$ in the second system. Finally, the $\mathrm{d}x_2/\mathrm{d}t$ equation is eliminated, since it is exactly the same as $\mathrm{d}x_1/\mathrm{d}t$ equation, and is superfluous. This then results in system [10]. For this reason, Pecora–Carroll called this construction a complete replacement. Thus, it is natural to think of the $x_1$ variable as driving the second system, but also to label the first system the drive and the second system the response. In fact, this method is a particular case of the unidirectional coupling method explained below. Note also that this method could be modified by using a partial substitution approach, in which a response variable is replaced with the drive counterpart only in certain locations (Pecora *et al.* 1997).

### Unidirectional IS

The IS synchronization has also been called as one-way diffusive coupling, drive–response coupling, master–slave coupling, or negative feedback control.

System [5], $F = G$ and $N = 0$, becomes unidirectionally coupled, and reads

$$\begin{aligned} \frac{\mathrm{d}X}{\mathrm{d}t} &= F(X) \\ \frac{\mathrm{d}Y}{\mathrm{d}t} &= F(Y) + kM(X - Y) \end{aligned} \qquad [11]$$

$M$ is then a matrix that determines the linear combination of $X$ components that will be used in the difference, and $k$ determines the strength of the coupling (see, for an interesting review on this subject, Pecora *et al.* (1997)). In unidirectional synchronization, the evolution of the first system (the drive) is unaltered by the coupling, the second system (the response) is then constrained to copy the dynamics of the first. Let us consider an example with two copies of system [9], and for

$$M = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \qquad [12]$$

that is, by adding a damping term to the first equation of the response system, we get a following unidirectionally coupled system, coupled through a linear term $k > 0$ according to variables $x_{1,2}$:

$$\begin{aligned} \dot{x}_1 &= -9x_1 - 9y_1 \\ \dot{y}_1 &= -17x_1 - y_1 - x_1 z_1 \\ \dot{z}_1 &= -z_1 + x_1 y_1 \\ \dot{x}_2 &= -9x_2 - 9y_2 - k(x_2 - x_1) \\ \dot{y}_2 &= -17x_2 - y_2 - x_2 z_2 \\ \dot{z}_2 &= -z_2 + x_2 y_2 \end{aligned} \qquad [13]$$

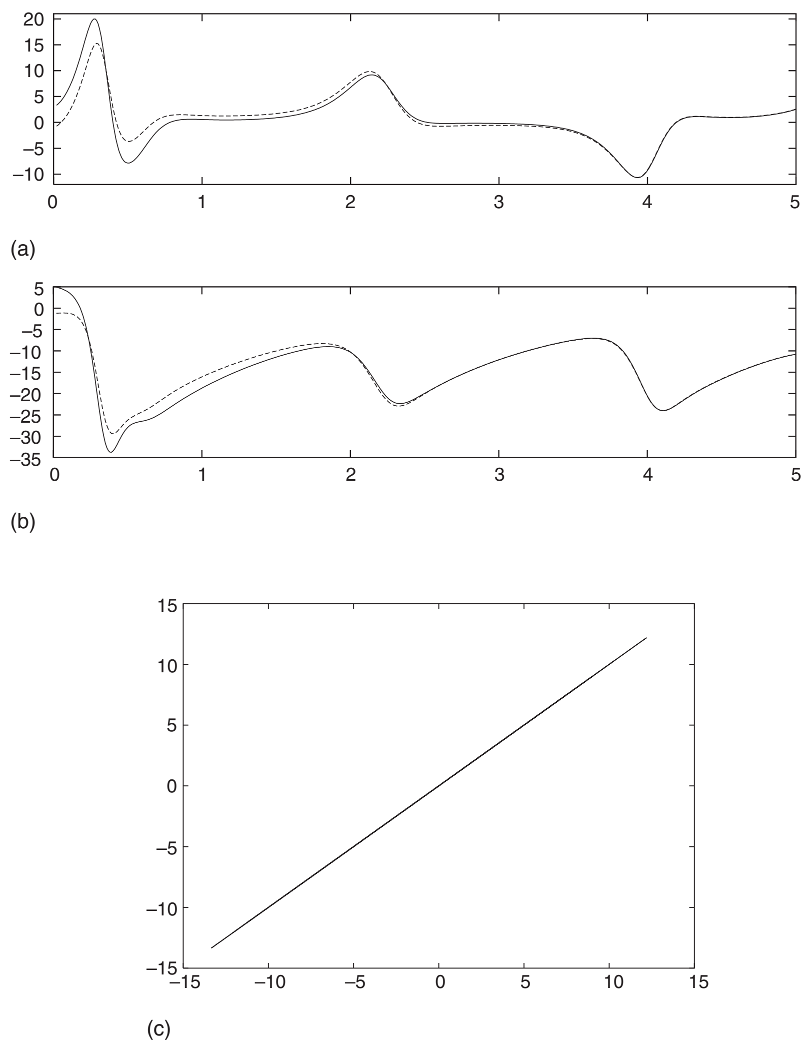

**Figure 2** Complete replacement synchronization. Time series for (a) $y_i(t)$ and (b) $z_i(t), i = 1, 2$, in system [10]. The difference between the variable of the transmitter and the variable of the receiver asymptotes tends to zero as time progresses, that is, synchronization occurs after transients die down. (c) The plot of amplitudes $y_1$ against $y_2$, after transients die down, shows a diagonal line, which also indicates that the receiver and the transmitter are maintaining synchronization. The plot of $z_1$ against $z_2$ shows a similar behavior.

For $k = 0$, the two subsystems are uncoupled; for $k > 0$ both subsystems are unidirectionally coupled; and for $k \longrightarrow +\infty$, we recover the complete replacement coupling scheme explained above. Our numerical computations yield the optimal value $\tilde{k}$ for the synchronization; we found that for $k \geq \tilde{k} = 4.999$, both subsystems of [13] synchronize. That is, starting from random initial conditions, and after some transient time, system [13] generates the same attractor as for system [9] (see **Figure 1**). Consequently, all the variables of the coupled chaotic subsystems converge: $x_2$ converges to $x_1$, $y_2$ to $y_1$, and $z_2$ to $z_1$ (see **Figure 3**). Thus, the second system (the response) is locked to the first one (the drive).

Alternatively, observation of diagonal lines in correlation diagrams, which plot the amplitudes $x_1$ against $x_2$, $y_1$ against $y_2$, and $z_1$ against $z_2$, can also indicate the occurrence of system synchronization.

IS was the first for which examples of unidirectionally coupled chaotic systems were presented. It is important for potential applications of chaos synchronization in communication systems, or for time-series analysis, where the information flow is also unidirectional.

## Bidirectional IS

A second brief example uses a bidirectional (also called mutual or two-way) coupling. In this situation, in contrast to the unidirectional coupling, both drive and response systems are connected in such a way that they influence each other's behavior. Many

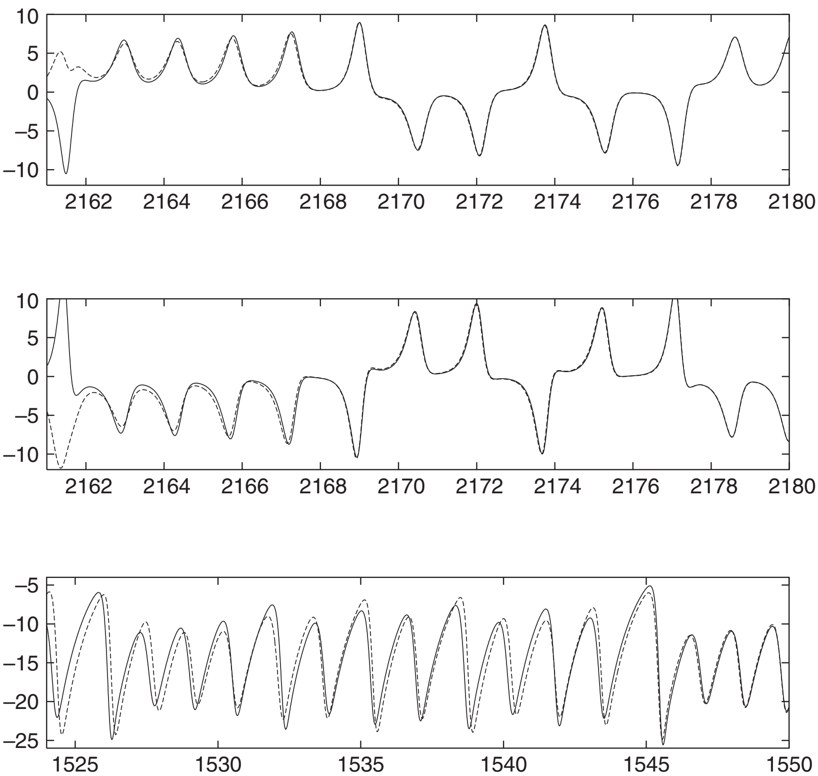

**Figure 3** Time series for $x_i(t), y_i(t)$, and $z_i(t) (i = 1, 2)$ in system [13] for the coupling constant $k = 5.0$, that is, beyond the threshold necessary for synchronization. After transients die down, the two subsystems synchronize perfectly.

biological or physical systems consist of bidirectionally interacting elements or components; examples range from cardiac and respiratory systems to coupled lasers with feedback. Let us then take two copies of the same system [9] as given above, but two-way coupled through a linear constant term $k > 0$ according to variables $x_{1,2}$:

$$\begin{aligned} \dot{x_1} &= -9x_1 - 9y_1 - k(x_1 - x_2) \\ \dot{y_1} &= -17x_1 - y_1 - x_1 z_1 \\ \dot{z_1} &= -z_1 + x_1 y_1 \\ \dot{x_2} &= -9x_2 - 9y_2 - k(x_2 - x_1) \\ \dot{y_2} &= -17x_2 - y_2 - x_2 z_2 \\ \dot{z_2} &= -z_2 + x_2 y_2 \end{aligned} \qquad [14]$$

We can get an idea of the onset of synchronization by plotting, for example, $x_1$ against $x_2$ for various values of the coupling-strength parameter $k$. Our numerical computations yield the optimal value $\tilde{k}$ for the synchronization: $\tilde{k} \simeq 2.50$ (**Figure 4**), both $(x_i, y_i, z_i)$ subsystems synchronize and system [14] also generates the attractor of **Figure 1**.

**Synchronization manifold and stability** Geometri-Geometrically, the fact that systems [13] and [14], beyond synchronization, generate the same attractor as system [9], implies that the attractors of these combined drive–response six-dimensional systems are confined to a three-dimensional hyperplane (the synchronization manifold) defined by $Y = X$. After the synchronization is reached, this manifold is a stable submanifold in the full phase space $\mathbb{R}^6$. **Figure 5** gives an idea of what the geometry of the synchronous attractor of system [13] or [14] looks like, by exhibiting the projection of the phase space $\mathbb{R}^6$ onto $(x_1, y_1, y_2)$ subspace. But, one can similarly plot any combination of variable $x_i$, $y_i$, and $z_i$ $(i = 1, 2)$, and get the same result, since the motion, in case of synchronization, is confined to the hyperplane defined in $\mathbb{R}^6$ by the equalities $x_1 = x_2$, $y_1 = y_2$, and $z_1 = z_2$.

This hyperplane is stable since small perturbations which take the trajectory off the synchronization manifold decay in time. Indeed, as stated earlier, CLEs of the linearization of the system around the synchronous state could determine the stability of the synchronized solution. This leads to requiring that the origin of the transverse system, $X_\perp$, is asymptotically stable. To see this, for both systems [13] and [14], we then switch to the new set of coordinates, $X_\perp = Y - X$, that is, $x_\perp = x_2 - x_1$, $y_\perp = y_2 - y_1$, and $z_\perp = z_2 - z_1$. The origin $(0, 0, 0)$ is obviously a fixed point for this transverse system,

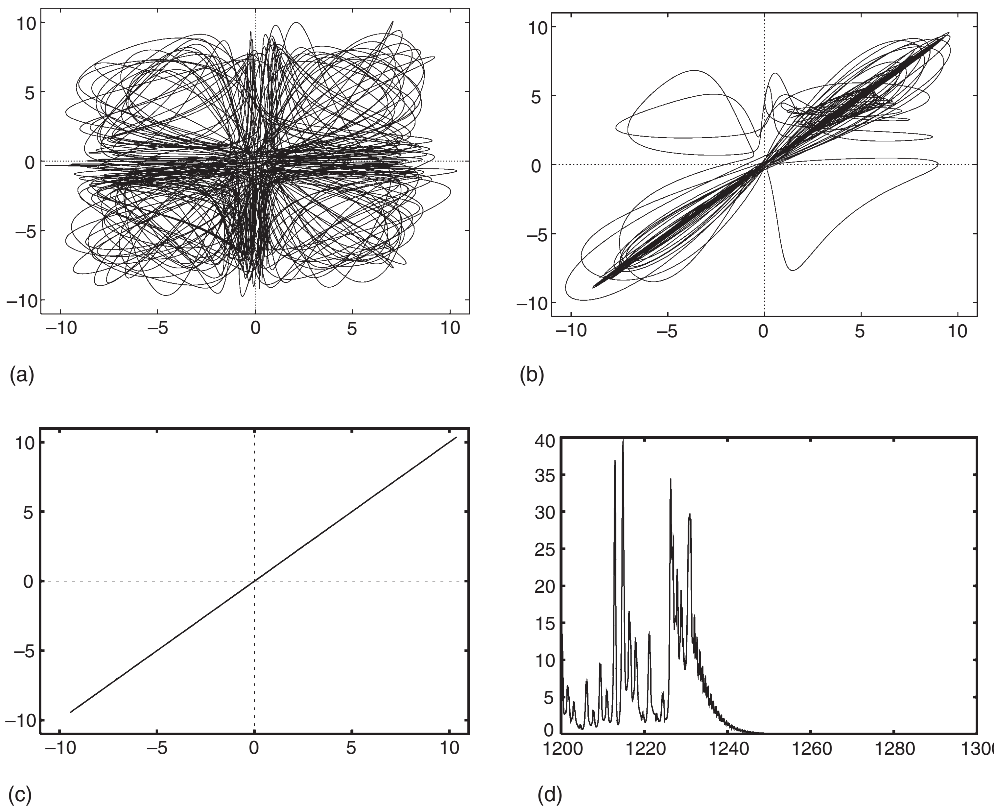

**Figure 4** Illustration of the onset of synchronization of system [14]. (a)–(c) Plots of amplitudes $x_1$ against $x_2$ for values of the coupling parameter $k = 0.5, 1.5, 2.8$, respectively. The system synchronizes for $k \geq 2.5$. (d) Plot, for $k = 2.8$, of the norm $N(X) = \|x_1 - x_2\| + \|y_1 - y_2\| + \|z_1 - z_2\|$ versus $t$, which shows that the system synchronizes very quickly.

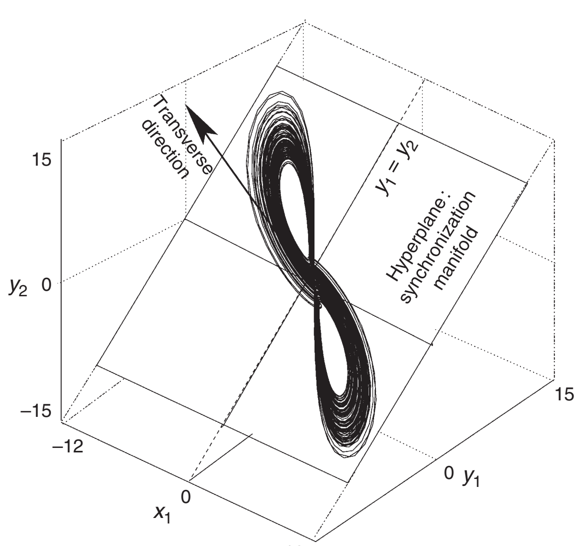

**Figure 5** The motion of synchronized system [13] or [14] takes place on a chaotic attractor which is embedded in the synchronization manifold, that is, the hyperplane defined by $x_1 = x_2$, $y_1 = y_2$, and $z_1 = z_2$.

within the synchronization manifold. Therefore, for small deviations from the synchronization manifold, this system reduces to a typical variational equation:

$$\frac{\mathrm{d}X_\perp}{\mathrm{d}t} = DF(X)X_\perp \qquad [15]$$

where $DF(X)$ is the Jacobian of the vector field evaluated onto the driving trajectory $X$, that is,

$$\begin{pmatrix} \frac{\mathrm{d}x_\perp}{\mathrm{d}t} \\ \frac{\mathrm{d}y_\perp}{\mathrm{d}t} \\ \frac{\mathrm{d}z_\perp}{\mathrm{d}t} \end{pmatrix} = V \begin{pmatrix} x_\perp \\ y_\perp \\ z_\perp \end{pmatrix} \qquad [16]$$

For systems [13] and [14], we obtain

$$V = V_i = \begin{pmatrix} -9 - k_i & -9 & 0 \\ -17 - z & -1 & -x \\ y & x & -1 \end{pmatrix} \qquad [17]$$

with $k_i = k$ for system [13] and $k_i = 2k$ for system [14]. Let us remark that the only difference between both matrices $V_i$ is the coupling $k$ which has a factor

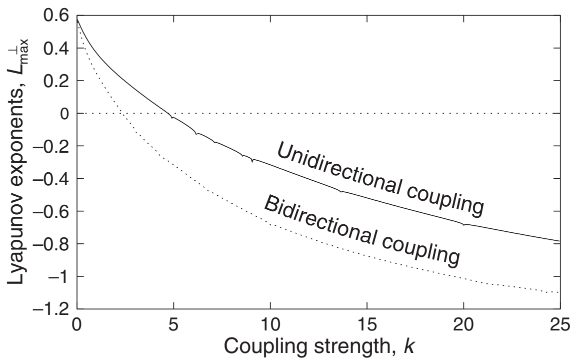

**Figure 6** The largest transverse Lyapunov exponents $L^{\perp}_{max}$ as a function of coupling strength $k$, in the unidirectional system [13] (solid) and the bidirectional system [14] (dotted).

2 in the bidirectional case. **Figure 6** shows the dependence of $L^{\perp}_{max}$ on $k$, for both examples of unidirectionally and bidirectionally coupling systems. $L^{\perp}_{max}$ becomes negative as $k$ increases, which insures the stability of the synchronized state for systems [13] and [14].

Let us note that this can also be proved analytically as done by Derivière and Aziz-Alaoui (2003) by using a suitable Lyapunov function, and using some new extended version of LaSalle invariance principle.

*Desynchronization motion* Synchronization depends not only on the coupling strength, but also on the vector field and the coupling function. For some choice of these quantities, synchronization may occur only within a finite range $[k_1, k_2]$ of coupling strength; in such a case a desynchronization phenomenon occurs. Thus, increasing $k$ beyond the critical value $k_2$ yields loss of the synchronized motion ($L^{\perp}_{max}$ becomes positive).

## Generalized Synchronization

Identical chaotic systems synchronize by following the same chaotic trajectory. However, real systems are in general not identical. For instance, when the parameters of two coupled identical systems do not match, or when these coupled systems belong to different classes, complete IS may not be expected, because there does not exist such an invariant manifold $Y = X$, as for IS. For non-identical systems, the possibility of some type of synchronization has been investigated (Afraimovich *et al.* 1986). It was shown that when two different systems are coupled with sufficiently strong coupling strength, a general synchronous relation between their states could exist and it could be expressed by a smooth invertible function, $Y(t) = \psi(X(t))$. This phenomenon, called GS, is thus a relaxed and extended form of IS in non-identical systems.

However, it may also occur for pairs of identical systems, for example, for systems having reflection symmetry, $F(-X) = -F(X)$. Besides these examples of GS, others also exist that exploit symmetries of the underlying systems (Parlitz and Kocarev 1999).

GS was introduced for unidirectionally coupled systems by Rulkov *et al.* (1995). For simplicity, we also focus on unidirectionally coupled continuous time systems:

$$\frac{dX}{dt} = F(X)$$
$$\frac{dY}{dt} = G(Y, u(t)) \quad [18]$$

where $X \in \mathbb{R}^n$, $Y \in \mathbb{R}^m$, $F : \mathbb{R}^n \longrightarrow \mathbb{R}^n$, $G : \mathbb{R}^m \times \mathbb{R}^k \longrightarrow \mathbb{R}^m$, and $u(t) = (u_1(t), \ldots, u_k(t))$ with $u_i(t) = h_i(X(t, X_o))$. Two (non-identical) dynamical systems are said to be synchronized in a generalized sense if there is a continuous function $\psi$ from the phase space of the first to the phase space of the second, taking orbits of the first system to orbits of the second.

The main problem is to know when and under what conditions system [18] undergoes GS. Many authors have addressed this question, and it has been shown that asymptotic stability is equally significant for this more universal concept (for some theoretical results, see Rulkov *et al.* (1995) and Parlitz and Kocarev (1999)). For unidirectionally coupled continuous time systems, the following results hold:

**Theorem** *A necessary and sufficient condition for system [18] to be synchronized in the generalized sense is that for each $u(t) = u(X(t, X_o))$ the system-is asymptotically stable.*

When it is not possible to find a Lyapunov function in order to use this theorem, one can numerically compute the CLEs of the response system, and use the following result:

**Theorem** *The drive and response subsystems of system [18] synchronize in the generalized sense iff all of the CLEs of the response subsystem are negative.*

The definition of $\psi$ has the advantage that it allows the discussion of synchronization of non-identical systems and, at the same time, to consider synchronization in terms of the property of synchronization manifold. Therefore, it is important to study the existence of the transformation $\psi$ and its nature

(continuity, smoothness, ...). Unfortunately, except in special cases (Afraimovich *et al.* 1986), rarely will one be able to produce formulas exhibiting the mapping $\psi$.

An example of two unidirectionally coupled chaotic systems which synchronize in the generalized sense is given below. Consider the following Rössler system driven by system [9]:

$$\begin{aligned} \dot{x}_1 &= -9x_1 - 9y_1 \\ \dot{y}_1 &= -17x_1 - y_1 - x_1z_1 \\ \dot{z}_1 &= -z_1 + x_1y_1 \\ \dot{x}_2 &= -y_2 - z_2 - k(x_2 - (x_1^2 + y_1^2)) \\ \dot{y}_2 &= x_2 + 0.2y_2 - k(y_2 - (y_1^2 + z_1^2)) \\ \dot{z}_2 &= 0.2 + z_2(x_2 - 9.0) - k(z_2 - (x_1^2 + z_1^2)) \end{aligned} \qquad [19]$$

As shown in **Figure 7**, it appears impossible to tell what the relation is between the transmitter subsystem $(x_1, y_1, z_1)$ in eqn [19] and the two Rössler response subsystems $(x_2, y_2, z_2)$ at $k = 1$ and $k = 100$.

However, GS occurs for large values of the coupling-strength parameter $k$. Therefore, for such values we expect that orbits of [19] will lie in the vicinity of a certain synchronization manifold. Indeed, let us define the set

$$S = \{(x_1, y_1, z_1, x_2, y_2, z_2) \in \mathbb{R}^6 : x_2 = x_1^2 + y_1^2, \\ y_2 = y_1^2 + z_1^2, z_2 = x_1^2 + z_1^2\}$$

Since the projections of $S$ onto the coordinates $(x_1, y_1, x_2), (y_1, z_1, y_2)$, and $(x_1, z_1, z_2)$ are paraboloids, we can see how the synchronization manifold is approached. This is illustrated in **Figure 8**, where the $(x_1, y_1, x_2)$ projections of typical trajectories are shown at four different coupling values. (See Josic (2000) for other examples and further developments; see also Pecora *et al.* (1997), where the authors summarize a method in order to get an idea on the functional relation occurring in case of GS, between two coupled systems.)

## Phase Synchronization

For coupled non-identical chaotic systems, other types of synchronizations exist. Recently, a rather weak degree of synchronization, the PS, of chaotic systems has been described (Pikovsky *et al.* 2001). The Greek meaning of the word synchronization, mentioned in the introduction, is closely related to this type of processes. The synchronous motion is actually not visible. Indeed, in PS the phases of chaotic systems with PS are locked, that is, there exists a certain relation between them, whereas the amplitudes vary chaotically and are practically uncorrelated. Thus, it is mostly close to synchronization of periodic oscillators.

**Definition** PS of two coupled chaotic oscillators occurs if, for arbitrary integers $n$ and $m$, the phase locking condition between the corresponding phases, $|n\phi_1(t) - m\phi_2(t)| \leq$ constant, holds and the amplitudes of both systems remain uncorrelated.

Let us note that such a phenomenon occurs when a zero Lyapunov exponent of the response system becomes negative, while, as explained above, identical chaotic systems synchronize by following the same chaotic trajectory, when their largest transverse Lyapunov exponent of the synchronized manifold decreases from positive to negative values.

Moreover, following the definition above, this phenomenon is best observed when a well-defined phase variable can be identified in both coupled systems. This can be done for strange attractors that spiral around a "hole," or a particular (fixed) point in a two-dimensional projection of the attractor. The typical example is given by the Rössler system, which, for some range of parameters, exhibits a Möbius-

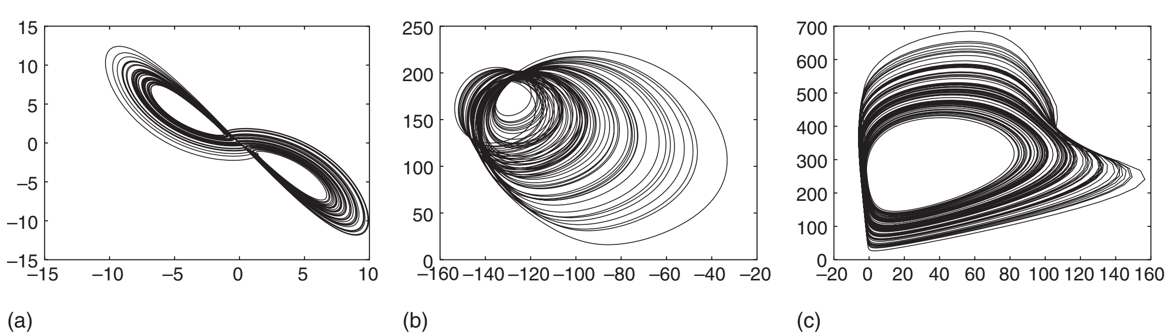

**Figure 7** Projections onto the ($x$–$y$) plane of typical trajectories of system [19]. (a) $(x_1, y_1)$ projection, that is, a typical trajectory of system [9]; (b) and (c) $(x_2, y_2)$ projections at, respectively, $k = 1$ and $k = 100$.

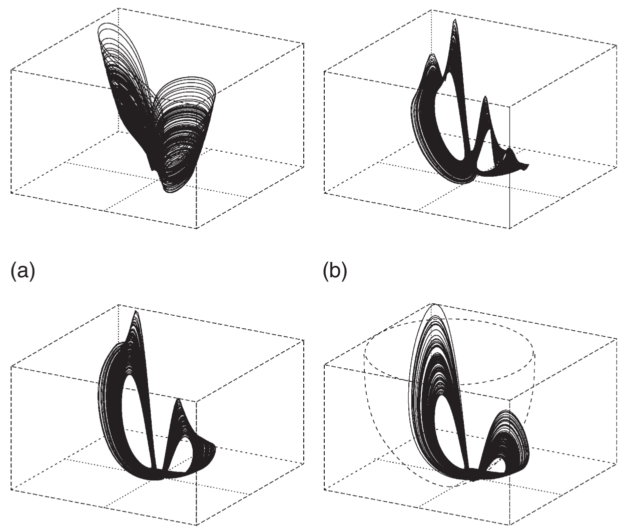

**Figure 8** Generalized synchronization. $(x_1, y_1, x_2)$ projections of typical trajectories of system [19] after transients die out, with (a) $k=1$, (b) $k=20$, (c) $k=100$, and (d) $k=200$. For the last value, the attractor lies in the set $S$, three-dimensional projections of which are paraboloïds.

strip-like chaotic attractor with a central hole. In such a case, a phase angle $\phi(t)$ can be defined that decreases or increases monotonically. For an illustration, we take the following two coupled Rössler oscillators:

$$\begin{aligned} \dot{x}_1 &= -\alpha_1 y_1 - z_1 + k(x_2 - x_1) \\ \dot{y}_1 &= \alpha_1 x_1 + 0.17 y_1 \\ \dot{z}_1 &= 0.2 + z_1(x_1 - 9.0) \\ \dot{x}_2 &= -\alpha_2 y_2 - z_2 + k(x_1 - x_2) \\ \dot{y}_2 &= \alpha_2 x_2 + 0.17 y_2 \\ \dot{z}_2 &= 0.2 + z_2(x_2 - 9.0) \end{aligned} \qquad [20]$$

with a small parameter mismatch $\alpha_{1,2} = 0.95 \pm 0.04, k$ governs the strength of coupling. If we can define a Poincaré section surface for the system, then, for each piece of a trajectory between two cross sections with this surface, we define the phase, as done in Pikovsky *et al.* (2001), as a piecewise linear function of time, so that the phase increment is $2\pi$ at each rotation:

$$\phi(t) = 2\pi \frac{t - t_n}{t_{n+1} - t_n} + 2\pi n, \quad t_n \le t \le t_{n+1}$$

where $t_n$ is the time of the $n$th crossing of the secant surface.

In our example, the last has been chosen as the negative $x$-axis and represented by the wide segment in Figure 9a. This definition of phases is clearly ambiguous since it depends on the choice of the Poincaré section; nevertheless, defined in this way, the phase has a physically important property, it does correspond to the direction with the zero Lyapunov exponent in the phase space, its perturbations neither grow nor decay in time. Figure 9c shows that there is a transition from the nonsynchronous phase regime, where the phase difference increases almost linearly with time ($k=0.01$ and $k=0.05$), to a synchronous state, where the relation $|\phi_1(t) - \phi_2(t)| < \text{constant}$ holds ($k=0.1$), that is, the phase difference does not grow with time. However, the amplitudes are obviously uncorrelated as seen in Figure 9b. This example shows that PS could takes place for weaker degree of synchronization in chaotic systems. Readers can find more rigorous mathematical discussion on this subject, and on the definition of phases of chaotic oscillators, in Pikovsky *et al.* (2001), see also Boccaletti *et al.* (2002) and references therein.

## Other Treatments and Types of Synchronization

### Lag Synchronization

PS synchronization occurs when non-identical chaotic oscillators are weakly coupled: the phases are locked, while the amplitudes remain uncorrelated. When the coupling strength becomes larger, some relationships between amplitudes may be established. Indeed, it has been shown (Rosenblum *et al.* 1997), in symmetrically coupled non-identical oscillators and in time-delayed systems, that there exists

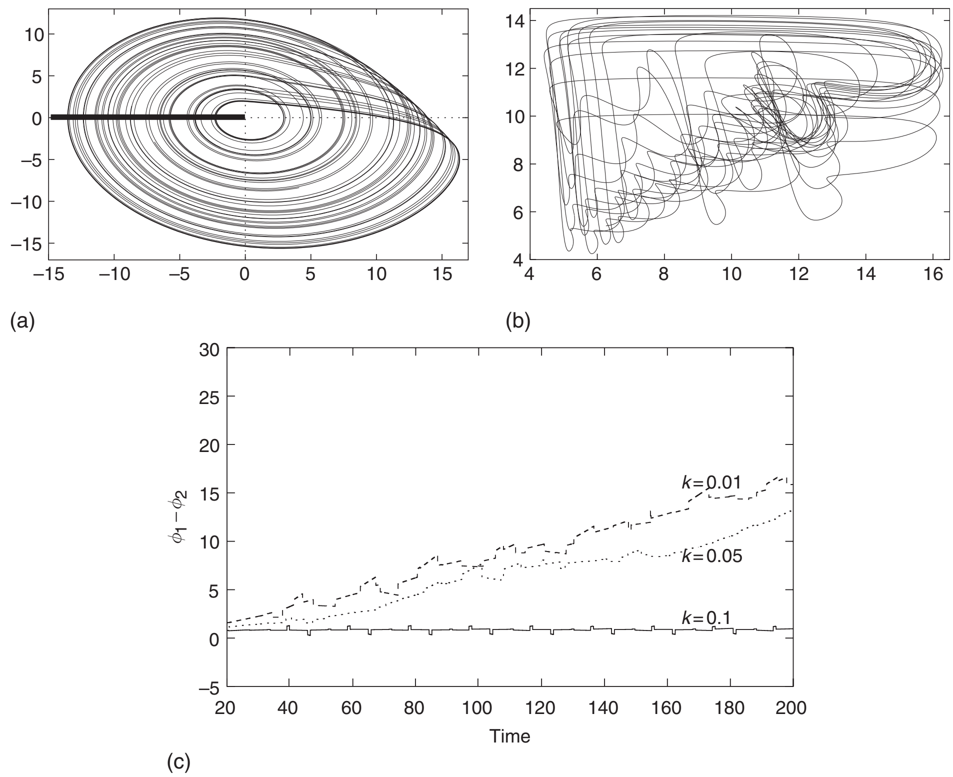

**Figure 9** (a) Rössler chaotic attractor projection onto *x*–*y* plane. (b) Amplitudes $A_1$ versus $A_2$ for the phase synchronized case at $k = 0.1$. (c) Time serie of phase difference for different coupling strengths $k$; for $k = 0.01$ PS is not achieved, while for $k = 0.1$ PS takes place. Although the phases are locked, for $k = 0.1$, the amplitudes remain chaotic and uncorrelated.

a regime of LS. This process appears as a coincidence of time-shifted states of two systems:

$$\lim_{t\to+\infty} ||Y(t) - X(t-\tau)|| = 0$$

where $\tau$ is a positive delay.

### Projective Synchronization

In coupled partially linear systems, it was reported by Mainieri and Rehacek (1999) that two identical systems could be synchronized up to a scaling factor. This type of chaotic synchronization is referred to as projective synchronization. Consider, for example, a three-dimensional chaotic system $\dot{X} = F(X)$, where $X = (x, y, z)$. Decompose $X$ into a vector $v = (x, y)$ and a scalar $z$; the system can then be rewritten as

$$\frac{\mathrm{d}u}{\mathrm{d}t} = g(v, z), \qquad \frac{\mathrm{d}z}{\mathrm{d}t} = h(v, z)$$

In projective synchronization, two identical systems $X_1 = (x_1, y_1, z_1)$ (drive) and $X_2 = (x_2, y_2, z_2)$ (response) are coupled through the scalar variable $z$. It occurs if the state vectors $v_1$ and $v_2$ synchronize up to a constant ratio, that is, $\lim_{t\to+\infty} ||\alpha v_1(t) - v_2(t)|| = 0$, where $\alpha$ is called a scaling factor. For partially linear systems, it may automatically occur provided that the systems satisfy some stability conditions.

However, this process could not be classified as GS, even if there exists a linear relation between the coupled systems, because the response system of projective synchronization is not asymptotically stable. For more information about this subject, the reader is referred to Mainieri and Rehacek (1999).

### Anticipating Synchronization

It is interesting to mention that a new form of synchronization has recently appeared, the so-called anticipating synchronization (Boccaletti *et al.* 2002). It shows that some coupled chaotic systems might synchronize such that their response anticipates the drivers by synchronizing with their future states.

It is also interesting to mention the nonlinear $H_\infty$ synchronization method for nonautonomous schemes introduced by Suykens *et al.* (1997).

### Spatio-Temporal Synchronization

Low-dimensional systems have rather limited usefulness in modeling real-world applications. This is why the synchronization of chaos has been carried

out in high dimensions (see Kocarev *et al.* (1997) for a review). See also Chen and Dong (2001) for a discussion of special high-dimensional systems, namely large arrays of coupled chaotic systems.

## Application to Transmission Systems and Secure Communication

Synchronization principles are useful in practical applications. Use of chaotic signals to transmit information has been a very active research topic in the last decade. Thus, it has been established that chaotic circuits may be used to transmit information by synchronization. As a result, several proposals for secure-communication schemes have been advanced (see, e.g., Cuomo *et al.* (1993), Hasler (1998), and Parlitz *et al.* (1999)). The first laboratory demonstration of a secure-communication system, which uses a chaotic signal for masking purposes, and which exploits the chaotic synchronization techniques to recover the signal, was reported by Kocarev *et al.* (1992).

It is difficult, within the scope of this article, to give a complete or detailed discussion, and it should be noted that there exist many competing and tested methods that are well established.

The main idea of the communication schemes is to encode a message by means of a chaotic dynamical system (the transmitter), and to decode it using a second dynamical system (the receiver) that synchronizes with the first. In general, secure-communication applications assume additionally that the coupled systems used are identical.

Different methods can be used to hide the useful information, for example, chaotic masking, chaotic switching, or direct chaotic modulation (Hasler 1998). For instance, in the chaotic masking method, an analog information carrying the signal $s(t)$ is added to the output $y(t)$ of the chaotic system in the transmitter. The receiver tries to synchronize with component $y(t)$ of the transmitted signal $s(t) + y(t)$. If synchronization takes place, the information signal can be retrieved by subtraction (**Figure 10**).

It is interesting to note that, in all proposed schemes for secure communications using the idea of synchronization (experimental realization or computer simulation), there is an inevitable noise degrading the fidelity of the original message.

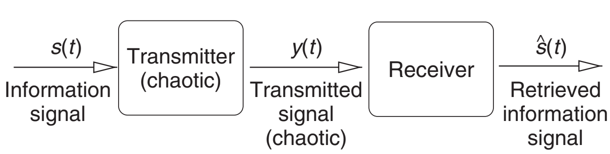

**Figure 10** A typical communication setup.

Robustness to parameter mismatch was addressed by many authors (Illing *et al.* 2002). Lozi *et al.* (1993) showed that, by connecting two identical receivers in cascade, a significant amount of the noise can be reduced, thereby allowing the recovery of a much higher quality signal.

Furthermore, different implementations of chaotic secure communication have been proposed during the last decades, as well as methods for cracking this encoding. The methods used to crack such a chaotic encoding make use of the low dimensionality of the chaotic attractors. Indeed, since the properties of low-dimensional chaotic systems with one positive Lyapunov exponent can be reconstructed by analyzing the signal, such as through the delay-time reconstruction methods, it seems unlikely that these systems might provide a secure encryption method. The hidden message can often be retrieved easily by an eavesdropper without using the receiver. But, chaotic masking and encoding are difficult to break, using the state-of-the-art analysis tools, if sufficiently high dimensional chaos generators with multiple positive Lyapunov exponents (i.e., hyperchaotic systems) are used (see Pecora *et al.* (1997), and references therein).

## Conclusion

In spite of the essential progress in theoretical and experimental studies, synchronization of chaotic systems continues to be a topic of active investigations and will certainly continue to have a broad impact in the future. Theory of synchronization remains a challenging problem of nonlinear science.

## Thermal Quantum Field Theory

**C D Jäkel**, Ludwig-Maximilians-Universität München, München, Germany

### Introduction

Quantum field theory was initially invented in order to describe high-energy elementary particles, thereby unifying quantum mechanics and special relativity. In other words, quantum field theory was addressed to the so-called vacuum sector, that is, roughly speaking physics at zero temperature and zero particle density.

The same applies to the various mathematically rigorous versions of quantum field theory that have been developed since the mid-1950s. Indeed, in Wightman's axiomatic setting, quantum field theory is describes in terms of a set of the so-called vacuum expectation values. The "algebraic approach" to quantum field theory developed by Araki, Haag, Kastler, and their collaborators is more flexible in nature. In fact, right from the beginning, the new algebraic tools were successfully applied to lattice models and other nonrelativistic systems with infinitely many degrees of freedom (see *Operator algebras and quantum statistical mechanics* by O Bratteli and D W Robinson). But the need to treat large systems of relativistic particles was apparently not felt. Even in Haag's recent monograph, *Local Quantum Physics*, the subjects of algebraic quantum field theory and algebraic quantum statistical mechanics are treated separately.

It is remarkable that constructive field theory was ahead of its time in this respect. The famous $P(\phi)_2$ model (first constructed by Glimm and Jaffe) was adapted to thermal states by Høegh-Krohn as early as 1974 (see Høegh-Krohn (1974)). His paper was properly named "Relativistic quantum statistical mechanics in two-dimensional space-time," but only recently has it received proper attention.

At the same time, around 1974, cosmology and heavy-ion collisions drew the interest of phyiscists towards the quantum statistical mechanics of hot relativistic quantum systems. Well-known papers from this early stage include those by Weinberg, Bernard, and Dolan and Jackiw. While most of the papers used Euclidean path integrals, Umezawa and his school developed a real-time framework called "thermo-field dynamics," which involved a doubling of the degrees of freedom. The excellent review by Landsman and van Weert (1987) covers these early attempts; it also explains the basic connection to the algebraic approach.

In the following years, it became evident that statistical mechanics (in its standard formulation) is barely sufficient to derive the properties of bulk matter from the underlying microscopic description provided by quantum field theory. Thus, various people began to establish mathematically rigorous foundations for the description of thermal field theory. The most successful approach was launched by D Buchholz (with various collaborators), who, from about 1985 onwards, started applying the KMS condition (which describes a thermal equilibrium state in the operator-algebraic framework of local quantum physics) to relativistic quantum field theory. In 1994, Buchholz and Bros managed to integrate the holomorphic structure of Wightman field theory into Haag's operator-algebraic framework, which led them to the notion of a relativistic KMS condition.

The advanced mathematical concepts involved in the formulation of entropy densities for thermal quantum fields (see Narnhofer (1994)) do not allow us to present this topic. The reader is referred to the excellent book *Quantum Entropy and Its Use* by M Ohya and D Petz for an introduction to the subject. A discussion of the so-called thermalization

effects that occur as a result of a curved spacetime is provided in Quantum Field Theory in Curved Spacetime. Another subject, which is missing almost completely, is perturbation theory. This subject has been covered extensively in three well-known textbooks by Kapusta, Le Bellac, and Umezawa.

### Observables and States

Following Heisenberg, we start from the basic assumption that quantum theory can be formulated in terms of observables which form an algebra $\mathcal{A}$, that is, a vector space with a (noncommutative) multiplication law. Although our emphasis on the abstract algebraic structure may look strange, there is a profound reason for starting out with an abstract algebra of observables: as soon as one considers systems with infinitely many degrees of freedom, one encounters a possibility to realize the abstract elements of the algebra $\mathcal{A}$ as operators on a Hilbert space in various inequivalent ways. The famous equivalence between the Heisenberg and the Schrödinger picture simply breaks down. States which are macroscopically different (e.g., thermal equilibrium states for different temperatures) give rise – in a natural way, which will be discussed in the sequel – to unitarily inequivalent representations of the abstract algebra of observables $\mathcal{A}$, while states which only differ microscopically can be accommodated by density matrices within the same Hilbert space. In other words, a physical state is described macroscopically by specifying a representation, and microscopically by a density matrix in this representation.

In a Lagrangian approach, the algebra of observables $\mathcal{A}$ may be thought of as being generated by the underlying fields, currents, etc. This leads to the so-called polynomial algebras. It is mathematically convenient to assume that $\mathcal{A}$ is an algebra of bounded operators, generated by the bounded functions of the underlying quantum fields. If $\phi(x)$ is any such field and if $f \in \mathcal{S}(\mathbb{R}^{d+1})$ is any real test function with support in a bounded region of spacetime, then the corresponding operator

$$W(f) = \exp\left(\mathrm{i}\int \mathrm{d}x\, f(x)\phi(x)\right)$$

would be a typical element of $\mathcal{A}$. The set of operators $\{W(f) \mid \operatorname{supp} f \subset \mathcal{O}\}$ will generate a subalgebra $\mathcal{A}(\mathcal{O})$ of $\mathcal{A}$. The underlying fields can be recovered by taking (functional) derivatives, once a representation of $\mathcal{A}$ on a Hilbert space is specified.

The spacetime symmetry of Minkowski space manifests itself in the existence of a representation

$$\alpha : (\Lambda, x) \mapsto \alpha_{\Lambda,x} \in \mathrm{Aut}(\mathcal{A}), \quad (\Lambda, x) \in \mathcal{P}_+^{\uparrow}$$

of the (orthochronous) Poincaré group $\mathcal{P}_+^{\uparrow}$. Here $\alpha_{\Lambda,x}$ is an automorphism of $\mathcal{A}$, that is, a mapping from $\mathcal{A}$ to $\mathcal{A}$ which preserves the algebraic structure. Once a Lorentz frame is fixed by choosing a timelike vector $e \in V_+$, the time evolution $t \mapsto \alpha_{1,te}$ will be denoted by $t \mapsto \tau_t$.

For the free field, the group of automorphisms $(\Lambda, x) \mapsto \alpha_{\Lambda,x}$ is defined by

$$\alpha_{\Lambda,x}(W(f)) := W\big(f(\Lambda^{-1}(. - x))\big)$$

As before, $f \in \mathcal{S}(\mathbb{R}^{d+1})$ is a Schwarz function over the Minkowski space $\mathbb{R}^{d+1}$.

While the invariance of the equations of motion is reflected in the existence of a representation of the Poincaré group in terms of automorphisms in the Heisenberg picture, at least the invariance with respect to Lorentz boosts is spontaneously broken in the Schrödinger picture for a thermal equilibrium state.

The usual notions of vector states and density matrices associated with a given Hilbert space (usually Fock space) are *a priori* not general enough to cover all cases of interest in thermal field theory. The following algebraic definition of a state substantially generalizes the notion of a state: A state $\omega$ is a positive, linear, and normalized functional, that is, a linear map $\omega : \mathcal{A} \to \mathbb{C}$ such that

$$\omega(a^*a) \geq 0 \quad \text{and} \quad \omega(\mathbb{1}) = 1$$

Once a state $\omega$ is distinguished on physical grounds, the GNS reconstruction theorem provides a Hilbert space $\mathcal{H}_\omega$ and a representation $\pi_\omega$ of $\mathcal{A}$, that is, a map from $\mathcal{A}$ to the set of bounded operators $\mathcal{B}(\mathcal{H}_\omega)$, which preserves the algebraic relations.

It is instructive to consider the GNS representation of the Pauli matrices $\{\sigma_0 = \mathbb{1}, \sigma_1, \sigma_2, \sigma_3\}$. Given a state (a diagonal $2 \times 2$ matrix $\rho$ with positive entries and $\operatorname{tr} \rho = 1$), the left regular representation (a construction well known from group theory)

$$\pi(\sigma_i)|\sqrt{\rho}> = |\sigma_i\sqrt{\rho}>, \quad i = 0, 1, 2, 3$$

defines a reducible representation on $\mathbb{C}^4$, unless one of the entries in the diagonal of $\rho$ is zero (which corresponds to a pure state). In the latter case, the GNS Hilbert space is $\mathbb{C}^2$. By construction, $<\sqrt{\rho}|\pi(\sigma_i)|\sqrt{\rho}> = \operatorname{tr} \rho\sigma_i$, $i = 1, 2, 3$.

## Thermal Equilibrium

The variety of nonequilibrium states ranges from mild perturbations of equilibrium states through steady states, whose properties are governed by external heat baths, or hydrodynamic flows up to totally chaotic states which no longer

admit a description in terms of thermodynamic notions. Buchholz *et al.* (2002) have initiated an investigation of nonequilibrium states that are locally (but not globally) close to thermal equilibrium. Unfortunately, we will not be able to cover this topic. Instead, we will concentrate on states which deviate from a true equilibrium state only microscopically.

### Characterization of Thermal Equilibrium States

When the time evolution $t \mapsto \tau_t \in \mathrm{Aut}(\mathcal{A})$ is changed by a local perturbation, which is slowly switched on and slowly switched off again, then an equilibrium state $\omega$ returns to its original form at the end of this procedure. This heuristic condition of adiabatic invariance can be expressed by the stability requirement

$$\lim_{t\to\infty} \int_{-t}^{t} \mathrm{d}t \; \omega([a, \tau_t(b)]) = 0 \quad \forall a, b \in \mathcal{A} \qquad [1]$$

In a pioniering work Haag, Kastler, and Trych-Pohlmeyer showed that the characterization [1] of an equilibrium state leads to a sharp mathematical criterion, first encountered by Haag, Hugenholtz, and Winnink and more implicitly by Kubo, Martin, and Schwinger:

**Definition 1** A state $\omega_\beta$ over $\mathcal{A}$ is called a KMS state for some $\beta > 0$, if for all $a, b \in \mathcal{A}$, there exists a function $F_{a,b}$ which is continuous in the strip $0 \leq \Im z \leq \beta$ and analytic and bounded in the open strip $0 < \Im z < \beta$, with boundary values given by

$$F_{a,b}(t) = \omega_\beta(a\tau_t(b)) \quad \text{and} \quad F_{a,b}(t + \mathrm{i}\beta) = \omega_\beta(\tau_t(b)a) \quad \forall t \in \mathbb{R} \qquad [2]$$

Before we start analyzing the properties of KMS states, we should mention an alternative characterization of thermal equilibrium states: passivity. The amount of work a cycle can perform when applied to a moving thermodynamic equilibrium state is bounded by the amount of work an ideal windmill or turbine could perform; this property is called semipassivity (Kuckert 2002): a state $\omega$ is called semipassive (passive) if there is an "efficiency bound" $E \geq 0$ ($E = 0$) such that

$$-(W\Omega_\omega, H_\omega W\Omega_\omega) \leq E \cdot (W\Omega_\omega, |P_\omega| W\Omega_\omega) \quad \forall W \in \pi_\omega(\mathcal{A})''$$

with $W^{-1} = W^*, [H_\omega, W] \in \pi_\omega(\mathcal{A})''$, and $[P_\omega, W] \in \pi_\omega(\mathcal{A})''$. Here $(H_\omega, P_\omega)$ denote the generators implementing the spacetime translations in the GNS representation $(\mathcal{H}_\omega, \Omega_\omega, \pi_\omega)$. Generalizing the notion of complete passivity, the state $\omega$ is called completely semipassive if all its finite tensorial powers are semipassive with respect to one fixed efficiency bound $E$. It has been shown by Kuckert (2002) that a state is completely semipassive in all inertial frames if and only if it is completely passive in some inertial frame. The latter implies that $\omega$ is a KMS state or a ground state (a result due to Pusz and Woronowicz).

Let us now turn to properties of thermal equilibrium states which are specific for relativistic models. It was first recognized by Bros and Buchholz (1994) that KMS states of a relativistic theory have stronger analyticity properties in configuration space than those imposed by the traditional KMS condition:

**Definition 2** A KMS state $\omega_\beta$ satisfies the relativistic KMS condition (Bros and Buchholz 1994) if there exists a unit vector $e$ in the forward light cone $V_+$ such that for every pair of local elements $a$, $b$ of $\mathcal{A}$ the function $F_{a,b}$

$$F_{a,b}(x_1, x_2) = \omega_\beta(\alpha_{x_1}(a)\alpha_{x_2}(b))$$

extends to an analytic function in the tube domain $-\mathcal{T}_{\beta e/2} \times \mathcal{T}_{\beta e/2}$, where $\mathcal{T}_{\beta e/2} = \{z \in \mathbb{C} \mid \Im z \in V_+ \cap (\beta e/2 - V_+)\}$.

The relativistic KMS condition can be understood as a remnant of the relativistic spectrum condition in the vacuum sector. It has been rigorously established (Bros and Bruchholz 1994) for the KMS states constructed by Buchholz and Junglas (1989) and by C Gérard and the author for the $P(\phi)_2$ model. In the thermal Wightman framework (Bros and Buchholz 1996) it has been shown that the relativistic KMS condition implies existence of model-independent analyticity properties of thermal $n$-point functions. These properties also appear in perturbative computations of the thermal Wightman functions (Steinmann 1995).

We now turn to the properties of the set of KMS states. For given $\beta$, the convex set $\mathcal{S}_\beta$ of all KMS states is known to form a simplex; the extreme points in the set $\mathcal{S}_\beta$ are called extremal KMS states. As a consequence, the extremal states in $\mathcal{S}_\beta$ can be distinguished with the help of "classical" (central) observables, that is, by observables which commute with all other observables.

If $\omega$ is an extremal KMS state and $\gamma$ is an automorphism which commutes with the time evolution $t \mapsto \tau_t$, then the state $\omega'$ defined by

$$\omega'(a) := \omega(\gamma(a)), \quad a \in \mathcal{A}$$

is again an extremal KMS state to the same parameter values. If $\omega' \neq \omega$, one says that the symmetry is spontaneously broken.

Lorentz invariance with respect to boosts is always broken by a KMS state, since the KMS condition distinguishes a rest frame. A KMS state might also break spatial translation or rotation invariance. However, by averaging over the different configurations one can usually construct a translation- and rotation-invariant state. The situation is drastically different with respect to supersymmetry. Buchholz and Ojima (1997) have shown that supersymmetry is broken in any thermal state and it is impossible to proceed from it by "symmetrization" to states on which an action of supercharges can be defined.

### Existence of Thermal Equilibrium States

Buchholz and Junglas (1989) demonstrated that the existence of KMS states can be guaranteed for a large class of quantum field-theoretic models. The basic assumption to be met concerns the phase-space properties of the model. A generalized trace norm (the so-called "nuclear norm") is used to estimate the "number" of degrees of freedom in phase space.

The first step is to construction a subspace $\mathcal{H}(\Lambda)$ of the vacuum Hilbert space $\mathcal{H}_{\text{vac.}}$, which represents excitations of the vacuum strictly localized inside of a bounded spacetime region $\hat{\mathcal{O}}$. Due to the strong correlations present in the vacuum state of any relativistic model, as a consequence of the Reeh–Schlieder property (see the section "Analyticity of n-point functions") this is a delicate procedure, which involves the so-called "split property." This property ensures that there exists a product vector $\eta$ in vacuum Hilbert space $\mathcal{H}_{\text{vac.}}$ such that

$$(\eta, \pi_{\text{vac.}}(ab)\eta) = \omega_{\text{vac.}}(a)\cdot\omega_{\text{vac.}}(b) \quad \forall a \in \mathcal{A}(\mathcal{O}),\ b \in \mathcal{A}(\hat{\mathcal{O}})^{\text{c}} \qquad [3]$$

Here $\mathcal{O} \subset \hat{\mathcal{O}}$ denotes a slightly smaller open spacetime region (such that the closure $\overline{\mathcal{O}}$ is inside the interior of $\hat{\mathcal{O}}$) and $\mathcal{A}(\hat{\mathcal{O}})^{\text{c}} := \{A \in \mathcal{A} \mid [A, B] = 0\ \forall B \in \mathcal{A}(\hat{\mathcal{O}})\}$. The existence of a product vector can be ensured if the nuclear norm satisfies some mild bounds which are expected to hold in all models of physical interest. Given a product vector $\eta$ which satisfies [3], the sought after subspace is

$$\mathcal{H}(\Lambda) := \overline{\pi_{\text{vac.}}(\mathcal{A}(\mathcal{O}))''\Omega_{\text{vac.}}}$$

The crucial step in the proof of existence of KMS states is to show that

$$\operatorname{tr} E(\Lambda)\mathrm{e}^{-\beta H}E(\Lambda) < \infty \quad \text{for } \beta > 0$$

if the nuclearity condition holds. Here $E(\Lambda)$ denotes the projection onto the subspace $\mathcal{H}(\Lambda)$ representing localized excitations and $H$ denotes the Hamiltonian in the vacuum representation $\pi_{\text{vac.}}$. Next it is shown that the function

$$t \mapsto \omega_{\beta,\Lambda}(a\tau_t(b)) = \frac{1}{Z}\operatorname{tr} E(\Lambda)\mathrm{e}^{-\beta H}E(\Lambda)\pi_{\text{vac.}}(a\tau_t(b))$$

allows an analytic extension to a strip of width $\beta$ which satisfies the KMS boundary condition [2] for $|t| < \delta$ if $a, b \in \mathcal{A}(\mathcal{O}_\circ)$ and $\mathcal{O}_\circ + te \subset \mathcal{O}$ for $|t| < \delta$. In the final step, Buchholz and Junglas were able to demonstrate that bounds on the nuclear norm are even sufficient to control the thermodynamic limit.

Given a thermal field theory, a slight variation of the method used by Buchholz and Junglas allows one to construct a KMS state for a new temperature (Jäkel 2004), that is, to change the temperature of a thermal state.

### Thermal Representations

Given a KMS state $\omega_\beta$, the GNS construction gives rise to a Hilbert space $\mathcal{H}_\beta$ and a representation $\pi_\beta$, called a thermal representation, of $\mathcal{A}$. The algebra $\mathcal{R}_\beta := \pi_\beta(\mathcal{A})''$ possesses a cyclic (due to the GNS construction) and separating (due to the KMS condition) vector $\Omega_\beta$ such that

$$\omega_\beta(a) = \left(\Omega_\beta, \pi_\beta(a)\Omega_\beta\right) \quad \forall a \in \mathcal{A}$$

The KMS condition implies that $\omega_\beta$ is invariant under time translations, that is, $\omega_\beta \circ \tau_t = \omega_\beta$ for all $t \in \mathbb{R}$. Thus,

$$U(t)\pi_\beta(a)\Omega_\beta = \pi_\beta(\tau_t(a))\Omega_\beta, \quad a \in \mathcal{A}$$

defines a strongly continuous unitary group $\{U(t)\}_{t\in\mathbb{R}}$ implementing the time evolution in the representation $\pi_\beta$. By Stone's theorem there exists a self-adjoint generator $L$ such that

$$U(t) = \mathrm{e}^{\mathrm{i}Lt}, \quad t \in \mathbb{R} \qquad [4]$$

For $0 \le \beta < \infty$, the Liouville operator $L$ is not bounded from below; its spectrum is symmetric and consists typically of the whole real line. However, the negative part of $L$ is "suppressed" with respect to the algebra of observables $\mathcal{R}_\beta := \pi_\beta(\mathcal{A})''$ in the following sense (Haag 1992): let $\mathbb{1}_{]-\infty,-\kappa]}$ be the spectral projection of $L$ for the interval $]-\infty, -\kappa] \subset \mathrm{Sp}(L)$, then

$$\|\mathbb{1}_{]-\infty,-\kappa]}A\Omega_\beta\| \le \mathrm{e}^{-\beta\kappa}\|A\| \quad \forall A \in \mathcal{R}_\beta$$

We now turn to structural aspects which are characteristic for a relativistic model, namely the existence of strong spatial correlations and the connection between the decay of these correlations and the spectral properties of the Liouville operator.

Let $\omega_\beta$ be a state, which satisfies the relativistic KMS condition. It follows (using a theorem of Glaser) that for $a \in \mathcal{A}$ the function $\Phi_a : \mathbb{R}^4 \to \mathcal{H}_\beta$,

$$x \mapsto \pi_\beta(\alpha_x(a))\Omega_\beta$$

can be analytically continued from the real axis into the domain $\mathcal{T}_{\beta e/2}$ such that it is weakly continuous for $\Im z \searrow 0$. If the usual additivity assumption $\cup_i \mathcal{O}_i = \mathcal{O} \Rightarrow \vee_i \mathcal{R}_\beta(\mathcal{O}_i) = \mathcal{R}_\beta(\mathcal{O})$ for the local von Neumann algebras holds, then

$$\mathcal{H}_\beta = \overline{\pi_\beta(\mathcal{A}(\mathcal{O}))\Omega_\beta} \qquad [5]$$

for any open spacetime region $\mathcal{O} \subset \mathbb{R}^{d+1}$. Junglas has shown that the thermal Reeh–Schlieder property [5] follows as well from the standard KMS condition, if $\omega_\beta$ is locally normal with respect to the vacuum representation.

The decay of spatial correlations depends on infrared properties of the model, and the essential ingredients for the following cluster theorem are the continuity properties of the spectrum of $L$ near zero.

**Theorem 3** *Let $\Omega_\beta$ denote the unique (up to a phase) normalized eigenvector with eigenvalue $\{0\}$ of the Liouvillean $L$ and let $P^+$ denote the projection onto the strictly positive part of the spectrum of $L$. Assume that there exist positive constants $m > 0$ and $C_1(\mathcal{O}) > 0$ such that*

$$\|e^{-\lambda L} P^+ \pi_\beta(a)\Omega_\beta\| \le C_1(\mathcal{O}) \cdot \lambda^{-m}\|a\| \quad \forall a \in \mathcal{A}(\mathcal{O})$$

*Here $\mathcal{O} \subset \mathbb{R}^{d+1}$ is an open and bounded spacetime region. Now consider two spacelike separated spacetime regions $\mathcal{O}_1, \mathcal{O}_2$, which can be embedded into $\mathcal{O}$ by translation and such that $\mathcal{O}_1 + \delta e \subset \mathcal{O}_2', \delta >> \beta$. then, for $a \in \mathcal{A}(\mathcal{O}_1)$ and $b \in \mathcal{A}(\mathcal{O}_2)$,*

$$|\omega_\beta(ba) - \omega_\beta(b)\omega_\beta(a)| \le C_2 \cdot \delta^{-2m}\|a\|\,\|b\|$$

*The constant $C_2(\beta, \mathcal{O}) \in \mathbb{R}^+$ may depend on the temperature $\beta^{-1}$ and the size of the region $\mathcal{O}$ but is independent of $\delta, a$, and $b$.*

From explicit calculations one expects that $m = 1/2$ for free massless bosons in $3+1$ spacetime dimensions. Consequently, the exponent given on the right-hand side is optimal since it is well known that in this case the correlations decay only like $\delta^{-1}$.

A description of thermal representations would be inadequate without pointing out one of the deepest connections between pure mathematics and physics that emerged in the last century: consider a von Neumann algebra $\mathcal{R}$ which possesses a cyclic and separating vector $\Omega$. Then polar decomposition of the closeable operator $S : A\Omega \mapsto A^*\Omega$, $A \in \mathcal{R}$, provides an antiunitary operator $J$ (the modular conjugation) and a self-adjoint operator $\Delta^{1/2}$. The connection to physics was established independently by Takesaki and Winnink, showing that the pair $(\mathcal{R}, \sigma)$ satisfies the KMS condition for $\beta = -1$, if one sets $\sigma_t(A) = \Delta^{it} A \Delta^{-it}$ for $A \in \mathcal{R}$.

Taking advantage of the Reeh–Schlieder property [5], one can associate modular objects to certain spacetime regions $\mathcal{O}$. In general, a physical interpretation of these modular objects is missing. But for two-dimensional thermal models, which factorize in light-cone coordinates, the modular group corresponding to the algebra of a spacelike wedge admits a simple description: at large distances (compared to $\beta$) from the boundary, the flow pattern is essentially the same as time translations. These are results due to Borchers and Yngvason (1999).

### Analyticity Properties of *n*-Point Functions

The correlation functions describe the full physical content of the theory: all observable quantities can in principle be derived from them. This is so because according to the Wightman reconstruction theorem (which is closely related to the GNS construction) knowledge of the correlation functions allows the reconstruction of the full representation of the field algebra. The Wightman distributions $\{\mathcal{W}_\beta^{(n)}\}_{n\in\mathbb{N}}$,

$$\mathcal{W}_\beta^{(n)}(t_2 - t_1, x_2 - x_1, \ldots, t_n - t_{n-1}, x_n - x_{n-1}) := (\Omega_\beta, \phi_\beta(t_1, x_1) \cdots \phi_\beta(t_n, x_n)\Omega_\beta) \qquad [6]$$

where $\pi_\beta(W(f)) =: \exp(i \int dt\, dx\, f(t,x)\phi_\beta(t,x))$, satisfy a number of key properties: locality, positivity, Poincaré covariance, and temperedness. These properties have been formulated for thermal field by Bros and Buchholz (1996), and this section is entirely based on their work.

The relativistic KMS condition implies that the Wightman distributions $\{\mathcal{W}_\beta^{(n)}\}_{n\in\mathbb{N}}$ of a translation-invariant equilibrium state admit in the corresponding set of spacetime variables $(t_2 - t_1, x_2 - x_1), \ldots, (t_n - t_{n-1}, x_n - x_{n-1})$ an analytic continuation into the union of domains

$$(\alpha_1 \mathcal{T}_{\beta e}) \times \cdots \times (\alpha_{n-1} \mathcal{T}_{\beta e})$$

for $\alpha_i > 0$, $i = 1, \ldots, n-1$ and $\sum_{i=1}^{n-1} \alpha_i = 1$. The tube domains $\mathcal{T}_{\beta e}$ were specified in Definition 2. For $\beta \to \infty$, the tube $\mathcal{T}_{\beta e}$ tends to the vacuum tube $\mathcal{T}_{\text{vac.}} = \mathbb{R}^{d+1} + iV_+$; thus, one recovers the spectrum condition for the vacuum expectation values.

Let us now turn to the Fourier transformed Wightman correlation functions. Translation invariance implies

$$\widetilde{\mathcal{W}}_\beta^{(n)}(\nu_1, p_1, \ldots, \nu_n, p_n)\delta(\nu_1 + \cdots + \nu_n)\delta(p_1 + \cdots + p_n)$$

The Wightman distribution $\widetilde{\mathcal{W}}_\beta^{(n)}$ satisfies on the linear manifold $(\nu_1, p_1) + \cdots + (\nu_n, p_n) = 0$ the KMS relation in the energy variables: for any pair of multi-indices $(I, J)$ the identity

$$\widetilde{\mathcal{W}}_\beta^{(n)}(J, I) = \mathrm{e}^{-\beta\nu_I}\widetilde{\mathcal{W}}_\beta^{(n)}(I, J)$$

holds, where $\widetilde{\mathcal{W}}_\beta^{(n)}(J, I)$ is an abbreviation for $\widetilde{\mathcal{W}}_\beta^{(n)}(\{p_i\}_{i\in I}, \{p_j\}_{j\in J})$ and $\nu_I = \sum_{i\in I}\nu_i$.

We now specialize to the two-point function $\mathcal{W}_\beta^{(2)}$. The corresponding commutation function $\mathcal{C}(x)$ is given by

$$\mathcal{C}(x_1 - x_2) = \mathcal{W}_\beta^{(n)}(x_1, x_2) - \mathcal{W}_\beta^{(2)}(x_2, x_1)$$

Locality implies that $\operatorname{supp}\mathcal{C} \subset \overline{V_+} \cup \overline{V_-}$. The retarded and the advanced propagator $r$ and $a$, formally given by

$$r(x) = \mathrm{i}\theta(x_\circ)\mathcal{C}(x), \quad a(x) = -\mathrm{i}\theta(-x_\circ)\mathcal{C}(x)$$

satisfy the relation

$$r - a = -\mathrm{i}\mathcal{C}$$

which corresponds to a partition of the support of $\mathcal{C}$ in its convex components: $\operatorname{supp} r \subset \overline{V_+}$ and $\operatorname{supp} a \subset \overline{V_-}$. For the free scalar field of mass $m$ the commutator function is

$$\mathcal{C}^{(m)}(x) = \frac{1}{(2\pi)^2}\int_{\mathbb{R}^4} \mathrm{d}p\, \mathrm{e}^{-\mathrm{i}px}\tilde{\mathcal{C}}^{(m)}(p)$$

with

$$\tilde{\mathcal{C}}^{(m)}(p) = \frac{1}{2\pi}\operatorname{sgn}(\nu)\delta(\nu^2 - \boldsymbol{p}^2 - m^2)$$

and subsequently the retarded and advanced propagators $r^{(m)}$ and $a^{(m)}$ are structural functions of the field algebra, which are determined by the c-number commutation relations of the fields. Thus, they are independent of the temperature, in contrast to the two-point function:

$$\tilde{\mathcal{W}}_\beta^{(2)}(p) = \frac{\tilde{\mathcal{C}}^{(m)}(p)}{1 - \mathrm{e}^{-\beta\nu}} \qquad [7]$$

Let now $\tilde{\tau}(p)$ be the Fourier transform of the time-ordered function $\tau(x)$. The relation

$$\tilde{\tau}(p) = \frac{-\mathrm{i}\tilde{r}(p) + -\mathrm{i}\tilde{a}(p)\mathrm{e}^{-\beta\nu}}{1 - \mathrm{e}^{-\beta\nu}}$$

shows that $\tilde{\tau}(p)$ and $-\mathrm{i}\tilde{r}(p)$ only "coincide up to an exponential tail" at very high energies (Bros and Buchholz 1996).

### Particle Aspects

The condition of locality (together with the relativistic KMS condition) leads to strong constraints on the general form of the thermal two-point functions that allow one to apply the techniques of the Jost–Lehmann–Dyson representation. As has been shown by Bros and Buchholz (1996), the interacting two-point function $\mathcal{W}_\beta$ can be represented in the form

$$\mathcal{W}_\beta(t, \boldsymbol{x}) = \int_0^\infty \mathrm{d}m\, \mathcal{D}_\beta(\boldsymbol{x}, m)\mathcal{W}_\beta^{(2)}(t, \boldsymbol{x}, m)$$

Here $\mathcal{D}_\beta(\boldsymbol{x}, m)$ is a distribution in $\boldsymbol{x}, m$ which is symmetric in $\boldsymbol{x}$, and

$$\mathcal{W}_\beta^{(2)}(t, \boldsymbol{x}, m) = (2\pi)^{-1}\int \mathrm{d}\nu\mathrm{d}\boldsymbol{p}\ \mathrm{e}^{\mathrm{i}(\nu t - \boldsymbol{p}\boldsymbol{x})}\tilde{\mathcal{W}}_\beta^{(2)}(\nu, \boldsymbol{p})$$

is the two-point correlation function of the free thermal field of mass $m$. In contrast to the vacuum case, the damping factors $\mathcal{D}_\beta(\boldsymbol{x}, m)$ depend in a nontrivial way on the spatial variables $\boldsymbol{x}$. The damping factors describe the dissipative effects of the thermal system on the propagation of sharply localized excitations. Bros and Buchholz suggested that the damping factor $\mathcal{D}_\beta(\boldsymbol{x}, m)$ can be decomposed into a discrete and an absolute continuous part

$$\mathcal{D}_\beta(\boldsymbol{x}, m) = \delta(m - m_0)\mathcal{D}_{\beta,\mathrm{d}}(\boldsymbol{x}) + \mathcal{D}_{\beta,\mathrm{c}}(\boldsymbol{x}, m)$$

and that the $\delta$-contribution in the damping factors is due to stable constituent particles of mass $m_0$ out of which the thermal states are formed, whereas the collective quasiparticle-like excitations only contribute to the continuous part of the damping factors (Bros and Buchholz 1996).

In the case of spontaneously broken internal symmetries Bros and Buchholz (1998) have shown that the damping factors $\mathcal{D}_\beta^{\pm}(\boldsymbol{x}, m)$ which appear in the representation of current-field correlations functions

$$(\Omega_\beta, j_0(t, \boldsymbol{x})\phi_\beta(0, 0)\Omega_\beta) = \int_0^\infty \mathrm{d}m\Big(\mathcal{D}_\beta^+(\boldsymbol{x}, m)\partial_t\mathcal{W}_\beta^{(2)}(t, \boldsymbol{x}, m) + \mathcal{D}_\beta^-(\boldsymbol{x}, m)\mathcal{W}_\beta^{(2)}(t, \boldsymbol{x}, m)\Big)$$

indeed contain a discrete (in the sense of measures) zero-mass contribution and are slowly decreasing in $|\boldsymbol{x}|$ for small values of $m$. Thus, these damping factors coincide locally with the Källén–Lehmann weights appearing in the case of spontaneous symmetry breaking in the vacuum sector (Bros and Buchholz 1998). It is easily seen in examples that there is no sharp energy–momentum dispersion law for the Goldstone particles. Thus, the Källén–Lehmann representation is better suited than Fourier transformation to uncover the particle aspects of thermal equilibrium states.

## Models of Thermal Field Theory

In the simplest case, the classical Lagrangian density of the so-called $P(\phi)_2$ models is given by

$$\mathcal{L} = (\partial_\nu \phi)(\partial^\nu \phi) - m^2\phi^2 - \frac{\lambda}{4}\phi^4 \qquad [8]$$

Here $\phi(t,x)$ denotes a real scalar field over spacetime. The construction of the corresponding quantized thermal field presented in this section (Gérard and Jäkel 2005) is based on the original ideas of Høegh-Krohn (1974).

### Free Fields

Let $\mathfrak{h}_m$ denote the $L^2$-closure of $C_0^\infty(\mathbb{R})$ with respect to the norm $\|f\| = (f, (1/2\epsilon)f)$, where $\epsilon(k) = \sqrt{k^2+m^2}$ denotes the one-particle energy for a single neutral scalar boson and the scalar product is the usual $L^2$-scalar product. The subspaces associated to a double cone $\mathcal{O}$ are given by

$$\mathfrak{h}_m(\mathcal{O}) := \{h \in \mathfrak{h}_m | \operatorname{supp} \Re h, \operatorname{supp} \nu^{-1}\Im h \subset O\}$$

where $O$ denotes the basis of the double cone $\mathcal{O}$. The corresponding free quantum field is described by the Weyl algebra $\mathcal{W}(\mathfrak{h}_m) := \{W(f) \,|\, f \in \mathfrak{h}_m\}$, together with the time evolution $\{\tau_t^\circ\}_{t\in\mathbb{R}}$,

$$\tau_t^\circ(W(f)) = W(\mathrm{e}^{\mathrm{i}t\epsilon}f), \quad f \in \mathfrak{h}_m$$

If $m > 0$, the KMS condition allows just one unique (quasifree) $(\tau^\circ, \beta)$-KMS state:

$$\omega_\beta^\circ(W(f)) := \mathrm{e}^{-(1/4)(f,(1+2\rho)f)_m}, \quad \rho := (\mathrm{e}^{\beta\epsilon} - 1)^{-1}$$

The GNS representation associated to the pair $(\mathcal{W}(\mathfrak{h}_m), \omega_\beta^\circ)$ is the well-known Araki–Woods representation, given by

$$\mathcal{H}_{\mathrm{AW}} := \Gamma\big(\mathfrak{h}_m \oplus \overline{\mathfrak{h}_m}\big), \quad \Omega_{\mathrm{AW}} := \Omega_{\mathcal{F}},$$
$$\pi_{\mathrm{AW}}(W(h)) := W_{\mathcal{F}}\Big((1+\rho)^{1/2}h \oplus \overline{\rho}^{1/2}\overline{h}\Big), \quad h \in \mathfrak{h}_m$$

Here $\overline{\mathfrak{h}_m}$ is the Hilbert space conjugate to $\mathfrak{h}_m$, $W_{\mathcal{F}}(.)$ denotes the usual Weyl operator on the Fock space $\Gamma(\mathfrak{h}_m \oplus \overline{\mathfrak{h}_m})$ and $\Omega_{\mathcal{F}} \in \Gamma(\mathfrak{h}_m \oplus \overline{\mathfrak{h}_m})$ is the Fock vacuum. The Liouvillean $L_{\mathrm{AW}}$ (see [4]) can be identified with $d\Gamma(\epsilon \oplus -\epsilon)$.

The local von Neumann algebra generated by $\{\pi_{\mathrm{AW}}(W(h)) \,|\, h \in \mathfrak{h}_m(\mathcal{O})\}$ is denoted by $\mathcal{R}_{\mathrm{AW}}(\mathcal{O})$. The algebra of observables for the free quantum field (and, as we will see, the $P(\phi)_2$ model) is the norm closure

$$\mathcal{A} := \overline{\bigcup_{\mathcal{O}\subset\mathbb{R}^2} \mathcal{R}_{\mathrm{AW}}(\mathcal{O})}^{C^*}$$

of the local von Neumann algebras.

### The Thermal $P(\phi)_2$ Model

In $1+1$ spacetime dimensions Wick ordering is sufficient to eliminate the UV divergences of polynomial interactions. As it turns out, the leading order in the UV divergences is independent of the temperature (in agreement with the results found in Kopper *et al.* (2001)). Thus, it is a matter of convenience whether one uses the thermal covariance function $C_\beta$,

$$C_\beta(h_1,h_2) := \left(h_1, \frac{(1+\mathrm{e}^{-\beta\epsilon})}{2\epsilon(1-\mathrm{e}^{-\beta\epsilon})}h_2\right)_{L^2(\mathbb{R})}$$
$$h_1, h_2 \in \mathcal{S}(\mathbb{R})$$

or the vacuum covariance function $C_{\mathrm{vac.}}$ to define the Wick ordering:

$$:\phi(f)^n:_C = \sum_{m=0}^{[n/2]} \frac{n!}{m!(n-2m!)}\phi(f)^{n-2m}\left(-\frac{1}{2}C(f,f)\right)^m$$

Now let $P(\lambda)$ be a real-valued polynomial, which is bounded from below. Then Euclidean techniques can be used to define the operator sum

$$H_l := L_{\mathrm{AW}} + \int_{-l}^{l} :P(\phi_\beta(x)):_{C_\beta} \,\mathrm{d}x$$

in the Araki–Woods representation and to show that $H_l$ is essentially self-adjoint Gérard and Jäkel (2005). Thus, (the closure of) $H_l$ can be used to define a perturbed time evolution $t \mapsto \tau_t^l$ on $\mathcal{A}$ and the vector

$$\Omega_l := \frac{\mathrm{e}^{-(\beta/2)H_l}\Omega_{\mathrm{AW}}}{\|\mathrm{e}^{-(\beta/2)H_l}\Omega_{\mathrm{AW}}\|}$$

induces a KMS state $\omega_l$ for the dynamical system $(\pi_{\mathrm{AW}}(\mathcal{A})'', \tau^l)$.

A finite propagation speed argument (using Trotter's product formula) shows that

$$\tau_t^l(A) := \mathrm{e}^{\mathrm{i}tH_l}A\mathrm{e}^{-\mathrm{i}tH_l}, \quad t \in \mathbb{R} \qquad [9]$$

is independent of $l$ for $A \in \mathcal{R}_{\mathrm{AW}}(\mathcal{O}), t \in \mathbb{R}$ fixed and $l$ sufficiently large. Thus, there exists a limiting dynamics $\tau$ such that

$$\lim_{l\to\infty} \|\tau_t^l(A) - \tau_t(A)\| = 0 \qquad [10]$$

for all $A \in \mathcal{R}_{\mathrm{AW}}(\mathcal{O}), \mathcal{O}$ bounded. This norm convergence extends to the norm closure $\mathcal{A}$ of the local von Neumann algebras.

The existence of weak* limit points (which are states) of the (generalized) sequence $\{\omega_l\}_{l>0}$ is a consequence of the Banach–Alaoglu theorem. The fact that all limit states satisfy the KMS condition with respect to the pair $(\mathcal{A}, \tau)$ follows from [10]. To

prove that the sequence $\{\omega_l\}_{l>0}$ has only one accumulation point,

$$\omega_\beta = \lim_{l\to\infty} \omega_l \qquad [11]$$

is more delicate. Following Høegh-Krohn, Nelson symmetry is used in Gérard and Jäkel (2005) to relate the interacting thermal theory on the real line to the $P(\phi)_2$ model on the circle $S^1$ of length at temperature 0. The existence of the limit [11] then follows from the uniqueness of the vacuum state on the circle. The relativistic KMS condition can be derived by Nelson symmetry as well, using the fact that the discrete spectrum of the model on the circle satisfies the spectrum condition. Since the limit [11] exists on the norm closure $\mathcal{A}$ of the weakly closed local algebras, it follows from a result of Takesaki and Winnink that $\omega_\beta$ is locally normal with respect to the Araki–Woods representation (which itself is locally normal with respect to the Fock representation). Consequently,

$$\mathcal{R}_\beta(\mathcal{O}) := \pi_\beta(\mathcal{A}(\mathcal{O}))'' \cong \mathcal{R}_{\mathrm{AW}}(\mathcal{O}), \quad \mathcal{O} \text{ bounded}$$

that is, $\mathcal{R}_\beta(\mathcal{O})$ is (isomorphic to) the unique hyperfinite factor of type $\mathrm{III}_1$. Moreover, the local Fock property implies that the split property holds.

### Perturbation Theory

Steinmann (1995) has shown that perturbative expansions for the Wightman distributions of the $:\phi^4:_4$ model can be derived directly in the thermodynamic limit, using as only inputs the equations of motion and the (thermal) Wightman axioms. The result can be represented as a sum over generalized Feynman graphs.

The method consists in solving the differential equations for the correlation functions which follow from the field equation, by a power series expansion in the coupling constant, using the axiomatic properties of the Wightman functions as subsidiary conditions. The Wightman axioms are expected to hold separately in each order of perturbation theory, with the exception of the cluster property.

As expected, the UV renormalization can be chosen to be temperature independent, that is, one can use the same counterterms as in the vacuum case. But the infrared divergencies are more severe, they cannot be removed by minor adjustments of the renormalization procedure. Various elaborate resummation techniques have been proposed to (at least partially) remove the infrared singularities.

Another approach has been pursued by Kopper *et al.* (2001). They have investigated the perturbation expansion of the $:\phi^4:_4$ model in the imaginary-time formalism, using Wilson's flow equations. The result is once again that all correlation functions become ultraviolet-finite in all orders of the perturbation expansion, once the theory has been renormalized at zero temperature by usual renormalization prescriptions.

### Asymptotic Dynamics of Thermal Fields

Timelike asymptotic properties of thermal correlation functions cannot be interpreted in terms of free fields due to persistent dissipative effects of a thermal system. This well-known fact manifests itself in a softened pole structure of the Green's functions in momentum space and is at the root of the failure of the conventional approach to thermal perturbation theory (Bros and Bruchholz 2002). In fact, assuming a sharp dispersion law, one would be forced to conclude that the scattering matrix is trivial (a famous no-go theorem by Narnhofer *et al.* (1983)).

However, there seems to be a possibility to find an effective theory, which is much simpler and still reproduces the correct asymptotic behavior of the full theory. Disregarding low-energy excitations, Bros and Buchholz (2002) have shown that the $\delta$-contributions in the damping factors give rise to asymptotically leading terms which have a rather simple form: they are products of the thermal correlation function of a free field and a damping factor describing the dissipative effects of the model-dependent thermal background. This result is based on the assumption that the truncated $n$-point functions satisfy

$$\lim_{\mathrm{T}\to\infty} \mathrm{T}^{3(n-1)/2-\kappa} \mathcal{W}_\beta^{(n)}(t_1, x_1, \ldots, t_n, x_n)^{\text{trunc.}} = 0$$
$$\kappa > 0$$

while the $\delta$-contribution in the damping factors exhibit, for large timelike separations $T$, a $T^{-3/2}$ type behavior (in $3+1$ spacetime dimensions).

Bros and Buchholz (2002) have shown that the asymptotically dominating parts of the correlation functions can be interpreted in terms of quasifree states acting on the algebra generated by a Hermitian field $\phi_0$ satisfying the commutation relations

$$[\phi_0(t_1, x_1), \phi_0(t_2, x_2)] = \Delta_{m_0}(t_1 - t_2, x_1, x_2) Z(x_1 - x_2)$$

Here $\Delta_{m_0}$ is the usual commutator function of a free scalar field of mass $m_0$ and $Z$ is an operator-valued distribution commuting with $\phi_0$ such that $\hat{\omega}_\beta(Z(x_1 - x_2)) = \mathcal{D}_{\beta,\mathrm{d}}(x_1 - x_2)$. (Here $\hat{\omega}_\beta$ denotes a KMS state for the algebra generated by $\phi_0$.) Intuitively speaking, the field $\phi_0$ carries an additional stochastic degree of freedom, which manifests itself in a central element that appears in the commutation relations and couples to the thermal background.

As $\phi_0$ describes the interacting field asymptotically, one may expect that $\phi_0$ satisfies the field

equation of the interacting field in an asymptotic sense. Buchholz and Bros (2002) have demonstrated that this assumption allows one to derive an explicit expression for the discrete part of the damping factors $\mathcal{D}_{\beta,\mathrm{d}}(x)$ in simple models.

# Toda Lattices

**Y B Suris**, Technische Universität München, München, Germany

Lattices, or differential–difference equations, are a special class of ordinary differential equations, with the dependent variable $t$ playing the role of time and an infinite number of dependent variables $q_n = q_n(t)$ numbered by integer indices $n$, characterized by a translational invariance with respect to the shift $n \to n+1$. Due to this property, such equations are well suited for description of processes in translationally symmetric systems like crystals. On his search for lattice models admitting interesting explicit solutions, M Toda discovered in 1967 the lattice which nowadays carries his name:

$$\ddot{q}_n = \mathrm{e}^{q_{n+1}-q_n} - \mathrm{e}^{q_n-q_{n-1}} \qquad [1]$$

Toda lattice is one of the most celebrated systems of mathematical physics, and a large amount of literature is devoted to it and to its various generalizations. Its most prominent property is "integrability," so that it is amenable to a rather complete exact treatment; moreover, it can be regarded as one of the basic models, illustrating all the relevant

paradigms, notions, methods, and results of the theory of integrable systems (sometimes called the theory of solitons). One has a rare possibility to read the first-hand presentation of a large body of relevant results, including the authentic story of the original discovery, in Toda (1989).

## The Infinite Toda Lattice

### Model

The classical infinite Toda lattice [1] describes a one-dimensional chain of unit mass particles, each one interacting with the nearest neighbors only, $q_n$ being the displacement of the $n$th particle from equilibrium. It can be treated within the Hamiltonian formalism of the classical mechanics (with some care, because of the infinite number of degrees of freedom). In this framework, the second-order Newtonian equations of motion [1] are replaced by the first-order Hamiltonian ones, for the coordinates $q_n$ and canonically conjugate momenta $p_n$:

$$\dot{q}_n = p_n, \qquad \dot{p}_n = \mathrm{e}^{q_{n+1}-q_n} - \mathrm{e}^{q_n - q_{n-1}} \qquad [2]$$

The corresponding Hamilton function is

$$H_2(p,q) = \frac{1}{2}\sum_{n\in\mathbb{Z}} p_n^2 + \sum_{n\in\mathbb{Z}} (\mathrm{e}^{q_{n+1}-q_n} - 1) \qquad [3]$$

One can understand infinite sums here formally, or, alternatively, one can impose suitable boundary conditions, like $q_{n+1} - q_n \to 0, p_n \to 0$ as $|n| \to \infty$ (usually one requires decay faster than any degree of $1/|n|$).

### Multisoliton Solutions

M Toda found in 1967 a number of exact traveling wave solutions of this system, including the 1-soliton solution:

$$q_n(t) = \log \frac{1 + \mathrm{e}^{-2(\gamma_1 n - \beta_1 t + \delta_1)}}{1 + \mathrm{e}^{-2(\gamma_1 (n-1) - \beta_1 t + \delta_1)}} \qquad [4]$$

or, equivalently,

$$\mathrm{e}^{q_{n+1}(t) - q_n(t)} = 1 + \frac{\beta_1^2}{\cosh^2(\gamma_1 n - \beta_1 t + \delta_1)} \qquad [5]$$

where $\gamma_1 > 0$, $\beta_1 = \pm\sinh\gamma_1$, and $\delta_1$ is an arbitrary phase. Such a soliton moves with the velocity $v_1 = \beta_1/\gamma_1$ (to the right, if $v_1 > 0$, and to the left, if $v_1 < 0$). Note that the faster the soliton is, the larger its amplitude. Multisoliton solutions were constructed in 1973 by R Hirota with the help of his ingenious "direct" (or bilinear) method. They can be written as

$$\mathrm{e}^{q_{n+1}(t) - q_n(t)} = \frac{\tau_{n+1}(t)\tau_{n-1}(t)}{\tau_n^2(t)} \qquad [6]$$

where, for an $M$-soliton solution, $\tau_n(t)$ can be represented through the $M \times M$ determinant depending on $2M$ parameters $z_j \in (-1,1)$ and $c_j \in \mathbb{R}$:

$$\tau_n(t) = \det\left(\delta_{ij} + \frac{c_i(t)c_j(t)(z_i z_j)^{n+1}}{1 - z_i z_j}\right)_{1\le i,j\le M} \qquad [7]$$

where $c_j(t) = c_j \mathrm{e}^{\beta_j t}$, $\beta_j = (1/2)(z_j^{-1} - z_j)$. If one sets $z_j = \pm\mathrm{e}^{-\gamma_j}$ with $\gamma_j > 0$, then $\beta_j = \pm\sinh\gamma_j$, and one can show that asymptotically both for $t \to -\infty$ and for $t \to +\infty$ the solution [6] looks like the sum of well-separated solitons [4] with the velocities $v_j = \beta_j/\gamma_j$ and the respective phases $\gamma_j n - \beta_j t + \delta_j^{(\pm)}$. This is usually interpreted as a particle-like behavior of solitons. One can show that the scattering of solitons is factorized:

$$\delta_j^{(+)} - \delta_j^{(-)} = \sum_{v_k < v_j} \log\left|\frac{1 - z_j z_k}{z_j - z_k}\right| - \sum_{v_k > v_j} \log\left|\frac{1 - z_j z_k}{z_j - z_k}\right| \qquad [8]$$

which means that the phase shifts of individual solitons can be interpreted as coming from the pairwise interactions only.

### Integrability

The infinite Toda lattice is completely integrable in the sense of the classical Hamiltonian mechanics: it admits an infinite number of functionally independent integrals of motion in involution. This was demonstrated in 1974 by M Hénon. An instance of these higher integrals of motion is given by

$$H_3(p,q) = \frac{1}{3}\sum_{n\in\mathbb{Z}} p_n^3 + \sum_{n\in\mathbb{Z}} (p_n + p_{n+1})\mathrm{e}^{q_{n+1}-q_n} \qquad [9]$$

Hamiltonian flows corresponding to the higher integrals of motion (usually referred to as higher Toda flows) form the "Toda lattice hierarchy." A beautiful approach to this hierarchy is based on the Lax representation of the Toda lattice, discovered in 1974 independently by H Flaschka and S Manakov. In the variables $a_n, b_n$, related to $q_n, p_n$ by

$$a_n = \mathrm{e}^{q_{n+1}-q_n}, \qquad b_n = p_n \qquad [10]$$

equations of motion of the Toda lattice [2] are rewritten as

$$\dot{a}_n = a_n(b_{n+1} - b_n), \qquad \dot{b}_n = a_n - a_{n-1} \qquad [11]$$

It turns out that eqns [11] are equivalent to the operator equation

$$\dot{L} = [L, A_+] = [A_-, L] \quad [12]$$

where $L$ and $A_\pm$ are linear difference operators with coefficients depending on $a_n, b_n$:

$$L = \sum_{n\in\mathbb{Z}} b_n E_{n,n} + \sum_{n\in\mathbb{Z}} a_n E_{n,n+1} + \sum_{n\in\mathbb{Z}} E_{n+1,n} \quad [13]$$

$$A_+ = \sum_{n\in\mathbb{Z}} b_n E_{n,n} + \sum_{n\in\mathbb{Z}} E_{n+1,n}$$
$$A_- = \sum_{n\in\mathbb{Z}} a_n E_{n,n+1} \quad [14]$$

Here difference operators are represented as infinite matrices, $E_{m,n}$ being the matrix with the only nonvanishing element equal to 1 in the position $(m, n)$. A diagonal similarity (gauge) transformation of the matrix $L$ leads to an equivalent Lax representation of the Toda lattice:

$$\dot{L_0} = [L_0, A_0] \quad [15]$$

with

$$L_0 = \sum_{n\in\mathbb{Z}} b_n E_{n,n} + \sum_{n\in\mathbb{Z}} a_n^{1/2}\left(E_{n+1,n} + E_{n,n+1}\right) \quad [16]$$

$$A_0 = \frac{1}{2}\sum_{n\in\mathbb{Z}} a_n^{1/2}\left(E_{n+1,n} - E_{n,n+1}\right) \quad [17]$$

Being equivalent for the Toda lattice, these two Lax representations admit nonequivalent generalizations (see below). Note that the matrices $A_\pm$ in [14] may be interpreted as $A_\pm = \pi_\pm(L)$, where $\pi_\pm$ stands for the lower-triangular, resp., strictly upper-triangular part. The commuting higher members of the Toda lattice hierarchy (enumerated by $s \in \mathbb{N}$) are characterized by the Lax equations of the form [12] with the same Lax matrix $L$ as in [13] and with $A_\pm = \pi_\pm(L^s)$. In the Lax representation [15], the higher Toda flows are obtained by choosing $A_0 = \mathrm{skew}(L_0^s)$, where "skew" denotes the skew-symmetric part (strictly lower-triangular part minus strictly upper-triangular part) of the symmetric matrix. The Hamilton functions of the higher flows are obtained as $H_s \sim \mathrm{tr}(L^s) = \mathrm{tr}(L_0^s)$.

### Inverse Scattering

H Flaschka and S Manakov laid the Lax representation into the base of the application of the inverse-scattering, or inverse-spectral, transformation method (IST) to the infinite Toda lattice. It was the first application of IST in the lattice context. The matrix $L_0$ in [16] is symmetric tridiagonal, which yields that the operator $L_0$ is second order and self-adjoint. The direct and inverse-spectral problem for $L_0\psi = \mu\psi$ with such operators $L_0$ is well studied and parallel, to a large extent, to the corresponding theory for second-order differential operators. In the rapidly decaying case, the set of spectral data of the operator $L_0$, allowing for a solution of the inverse problem, consists of:

1. eigenvalues $\mu_j = z_j + z_j^{-1}$ of the discrete spectrum, with $z_j \in (-1, 1)$;
2. normalizing coefficients $\gamma_j$ of the corresponding eigenfunctions; and
3. reflection coefficient $r(z)$ for $|z| = 1$, characterizing the continuous spectrum $\mu = z + z^{-1} \in [-2, 2]$.

The solution of the inverse-spectral problem is given in terms of the Riemann–Hilbert problem or its variants, like the Gelfand–Levitan equation. Equation [12] means that the evolution of the operator $L$, induced by the evolution of $q_n(t), p_n(t)$ in virtue of the Toda lattice equations [2], is "isospectral." More precisely, the discrete eigenvalues are integrals of motion, while the evolution of other spectral data is governed by simple linear equations:

$$z_j = \text{const.}, \qquad \gamma_j(t) = \gamma_j(0)\mathrm{e}^{\left(z_j^{-1} - z_j\right)t}$$
$$r(z, t) = r(z, 0)\mathrm{e}^{(z^{-1} - z)t} \quad [18]$$

In particular, the multisoliton solutions correspond to the reflectionless case $r(z, t) \equiv 0$. The IST solution of the initial-value problem for the infinite Toda lattice can be schematically depicted as in Figure 1.

### Bi-Hamiltonian Structure

The canonical Poisson bracket for the variables $q_n, p_n$ turns in the Flaschka–Manakov variables [10] into

$$\{b_n, a_n\}_1 = -a_n, \qquad \{a_n, b_{n+1}\}_1 = -a_n \quad [19]$$

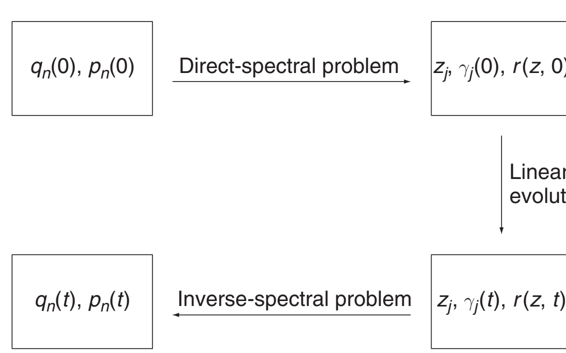

**Figure 1** General scheme of the IST.

(all other brackets of the coordinate functions vanish), and the system [11] is Hamiltonian with respect to this bracket, with the Hamilton function

$$H_2 = \frac{1}{2}\sum b_n^2 + \sum a_n$$

However, one can define also a different Poisson bracket for the variables $a_n, b_n$:

$$\begin{aligned} \{b_n, a_n\}_2 &= -b_n a_n \\ \{a_n, b_{n+1}\}_2 &= -a_n b_{n+1} \\ \{b_n, b_{n+1}\}_2 &= -a_n \\ \{a_n, a_{n+1}\}_2 &= -a_n a_{n+1} \end{aligned} \qquad [20]$$

with the following properties: it is compatible with the first one (i.e., their linear combinations are again Poisson brackets), and the system [11] is Hamiltonian with respect to this bracket, with the Hamilton function $H_1 = \sum b_n$. So, the Toda lattice in the form [11] is a bi-Hamiltonian system. This result is due to M Adler (1979). The bi-Hamiltonian property, introduced by F Magri in 1978 on the example of the Korteweg–de Vries equation, has been established since then as an alternative (and highly effective and informative) definition of integrability. Actually, the Toda lattice [11] is even tri-Hamiltonian, since there exists one more local Poisson bracket for the variables $a_n, b_n$ with similar properties, discovered by B Kupershmidt in 1985.

### Darboux–Bäcklund Transformations and Discretization

A further indispensable attribute of integrable systems are the so-called Darboux–Bäcklund transformations. For the Toda lattice they were first found by M Toda and M Wadati in 1975. A Bäcklund transformation $(q_n, p_n) \mapsto (\widetilde{q}_n, \widetilde{p}_n)$ with the parameter $h$ can be written as

$$\begin{aligned} 1 + hp_n &= e^{\tilde{q}_n - q_n} + h^2 e^{q_n - \tilde{q}_{n-1}} \\ 1 + h\widetilde{p}_n &= e^{\tilde{q}_n - q_n} + h^2 e^{q_{n+1} - \tilde{q}_n} \end{aligned} \qquad [21]$$

This is a canonical transformation, possessing a classical generating function. These formulas can be given a fundamentally important interpretation in terms of the matrices

$$U_+ = \sum_{n \in \mathbb{Z}} e^{\tilde{q}_n - q_n} E_{n,n} + h \sum_{n \in \mathbb{Z}} E_{n+1,n} \qquad [22]$$

$$U_- = I + h \sum_{n \in \mathbb{Z}} e^{q_{n+1} - \tilde{q}_n} E_{n,n+1} \qquad [23]$$

The first formula in [21] is equivalent to the factorization $I + hL = U_+ U_-$, while the second one is equivalent to the factorization $I + h\widetilde{L} = U_- U_+$ with the flipped factors. The Bäcklund transformation [21] serves also as an integrable discretization of the Toda flow [2] with the time step $h$.

## Finite Open-End Toda Lattice

### Model

The infinite Toda lattice [1] can be reduced to finite-dimensional systems by imposing suitable boundary conditions, different from the rapidly decaying ones. Particularly important are "open-end boundary conditions," which correspond to placing the particles 0 and $N+1$ at $q_0 = +\infty$ and $q_{N+1} = -\infty$, respectively. In terms of the Flaschka–Manakov variables, this means that $a_0 = a_N = 0$ and $b_0 = b_{N+1} = 0$. The Hamilton function of the resulting system with $N$ degrees of freedom is

$$H_2(p, q) = \frac{1}{2}\sum_{n=1}^{N} p_n^2 + \sum_{n=1}^{N-1} e^{q_{n+1} - q_n} \qquad [24]$$

This system consists of $N$ particles subject to repulsive forces between nearest neighbors, and exhibits a scattering behavior both as $t \to -\infty$ and $t \to +\infty$. It admits a Lax representation of the same form [12] or [15] as in the infinite case, but with all the matrices being now of finite size $N \times N$, so that [13]–[14] and [16]–[17] are replaced by

$$L = \sum_{n=1}^{N} b_n E_{n,n} + \sum_{n=1}^{N-1} a_n E_{n,n+1} + \sum_{n=1}^{N-1} E_{n+1,n} \qquad [25]$$

$$\begin{aligned} A_+ &= \sum_{n=1}^{N} b_n E_{n,n} + \sum_{n=1}^{N-1} E_{n+1,n} \\ A_- &= \sum_{n=1}^{N-1} a_n E_{n,n+1} \end{aligned} \qquad [26]$$

and

$$L_0 = \sum_{n=1}^{N} b_n E_{n,n} + \sum_{n=1}^{N-1} a_n^{1/2} \left(E_{n+1,n} + E_{n,n+1}\right) \qquad [27]$$

$$A_0 = \frac{1}{2}\sum_{n=1}^{N-1} a_n^{1/2} \left(E_{n+1,n} - E_{n,n+1}\right) \qquad [28]$$

The qualitative behavior of the solutions is easily understood: as a consequence of repulsive interactions, the pairwise distances between particles grow infinitely, $a_n(t) = e^{q_{n+1}(t) - q_n(t)} \to 0$ as $t \to \pm\infty$, so that the matrix $L_0$ becomes asymptotically diagonal, with the limit velocities $b_n(\pm\infty) = \dot{q}_n(\pm\infty)$ as the diagonal entries. Due to the isospectral evolution of $L_0$, these limit velocities have to coincide with the eigenvalues $\mu_j$ of $L_0$, which are integrals of motion.

As $t \to -\infty$, they appear on the diagonal in the increasing order (the rightmost particle $q_1$ being the slowest, and the leftmost $q_N$ being the fastest), while as $t \to +\infty$, their order on the diagonal changes to the decreasing one (the particle $q_1$ becoming the fastest and $q_N$ becoming the slowest).

### Moser's Solution

Integration of this system has been first performed by J Moser in 1975. His solution can be interpreted within the general scheme of the IST (see **Figure 1**). The spectral data in this case consist, for example, of the eigenvalues $\mu_j (j = 1, \ldots, N)$ of the matrix $L_0$ and the first components $r_j$ of the corresponding orthonormal eigenvectors. The evolution of these data induced by the Toda flow [2] turns out to be simple:

$$\mu_j = \text{const.}, \qquad r_j^2(t) = \frac{r_j^2(0)\mathrm{e}^{\mu_j t}}{\sum_{i=1}^{N} r_i^2(0)\mathrm{e}^{\mu_i t}} \qquad [29]$$

The IST is expressed by the identity

$$\sum_{j=1}^{N} \frac{r_j^2}{\mu - \mu_j} = \cfrac{1}{\mu - b_1 - \cfrac{a_1}{\mu - b_2 - \ddots - \cfrac{a_{N-1}}{\mu - b_N}}} \qquad [30]$$

both parts of which represent the entry $(1, 1)$ of the matrix $(\mu I - L_0)^{-1}$. It implies that all variables $a_n(t), b_n(t)$ are rational functions of $\mu_j$ and $\mathrm{e}^{\mu_j t}$; in particular, one finds:

$$a_n(t) = \mathrm{e}^{q_{n+1}(t) - q_n(t)} = \frac{\tau_{n-1}(t)\tau_{n+1}(t)}{\tau_n^2(t)} \qquad [31]$$

where $\tau_n(t)$ can be represented as an $n \times n$ Hankel determinant

$$\tau_n(t) = \det\big(c_{j+k}(t)\big)_{0 \le j,k \le n-1}$$
$$c_j(t) = \sum_{i=1}^{N} \mu_i^j r_i^2(t) \qquad [32]$$

### Factorization Solution

The Lax representation [12] is a particular instance of a general construction, known under the name of Adler–Kostant–Symes (AKS) method and found around 1980. The ingredients of this construction are:

- a Lie algebra $\mathfrak{g}$, equipped with a nondegenerate scalar product which is used to identify $\mathfrak{g}$ with its dual space $\mathfrak{g}^*$;
- a splitting of $\mathfrak{g}$ into a direct sum of its two subspaces $\mathfrak{g}_\pm$ which are also Lie subalgebras, with $\pi_\pm : \mathfrak{g} \to \mathfrak{g}_\pm$ being the corresponding projections;
- the Lie group $G$ of the Lie algebra $\mathfrak{g}$, and its Lie subgroups $G_\pm$ with the Lie algebras $\mathfrak{g}_\pm$; and
- a function $\phi : \mathfrak{g} \to \mathfrak{g}$ covariant with respect to the adjoint action of $G$ (in the case of matrix Lie algebras and groups, one can take, e.g., $\phi(L) = L^s$).

The AKS method provides a formula for the solution of the initial-value problem for Lax equations of the form [12] with the Lax matrix $L \in \mathfrak{g}$ and $A_\pm = \pi_\pm(\phi(L))$. The solution is given by

$$L(t) = U_+^{-1}(t)L(0)U_+(t) = U_-(t)L(0)U_-^{-1}(t) \qquad [33]$$

where the elements $U_\pm(t) \in G_\pm$ solve the factorization problem

$$\exp\big(t\phi(L(0))\big) = U_+(t)U_-(t) \qquad [34]$$

For the open-end Toda lattice $\mathfrak{g} = \mathrm{gl}(N)$, the Lie algebra of all $N \times N$ matrices, $\mathfrak{g}_\pm$ consist of all lower-triangular, resp., strictly upper-triangular, matrices. Accordingly, $G = \mathrm{GL}(N)$, the Lie group of all nondegenerate $N \times N$ matrices, and $G_\pm$ consist of all nondegenerate lower-triangular matrices, resp., of upper-triangular matrices with units on the diagonal. The corresponding factorization problem in $G$ is well known in the linear algebra under the name of LR factorization, and is related to the Gaussian elimination. From [33] and the well-known expression of the diagonal elements of the lower-triangular factor in the LR factorization through the minors of the factorized matrix, we find:

$$a_n(t) = \frac{\tau_{n+1}(t)\tau_{n-1}(t)}{\tau_n^2(t)} a_n(0) \qquad [35]$$

where $\tau_n(t)$ is the upper-left $n \times n$ minor of the matrix $\exp(tL(0))$. If $L(t)$ is the Lax matrix along the solution of the Toda flow ($\phi(L) = L$), then the sampling of the matrix $\exp(L(t))$ at the integer times $t \in \mathbb{Z}$ coincides with the result of application of the Rutishauser's *LR* algorithm to the matrix $\exp(L(0))$. The *LR* algorithm applied to the matrix $I + hL(0)$ is nothing other but the Bäcklund transformation [21] in the open-end situation.

## Finite Periodic Toda Lattice

### Model

A different reduction of the infinite Toda lattice to a finite-dimensional system appears by imposing periodic boundary conditions, $q_{n+N}(t) \equiv q_n(t)$ for all $n \in \mathbb{Z}$ (of course, such relations hold also for the Flaschka–Manakov variables $a_n, b_n$). The Hamilton

function of the resulting system with $N$ degrees of freedom is

$$H_2(p,q) = \frac{1}{2}\sum_{n\in\mathbb{Z}/N\mathbb{Z}} p_n^2 + \sum_{n\in\mathbb{Z}/N\mathbb{Z}} e^{q_{n+1}-q_n} \qquad [36]$$

This system consists of $N$ particles $q_n (n = 1, \ldots, N)$, and it is always assumed that $q_{N+1} \equiv q_1$ and $q_0 \equiv q_N$. Thus, the potential energy in [36] differs from the potential energy in [24] by one additional term $e^{q_1-q_N}$. However, this modest difference leads to much more complicated dynamics of the system (quasiperiodic instead of scattering). It is convenient to replace infinite matrices in the Lax representation [12] by finite ones, of size $N \times N$, but depending on an additional parameter $\lambda$ (called the spectral parameter):

$$L = \sum_{n\in\mathbb{Z}/N\mathbb{Z}} b_n E_{n,n} + \lambda^{-1} \sum_{n\in\mathbb{Z}/N\mathbb{Z}} a_n E_{n,n+1} + \lambda \sum_{n\in\mathbb{Z}/N\mathbb{Z}} E_{n+1,n} \qquad [37]$$

$$A_+ = \sum_{n\in\mathbb{Z}/N\mathbb{Z}} b_n E_{n,n} + \lambda \sum_{n\in\mathbb{Z}/N\mathbb{Z}} E_{n+1,n} \qquad [38]$$

$$A_- = \lambda^{-1} \sum_{n\in\mathbb{Z}/N\mathbb{Z}} a_n E_{n,n+1} \qquad [39]$$

The Lax representation [12] holds identically in $\lambda$, so that the spectral parameter drops out of the equations of motion. Note that, unlike the open-end case, $L$ is no more a tridiagonal matrix, because of the nonvanishing entries in the positions $(N, 1)$ and $(1, N)$.

### Inverse-Spectral Transformation

Solution of the periodic lattice in terms of multidimensional theta functions has been given independently by E Date and S Tanaka, and by I Krichever in 1976. In this case, the set of the spectral data is more complicated; it includes:

- a hyperelliptic Riemann surface $\mathcal{R}$ of genus $N-1$ determined by the eigenvalues of the periodic boundary-value problem for the operator $L$, or, in other words, by the equation $R(\lambda,\mu) = \det(L(\lambda) - \mu I) = 0$; and
- $N-1$ points $P_k$ on $\mathcal{R}$, which correspond to the eigenvalues of $L$ with vanishing boundary conditions.

Due to [12], the Riemann surface $\mathcal{R}$ itself is an integral of motion, and the evolution of points $P_k$ is such that the image of the divisor $P_1 + \cdots + P_{N-1}$ under the Abel map moves along a straight line in the Jacobi variety of $\mathcal{R}$. Solution of the inverse-spectral problem is given in terms of multidimensional theta-functions by formula [35] with $\tau_n(t) = \theta(nU - tV + D)$, where $U, V, D$ are certain vectors on the Jacobian of $\mathcal{R}$ (the first two of them depending on the spectrum $\mathcal{R}$ only).

### Loop Algebras

The periodic Toda lattice can be included into the general AKS scheme, if one interprets the Lax matrix $L$ as an element of the loop algebra $\boldsymbol{g}$ which consists of Laurent polynomials (in $\lambda$) with coefficients from $\mathrm{gl}(N)$, singled out by the additional condition

$$\boldsymbol{g} = \left\{ L(\lambda) \in \mathrm{gl}(N)[\lambda, \lambda^{-1}] : \Omega L(\lambda)\Omega^{-1} = L(\omega\lambda) \right\}$$

where $\Omega = \mathrm{diag}(1, \omega, \ldots, \omega^{N-1})$, $\omega = \exp(2\pi i/N)$. Subalgebras $\boldsymbol{g}_\pm$ consist of Laurent polynomials with respect to non-negative, resp., strictly negative powers of $\lambda$. The Lie group $\boldsymbol{G}$ corresponding to the Lie algebra $\boldsymbol{g}$ consists of $\mathrm{GL}(N)$-valued functions $U(\lambda)$ of the complex parameter $\lambda$, regular in $\mathbb{C}P^1 \backslash \{0, \infty\}$ and satisfying $\Omega U(\lambda)\Omega^{-1} = U(\omega\lambda)$. Its subgroups $\boldsymbol{G}_\pm$ corresponding to the Lie algebras $\boldsymbol{g}_\pm$ are singled out by the following conditions: elements of $\boldsymbol{G}_+$ are regular in the neighborhood of $\lambda = 0$, while elements of $\boldsymbol{G}_-$ are regular in the neighborhood of $\lambda = \infty$ and take at $\lambda = \infty$ the value $I$. The corresponding factorization is called the generalized LR factorization. As opposed to the open-end case, finding such a factorization is a problem of the Riemann–Hilbert type which is solved in terms of algebraic geometry and theta-functions rather than in terms of linear algebra and exponential functions. This approach to the periodic Toda lattice is due to Reyman and Semenov-Tian-Shansky (1979) and, independently, to M Adler and P van Moerbeke (1980).

## Generalizations: Lie-Algebraic Systems

The AKS interpretation of the finite Toda lattices leads directly to their generalizations by replacing the algebra $\mathrm{gl}(N)$, resp., the loop algebra over $\mathrm{gl}(N)$, by simple Lie algebras, resp. affine Lie algebras. These generalized Toda systems were introduced in 1976 by O Bogoyavlensky and solved in 1979 independently by M Olshanetsky, A Perelomov, and by B Kostant.

### Simple Lie Algebras

Let $\mathfrak{g}$ be a simple Lie algebra (complex or real split), and $\mathfrak{h}$ its Cartan subalgebra. Let further $\Delta = \Delta_+ \cup \Delta_-$ be the root system of $\mathfrak{g}$, decomposed into the sets of positive roots $\Delta_+$ and the set of negative roots $\Delta_-$. One has a direct vector space $\mathfrak{g} = \mathfrak{g}_+ \oplus \mathfrak{g}_-$, where $\mathfrak{g}_+$ is spanned by the root spaces for positive roots and by $\mathfrak{h}$,

while $\mathfrak{g}_-$ is spanned by the root spaces for negative roots (Borel decomposition). For $\alpha \in \Delta$ let $E_\alpha$ be a corresponding root vector. So, $[H, E_\alpha] = \alpha(H)E_\alpha$ for all $H \in \mathfrak{h}$. The root $\alpha \in \mathfrak{h}^*$ may be identified with $H_\alpha \in \mathfrak{h}$ defined by $\langle H_\alpha, H\rangle = \alpha(H)$ for all $H \in \mathfrak{h}$. It is easy to deduce that $[E_\alpha, E_{-\alpha}] = c_\alpha H_\alpha$, where $c_\alpha = \langle E_\alpha, E_{-\alpha}\rangle$. The system of simple roots will be denoted by $\Phi \subset \Delta_+$.

The generalized Toda lattice for the Lie algebra $\mathfrak{g}$ is the following system of differential equations on $\mathfrak{h} \times \mathfrak{h}$:

$$\begin{aligned} \dot{Q} &= P \\ \dot{P} &= -\sum_{\alpha\in\Phi} \mathrm{e}^{\alpha(Q)}[E_\alpha, E_{-\alpha}] = -\sum_{\alpha\in\Phi} c_\alpha \mathrm{e}^{\alpha(Q)} H_\alpha \end{aligned} \qquad [40]$$

This system can be given a Hamiltonian formulation, with the Hamilton function

$$H_{\mathfrak{g}} = \frac{1}{2}\langle P, P\rangle + \sum_{\alpha\in\Phi} c_\alpha \mathrm{e}^{\alpha(Q)} \qquad [41]$$

It is completely integrable, and has a Lax representation [12] with

$$L = P + \sum_{\alpha\in\Phi} E_\alpha + \sum_{\alpha\in\Phi} \mathrm{e}^{\alpha(Q)} E_{-\alpha} \qquad [42]$$

$$A_+ = P + \sum_{\alpha\in\Phi} E_\alpha, \quad A_- = \sum_{\alpha\in\Phi} \mathrm{e}^{\alpha(Q)} E_{-\alpha} \qquad [43]$$

The usual open-end Toda lattice corresponds to the algebra sl($N$) (series $A_{N-1}$), so that the Hamilton function [24] can be denoted by $H_{A_{N-1}}$. The Hamilton functions of the generalized lattices corresponding to other classical algebras so($2N+1$) (series $B_N$), sp($N$) (series $C_N$), and so($2N$) (series $D_N$) can be written in the canonically conjugate variables $q_n, p_n (n = 1, \ldots, N)$ as

$$H_{\mathfrak{g}}(p,q) = H_{A_{N-1}}(p,q) + \begin{cases} \mathrm{e}^{-q_N}, & \mathfrak{g} = B_N \\ \mathrm{e}^{-2q_N}, & \mathfrak{g} = C_N \\ \mathrm{e}^{-q_N - q_{N-1}}, & \mathfrak{g} = D_N \end{cases} \qquad [44]$$

### Affine Lie Algebras

Turning to the generalizations of the periodic Toda lattice, let $\theta$ be a Coxeter automorphism of a simple complex algebra $\mathfrak{g}$, the order of $\theta$ being $m$. Introduce the loop algebra $\boldsymbol{g}$ as the Lie algebra of Laurent polynomials

$$\boldsymbol{g} = \left\{ L(\lambda) \in \mathfrak{g}[\lambda, \lambda^{-1}] : \theta(L(\lambda)) = L(\omega\lambda) \right\}$$

where $\omega = \exp(2\pi\mathrm{i}/m)$. Denote by $\mathfrak{g}_j$ the eigenspaces of $\theta$ corresponding to the eigenvalues $\omega^j (j \in \mathbb{Z}/m\mathbb{Z})$. Set $\mathfrak{a} = \mathfrak{g}_0$, and let $s$ denote the dimension of $\mathfrak{a}$. By definition of the Coxeter automorphism, $\mathfrak{a}$ is an abelian subalgebra of $\mathfrak{g}$. Denote by $\Psi$ the set of $\alpha \in \mathfrak{a}^*$ for which there exist nonzero elements $E_\alpha \in \mathfrak{g}_1$ with $[H, E_\alpha] = \alpha(H)E_\alpha$ for all $H \in \mathfrak{a}$. The elements $E_{-\alpha} \in \mathfrak{g}_{-1}$ are defined similarly. It can be shown that $\Psi$ contains $s+1$ elements, so that between them there exists exactly one linear relation. The elements of $\Psi$ are called simple weights of the loop algebra $\boldsymbol{g}$. The Lie algebra $\boldsymbol{g}$ is a direct sum of its two subspaces $\boldsymbol{g}_\pm$ consisting of Laurent polynomials with non-negative, resp., with strictly negative powers of $\lambda$; these subspaces are also Lie subalgebras.

Now the generalized Toda lattice related to the loop algebra $\boldsymbol{g}$ can be introduced as the system of differential equations on $\mathfrak{a} \times \mathfrak{a}$, which looks formally exactly as [40], and has the Hamilton function which looks exactly as [41], but with the set of simple roots $\Phi$ of $\mathfrak{g}$ being replaced by the set of simple weights $\Psi$ of $\boldsymbol{g}$. The matrices participating in the Lax representation [12] belong now to the loop algebra $\boldsymbol{g}$:

$$L(\lambda) = P + \lambda \sum_{\alpha\in\Psi} E_\alpha + \lambda^{-1} \sum_{\alpha\in\Psi} \mathrm{e}^{\alpha(Q)} E_{-\alpha} \qquad [45]$$

$$\begin{aligned} A_+(\lambda) &= P + \lambda \sum_{\alpha\in\Psi} E_\alpha \\ A_-(\lambda) &= \lambda^{-1} \sum_{\alpha\in\Psi} \mathrm{e}^{\alpha(Q)} E_{-\alpha} \end{aligned} \qquad [46]$$

For the classical series of loop algebras, the Hamilton functions $H_{\boldsymbol{g}}$ in the canonically conjugate variables $q_n, p_n (n = 1, \ldots, N)$ can be presented as

$$H_{\boldsymbol{g}}(p,q) = H_{A_{N-1}}(p,q) + \begin{cases} \mathrm{e}^{-q_N} + \mathrm{e}^{q_1+q_2}, & \boldsymbol{g} = B_N^{(1)} \\ \mathrm{e}^{-2q_N} + \mathrm{e}^{2q_1}, & \boldsymbol{g} = C_N^{(1)} \\ \mathrm{e}^{-q_N - q_{N-1}} + \mathrm{e}^{q_1+q_2}, & \boldsymbol{g} = D_N^{(1)} \\ \mathrm{e}^{-2q_N} + \mathrm{e}^{q_1+q_2}, & \boldsymbol{g} = A_{2N-1}^{(2)} \\ \mathrm{e}^{-q_N} + \mathrm{e}^{2q_1}, & \boldsymbol{g} = A_{2N}^{(2)} \\ \mathrm{e}^{-q_N} + \mathrm{e}^{q_1}, & \boldsymbol{g} = D_{N+1}^{(2)} \end{cases} \qquad [47]$$

Actually, one can find even more general integrable systems of the Toda type: one can add to $H_{A_{N-1}}(p,q)$ any of the two potentials $\mathrm{e}^{-q_N - q_{N-1}}$ or $\alpha\mathrm{e}^{-q_N} + \beta\mathrm{e}^{-2q_N}$ on one end combined with any of the two potentials $\mathrm{e}^{q_1+q_2}$ or $\gamma\mathrm{e}^{q_1} + \delta\mathrm{e}^{2q_1}$ on the other end, where $\alpha, \beta, \gamma, \delta$ are arbitrary constants. This result is due to E Sklyanin (1987).

## Generalizations: Lattices with Nearest-Neighbor Interactions

There exist further integrable lattice systems with the nearest-neighbor interaction apart from the classical exponential Toda lattice [1]. Those of the

type $\ddot{q}_n = r(\dot{q}_n)(g(q_{n+1} - q_n) - g(q_n - q_{n-1}))$ have been classified by R Yamilov in 1982, and the list contains, apart from the usual Toda lattice [1], the following ones:

$$\ddot{q}_n = \dot{q}_n(e^{q_{n+1}-q_n} - e^{q_n-q_{n-1}}) \quad [48]$$

$$\ddot{q}_n = \dot{q}_n(q_{n+1} - 2q_n + q_{n-1}) \quad [49]$$

$$\ddot{q}_n = -(\dot{q}_n^2 - \nu^2)\left(\frac{1}{q_{n+1} - q_n} - \frac{1}{q_n - q_{n-1}}\right) \quad [50]$$

$$\ddot{q}_n = -(\dot{q}_n^2 - \nu^2)(\coth(q_{n+1} - q_n) - \coth(q_n - q_{n-1})) \quad [51]$$

Equations [48] are known as the "modified Toda lattice." Equations [49] describe the "dual Toda lattice" which was instrumental in the original discovery by Toda (see Toda (1989)). All systems [49]–[51] can be obtained from [11] via suitable parametrizations of the variables $a_n, b_n$ by canonically conjugate ones $q_n, p_n$, similar to [10] for [1], see Suris (2003).

A remarkable discovery of the integrable relativistic Toda lattice is due to S Ruijsenaars (1990). This lattice with the equations of motion

$$\ddot{q}_n = (1 + \alpha\dot{q}_n)\left((1 + \alpha\dot{q}_{n+1})\frac{e^{q_{n+1}-q_n}}{1 + \alpha^2 e^{q_{n+1}-q_k}} - (1 + \alpha\dot{q}_{n-1})\frac{e^{q_n-q_{n-1}}}{1 + \alpha^2 e^{q_n-q_{n-1}}}\right) \quad [52]$$

can be considered as the perturbation of the usual Toda lattice with the small parameter $\alpha$ (the inverse speed of light).

A class of integrable lattice systems of the relativistic Toda type $\ddot{q}_n = r(\dot{q}_n)(\dot{q}_{n+1}f(q_{n+1} - q_n) - \dot{q}_{n-1}f(q_n - q_{n-1}) + g(q_{n+1} - q_n) - g(q_n - q_{n-1}))$ is richer than that of the Toda type, and has been isolated by Yu B Suris and by V Adler and A Shabat in 1997. The list contains, apart from the relativistic Toda lattice [52], two more $\alpha$-perturbations of the usual Toda lattice [1]:

$$\ddot{q}_n = (1 + \alpha\dot{q}_{n+1})e^{q_{n+1}-q_n} - (1 + \alpha\dot{q}_{n-1})e^{q_n-q_{n-1}} - \alpha^2\left(e^{2(q_{n+1}-q_n)} - e^{2(q_n-q_{n-1})}\right) \quad [53]$$

$$\ddot{q}_n = (1 - \alpha\dot{q}_n)^2\left((1 - \alpha\dot{q}_{n+1})e^{q_{n+1}-q_n} - (1 - \alpha\dot{q}_{n-1})e^{q_n-q_{n-1}}\right) \quad [54]$$

two $\alpha$-perturbations of the modified Toda lattice [48]:

$$\ddot{q}_k = \dot{q}_n\left(e^{q_{n+1}-q_n} - e^{q_n-q_{n-1}} + \alpha\dot{q}_{n+1}\frac{e^{q_{n+1}-q_n}}{1 + \alpha e^{q_{n+1}-q_n}} - \alpha\dot{q}_{n-1}\frac{e^{q_n-q_{n-1}}}{1 + \alpha e^{q_n-q_{n-1}}}\right) \quad [55]$$

$$\ddot{q}_n = \dot{q}_n(1 - \alpha\dot{q}_n)\left((1 - \alpha\dot{q}_{n+1})\frac{e^{q_{n+1}-q_n}}{1 + \alpha e^{q_{n+1}-q_n}} - (1 - \alpha\dot{q}_{n-1})\frac{e^{q_n-q_{n-1}}}{1 + \alpha e^{q_n-q_{n-1}}}\right) \quad [56]$$

two $\alpha$-perturbations of the dual Toda lattice [49]:

$$\ddot{q}_n = \dot{q}_n(q_{n+1} - 2q_n + q_{n-1}) + \frac{\alpha\dot{q}_{n+1}\dot{q}_n}{1 + \alpha(q_{n+1} - q_n)} - \frac{\alpha\dot{q}_n\dot{q}_{n-1}}{1 + \alpha(q_n - q_{n-1})} \quad [57]$$

$$\ddot{q}_n = \dot{q}_n(1 + \alpha^2\dot{q}_n)\left(\frac{q_{n+1} - q_n - \alpha\dot{q}_{n+1}}{1 + \alpha(q_{n+1} - q_n)} - \frac{q_n - q_{n-1} - \alpha\dot{q}_{n-1}}{1 + \alpha(q_n - q_{n-1})}\right) \quad [58]$$

and one $\alpha$-perturbation of each of the systems [50] and [51]:

$$\ddot{q}_n = -(\dot{q}_n^2 - \nu^2)\left(\frac{q_{n+1} - q_n - \alpha\dot{q}_{n+1}}{(q_{n+1} - q_n)^2 - (\nu\alpha)^2} - \frac{q_n - q_{n-1} - \alpha\dot{q}_{n-1}}{(q_n - q_{n-1})^2 - (\nu\alpha)^2}\right) \quad [59]$$

$$\ddot{q}_n = -\frac{1}{2}(\dot{q}_n^2 - \nu^2) \times \left(\frac{\sinh 2(q_{n+1} - q_n) - \nu^{-1}\sinh(2\nu\alpha)\dot{q}_{n+1}}{\sinh^2(q_{n+1} - q_n) - \sinh^2(\nu\alpha)} - \frac{\sinh 2(q_n - q_{n-1}) - \nu^{-1}\sinh(2\nu\alpha)\dot{q}_{n-1}}{\sinh^2(q_n - q_{n-1}) - \sinh^2(\nu\alpha)}\right) \quad [60]$$

A detailed study of all these systems, their interrelations, and time discretizations can be found in Suris (2003).

There exist also lattices with more complicated nearest-neighbor interactions, involving elliptic functions. They were discovered by A Shabat and R Yamilov (1990), and by I Krichever (2000). For example, the nonrelativistic elliptic Toda lattice is governed by the equations

$$\ddot{q}_n = (\dot{q}_n^2 - 1)(V(q_n, q_{n+1}) + V(q_n, q_{n-1})) \quad [61]$$

where $V(q, q') = \zeta(q + q') + \zeta(q - q') - \zeta(2q)$ is an elliptic function in both arguments $q, q'$ (here $\zeta(q)$ is the Weierstrass $\zeta$-function).

## Further Developments and Generalizations

### Sato's Theory

Formulas [6], [31], and [35] have the same structure, with the case-dependent functions $\tau_n(t)$ given by the determinants [7] for the multisoliton solution in the

infinite case, by the Hankel determinants [32] or by the minors of the matrix $\exp(L(0))$ in the open case, and by the multidimensional theta functions in the periodic case. All these seemingly different objects are actually particular cases of a beautiful construction due to M Sato (1981), developed by E Date, M Jimbo, M Kashiwara, T Miwa (1981–83), and by G Segal and G Wilson (1985), which provides one of the major unifying schemes for the theory of integrable systems. In this construction, integrable systems are interpreted as simple dynamical systems on an infinite-dimensional Grassmannian. The $\tau$-function (first invented by R Hirota in 1971) receives in this theory a representation-theoretical interpretation in terms of the determinant bundle over the Grassmannian.

#### Band Matrices

The Lax matrices [13] and [16] in the Manakov–Flaschka variables can be easily generalized: in the symmetric matrix $L_0$ one can admit nonvanishing elements in the band of the width $2s+1>3$ around the main diagonal, in the Heisenberg matrix $L$ one can admit more nonvanishing diagonals in the upper-triangle part. A systematic presentation of a large body of relevant results is given in Kupershmidt (1985). In the setting of finite lattices, the integrability of such systems becomes a non-trivial problem (as opposed to the tridiagonal situation), because the number of independent conjugation-invariant functions $\mathrm{tr}(L^s)$ becomes less than the number of degrees of freedom. An effective approach to this problem based on the semi-invariant functions has been found by P Deift, L-Ch Li, T Nanda, and C Tomei in 1986.

#### Two-Dimensional Toda Lattices

Up to now, we considered integrable lattices with one continuous and one discrete independent variables. This allows for a further generalization. Integrable systems with two continuous and one discrete independent variables are well known and widely used as models of the field theory. For instance, the Toda field theory deals with the system

$$(q_n)_{xy} = \mathrm{e}^{q_{n+1}-q_n} - \mathrm{e}^{q_n-q_{n-1}} \qquad [62]$$

introduced in the soliton theory by A Mikhailov in 1979. This two-dimensional system admits all possible kinds of reductions and generalizations mentioned above for the usual Toda lattice. In particular, the periodic two-dimensional Toda lattice is referred to as the affine Toda field theory (with the prominent example of the sine-Gordon field which corresponds to the period 2). Later, it was realized that the equivalent equation $(\log v_n)_{xy} = v_{n+1} - 2v_n + v_{n-1}$, which is obtained from [62] by setting $v_n = \exp(q_{n+1}-q_n)$, already appeared in studies by G Darboux in the 1880s, as the equation satisfied by the Laplace invariants of the chain of Laplace transformations of a given conjugate net. This relation to the classical differential geometry was extensively studied by G Darboux, G Tzitzéica, and others long before the advent of the theory of integrable systems. Another link to the differential geometry is a more recent observation, and relates the two-dimensional Toda lattice, with the d'Alembert operator $(\cdot)_{xy}$ on the left-hand side of [62] replaced by the Laplace operator $(\cdot)_{z\bar{z}}$, to harmonic maps. For instance, the sinh-Gordon equation $u_{z\bar{z}} = \sinh u$ governs harmonic maps from $\mathbb{C}$ into the unit sphere $\mathbb{S}^2$, which can be interpreted also as Gauss maps of the constant mean curvature surfaces in $\mathbb{R}^3$. A review of this topic can be found in Guest (1997).

Discretization of Toda lattices, nonabelian Toda Lattices, quantization of Toda lattices, dispersionless limit of Toda lattices, etc., are only some of the further relevant topics, which cannot be discussed in any detail in the restricted frame of this article, and the same holds, unfortunately, for such fascinating applications of the Toda lattice as the Frobenius manifolds, Laplacian growth problem, quantum cohomology, random matrix theory, two-dimensional gravity, etc.

# Toeplitz Determinants and Statistical Mechanics

**E L Basor**, California Polytechnic State University, San Luis Obispo, CA, USA

## Introduction

A finite Toeplitz matrix is an $n \times n$ matrix with the following structure:

$$\begin{pmatrix} a_0 & a_{-1} & a_{-2} & \cdots & a_{-n+1} \\ a_1 & a_0 & a_{-1} & \cdots & a_{-n+2} \\ a_2 & a_1 & a_0 & \cdots & a_{-n+3} \\ \vdots & \vdots & \vdots & & \vdots \\ a_{n-1} & a_{n-2} & a_{n-3} & \cdots & a_0 \end{pmatrix} \qquad [1]$$

The entries depend on the difference $i - j$ and hence they are constant down all the diagonals. There are two cases when the determinant is easy to compute. One is when the matrix is upper- or lower-triangular and the determinant is $a_0^n$. The other case is when the matrix is of the form

$$\begin{pmatrix} a_0 & a_{n-1} & a_{n-2} & \cdots & a_1 \\ a_1 & a_0 & a_{n-1} & \cdots & a_2 \\ a_2 & a_1 & a_0 & \cdots & a_3 \\ \vdots & \vdots & \vdots & & \vdots \\ a_{n-1} & a_{n-2} & a_{n-3} & \cdots & a_0 \end{pmatrix} \qquad [2]$$

In this latter case, the matrix is called a circulant matrix and the eigenvalues are given by the formula

$$\psi_n(\mathrm{e}^{\mathrm{i}2\pi k/n}), \quad 0 \le k \le n-1$$

where

$$\psi_n(\mathrm{e}^{\mathrm{i}\theta}) = \sum_{j=0}^{n-1} a_i \mathrm{e}^{\mathrm{i}j\theta}$$

The corresponding eigenvector for eigenvalue $\psi_n(e^{i2\pi k/n})$ is

$$[1, e^{i2\pi k/n}, \ldots, e^{i2\pi k(n-1)/n}]$$

This can be verified by direct computation. The role of circulant matrices will not be emphasized in this article, although they are used in the computation of the generating function for certain dimer configurations and also in applications using the discrete Fourier transform.

The most common way to generate a finite Toeplitz matrix is with the Fourier coefficients of an integrable function. Let $\phi : T \to \mathbb{C}$ be a function defined on the unit circle with Fourier coefficients

$$\phi_k = \frac{1}{2\pi}\int_{-\pi}^{\pi} \phi(e^{i\theta})e^{-ik\theta}d\theta \qquad [3]$$

We define $T_n(\phi)$ to be the Toeplitz matrix:

$$T_n(\phi) = (\phi_{i-j})_{i,j=0}^{n-1}$$

A basic problem that in large part has been motivated by statistical mechanics is to determine the behavior of the asymptotics of the determinant of $T_n(\phi)$ as $n \to \infty$. The determinant will be referred to as $D_n(\phi)$, where $\phi$ is called the generating function of the determinant. If the generating function has the property that its Fourier coefficients vanish for negative index (positive index) then the corresponding matrix is lower-triangular (upper-triangular) and hence the determinant is $\phi_0^n$. For other cases, the determinant is not easy to determine and requires additional mathematical machinery.

Some of the primary motivation to study the determinant of these matrices comes from the two-dimensional Ising model. We consider the Onsager lattice in the absence of a magnetic field with sites labeled by

$$(i,j), \quad 0 \le i \le M,\ 0, \le j \le N$$

and with a value $\sigma_{i,j} = \pm 1$ assigned to each site. In the Ising model, $\sigma_{i,j}$ signifies the state of the spin at the site $(i,j)$. To each possible configuration of spins, we define an energy

$$\mathcal{E}(\sigma) = -E_1\sum_{i,j}\sigma_{i,j}\sigma_{i+1,j} - E_2\sum_{i,j}\sigma_{i,j}\sigma_{i,j+1}$$

Let

$$Z = \sum_{\sigma} e^{-\beta\mathcal{E}(\sigma)}$$

be the partition function. Then the probability of a given configuration is

$$\frac{1}{Z}e^{-\beta\mathcal{E}(\sigma)}$$

Here $E_1$, $E_2$, and $\beta = 1/kT$ are, without loss of generality, assumed to be positive constants, $T$ is the temperature, and $k$ is the Boltzmann constant. If $X$ is a random variable defined on the space of configurations, the expectation is given by

$$E(X) = \frac{1}{Z}\sum_{\sigma=\pm 1} X(\sigma)e^{-\beta\mathcal{E}(\sigma)}$$

Let $n$ be fixed for the moment and assume toroidal boundary conditions for the lattice and then let $N, M \to \infty$. It is known that the random variable

$$X(\sigma) = \sigma_{0,0}\sigma_{0,n}$$

has expectation $\langle\sigma_{0,0}\sigma_{0,n}\rangle$ given by $D_n(\phi)$, where

$$\phi(e^{i\theta}) = \left(\frac{(1-\alpha_1 e^{i\theta})(1-\alpha_2 e^{-i\theta})}{(1-\alpha_1 e^{-i\theta})(1-\alpha_2 e^{i\theta})}\right)^{1/2}$$

$$\alpha_1 = z_1\left(\frac{1-z_2}{1+z_2}\right), \quad \alpha_2 = z_1^{-1}\left(\frac{1-z_2}{1+z_2}\right)$$

and

$$z_1 = \tanh\beta E_1, \qquad z_2 = \tanh\beta E_2$$

The square root is taken so that $\phi(e^{i\pi}) = 1$. This formula was first stated by Onsager and later verified in a difficult computation by Montroll, Potts, and Ward.

The spontaneous magnetization $M$ for the Ising model is defined by

$$M^2 = \lim_{n\to\infty}\langle\sigma_{0,0}\sigma_{0,n}\rangle = \lim_{n\to\infty} D_n(\phi)$$

Note that it is the square root of the correlation between two distant sites. Hence, the asymptotics of the Toeplitz determinants will determine whether the magnetization is positive or tends to zero as $n \to \infty$.

## Strong Szegö Limit Theorem

To determine the behavior of the determinants, we need to analyze the generating function $\phi$. Let us first consider the case where $\alpha_2 < 1$. (It is always the case that $0 < \alpha_1 < 1$.) This generating function is differentiable, nonzero and has winding number zero, and it is for functions of this type that a second-order expansion of the Toeplitz determinants can be described. The expansion first formulated by Szegö, in response to the question concerning the

spontaneous magnetization, is called the "strong Szegö limit theorem."

Before proving the Szegö theorem, it should be remarked that we can view the finite Toeplitz matrix as a truncation of an infinite array,

$$\begin{pmatrix} \phi_0 & \phi_{-1} & \phi_{-2} & \\ \phi_1 & \phi_0 & \phi_{-1} & \ddots \\ \phi_2 & \phi_1 & \phi_0 & \ddots \\ & \ddots & \ddots & \ddots \end{pmatrix} \qquad [4]$$

The above infinite array is the matrix representation for the Toeplitz operator

$$T(\phi) : H^2 \to H^2$$

defined by

$$T(\phi)f = P(\phi f)$$

where $H^2$ is the Hardy space

$$\{f \in L^2(T) \mid f_k = 0,\ k < 0\}$$

the function $\phi \in L^\infty(T)$, and $P$ is the orthogonal projection of $L^2(T)$ onto $H^2$. The matrix representation given in [4] is with respect to the Hilbert space basis of $H^2$,

$$\{e^{ik\theta} \mid 0 \le k < \infty\}$$

and $\phi$ is called the symbol of the operator. Now define $P_n : H^2 \to H^2$ by

$$P_n(f_0, f_1, f_2, \ldots) = (f_0, f_1, f_2, \ldots, f_{n-1}, 0, 0, \ldots)$$

The finite Toeplitz matrix can be thought of as the upper-left corner of the array given in [4] or as $P_nT(\phi)P_n$.

To prove the Strong Szegö limit theorem, we introduce the Banach algebra $\mathcal{B}$ of bounded functions $f$ satisfying $\sum_{k=-\infty}^{\infty} |k||f_k|^2 < \infty$.

**Theorem 1** (Strong Szegö limit theorem). *Assume $\phi = \phi_-\phi_+$, where $\phi_\pm$ have logarithms in $\mathcal{B}$. Suppose $\log\phi_-,\ \log\phi_+ \in H^2$. Then*

$$\lim_{n\to\infty} D_n(\phi)/G(\phi)^n = E(\phi) = \exp\left(\sum_{k=1}^{\infty} k s_k s_{-k}\right)$$

*where $G(\phi) = \exp((\log\phi)_0)$ and $s_k = \log\phi_k$.*

Since $\mathcal{B}$ is a Banach algebra, it follows that if $\log\phi_\pm$ belong to $\mathcal{B}$ so do

$$\phi_-,\ \phi_+,\ \phi_+^{-1},\ \phi_-^{-1},\ \phi,\ \phi^{-1}$$

and hence they are bounded. Since $\phi_+$ is in $H^2$ as well, its Fourier coefficients vanish for negative index and the Toeplitz operator has a corresponding infinite array that is lower-triangular. The Fourier coefficients vanish for positive index for $\phi_-$ and hence the infinite array is upper triangular. From this, it follows that

$$T(\phi_+)T(\phi_+^{-1}) = T(\phi_-^{-1})T(\phi_-) = I \qquad [5]$$

$$T(\phi_-)T(\phi_+) = T(\phi) \qquad [6]$$

and

$$\begin{aligned} P_nT(\phi_+) &= P_nT(\phi_+)P_n \\ P_nT(\phi_-)P_n &= T(\phi_-)P_n \end{aligned} \qquad [7]$$

This yields

$$D_n(\phi) = \det T_n(\phi) = \det P_nT(\phi)P_n \qquad [8]$$

$$= \det P_nT(\phi_+)T(\phi_+^{-1})T(\phi)T(\phi_-^{-1})T(\phi_-)P_n \qquad [9]$$

$$= \det P_nT(\phi_+)P_nT(\phi_+^{-1})T(\phi)T(\phi_-^{-1})P_nT(\phi_-)P_n \qquad [10]$$

$$z = \det P_nT(\phi_+)P_n \det(P_nT(\phi_+^{-1})T(\phi)T(\phi_-^{-1})P_n) \times \det P_nT(\phi_-)P_n \qquad [11]$$

The determinants of the right-hand side and the left-hand side of the above expression are $((\phi_\mp)_0)^n$, respectively. Now given the Banach algebra conditions imposed on the symbol $\phi$, it follows that the operator

$$T(\phi_+^{-1})T(\phi)T(\phi_-^{-1})$$

is of the form $I + K$, where $K$ is trace class. Hence, the eigenvalues $\lambda_i$ of $K$ satisfy

$$\sum |\lambda_i| < \infty$$

and the infinite (Fredholm) determinant of $I + K$ is defined. To verify the claim that the operator

$$T(\phi_+^{-1})T(\phi)T(\phi_-^{-1}) = T(\phi_+^{-1})T(\phi_-)T(\phi_+)T(\phi_-^{-1})$$

is $I$ plus a trace class operator, we use the identity

$$T(fg) - T(f)T(g) = H(f)H(\tilde{g}) \qquad [12]$$

where $H(f)$ has matrix form $(f_{i+j+1})_{i,j=0}^{\infty}$, and $\tilde{g}(e^{i\theta}) = g(e^{-i\theta})$. Our Banach algebra conditions show that if $f$ is in $\mathcal{B}$ then the operator $H(f)$ satisfies $\sum_{i,j} |a_{ij}|^2 < \infty$, where the $a_{ij}$ are the matrix entries of the operator. Any operator satisfying this is called a Hilbert–Schmidt operator, and it is known that the product of two Hilbert–Schmidt is trace class. Applying the identity to

$$T(\phi_+^{-1})T(\phi_-)$$

shows that this operator is $T(\phi_+^{-1}\phi_-)$ plus trace class. The operator

$$T(\phi_+)T(\phi_-^{-1})$$

is thus $T(\phi_+\phi_-^{-1})$ plus trace class and one more application of the identity combined with the fact that trace class operators form an ideal yield the desired result.

From the theory of infinite determinants, as $n \to \infty$,

$$\det P_n T(\phi_+^{-1}) T(\phi) T(\phi_-^{-1}) P_n \qquad [13]$$

converges to

$$\det\left(T(\phi_+^{-1}) T(\phi) T(\phi_-^{-1})\right) \qquad [14]$$

At this point, we have proved that

$$\begin{aligned} &\lim_{n\to\infty} D_n(\phi)/((\phi_-)_0)^n((\phi_+)_0)^n \\ &\quad = \lim_{n\to\infty} \det P_n T(\phi_+^{-1}) T(\phi) T(\phi_-^{-1}) P_n \\ &\quad = \det\left(T(\phi_+^{-1}) T(\phi) T(\phi_-^{-1})\right) \qquad [15] \end{aligned}$$

It only remains to identify the constants. To see that

$$G(\phi) = ((\phi_-)_0)^n((\phi_+)_0)^n$$

we note that

$$\begin{aligned} G(\phi) &= \exp((\log\phi)_0) = \exp\left(\frac{1}{2\pi}\int_0^{2\pi} \log\phi(\mathrm{e}^{\mathrm{i}\theta})\mathrm{d}\theta\right) \\ &= \exp\left(\frac{1}{2\pi}\int_0^{2\pi} (\log\phi_-(\mathrm{e}^{\mathrm{i}\theta}) + \log\phi(\mathrm{e}^{\mathrm{i}\theta}))\mathrm{d}\theta\right) \\ &= \exp(\log\phi_-)_0 \exp(\log\phi_+)_0 = (\phi_-)_0(\phi_+)_0 \end{aligned}$$

To compute the determinant of

$$T(\phi_+^{-1}) T(\phi) T(\phi_-^{-1})$$

we write

$$\begin{aligned} &\det T(\phi_+^{-1}) T(\phi) T(\phi_-^{-1}) \\ &\quad = \det T(\phi_+^{-1}) T(\phi_-\phi_+) T(\phi_-^{-1}) \\ &\quad = \det T(\phi_+^{-1}) T(\phi_-) T(\phi_+) T(\phi_-^{-1}) \end{aligned}$$

This last expression is the form

$$\mathrm{e}^A \mathrm{e}^B \mathrm{e}^{-A} \mathrm{e}^{-B}$$

where

$$A = -T(\log\phi_+) \quad \text{and} \quad B = T(\log\phi_-)$$

If $AB - BA$ is trace class then

$$\det \mathrm{e}^A \mathrm{e}^B \mathrm{e}^{-A} \mathrm{e}^{-B} = \mathrm{e}^{\mathrm{tr}(AB-BA)}$$

The operator $AB - BA$ is

$$-T(\log\phi_+)T(\log\phi_-) + T(\log\phi_-)T(\log\phi_+)$$

which equals

$$-T(\log\phi_+)T(\log\phi_-) + T((\log\phi_-)(\log\phi_+))$$

and, by the identity from eqn [12], becomes

$$H(\log\phi_-)H(\log\phi_+)$$

It can be directly computed that

$$\mathrm{tr}(H(\log\phi_-)H(\log\phi_+))$$

equals

$$\sum_{k=1}^{\infty} k s_k s_{-k}$$

and the theorem is proved.

Returning to the Ising model, one needs to compute the asymptotics of the determinants for the generating function

$$\phi(\mathrm{e}^{\mathrm{i}\theta}) = \left(\frac{(1-\alpha_1\mathrm{e}^{\mathrm{i}\theta})(1-\alpha_2\mathrm{e}^{-\mathrm{i}\theta})}{(1-\alpha_1\mathrm{e}^{-\mathrm{i}\theta})(1-\alpha_2\mathrm{e}^{\mathrm{i}\theta})}\right)^{1/2}$$

The term $G(\phi) = 1$ and for $k > 0$

$$k s_k s_{-k} = \frac{1}{4}\left(\frac{-\alpha_1^{2k}}{k} + \frac{-\alpha_2^{2k}}{k} + 2\frac{-\alpha_1^k\alpha_2^k}{k}\right)$$

from which it follows that

$$\lim_{n\to\infty} D_n(\phi) = \left[\frac{(1-\alpha_1^2)(1-\alpha_2^2)}{(1-\alpha_1\alpha_2)^2}\right]^{1/4}$$

Recalling the definition of $\alpha_1$ and $\alpha_2$ yields

$$\lim_{n\to\infty}\langle\sigma_{0,0}\sigma_{0,n}\rangle = \left[1 - \frac{1}{(\sinh 2\beta E_1 \ \sinh 2\beta E_2)^2}\right]^{1/4}$$

or the spontaneous magnetization $M$ as

$$M = \left(1 - \frac{1}{(\sinh 2\beta E_1 \ \sinh 2\beta E_2)^2}\right)^{1/8}$$

In order for this computation to be valid, it was necessary for $0 < \alpha_2 < 1$, and by elementary computations one can show that this is equivalent to the inequality

$$\sinh 2\beta E_1 \sinh 2\beta E_2 > 1$$

## Nonsmooth Symbols or $T = T_c$

A problem occurs in the analysis just outlined when the inequality $0 < \alpha_2 < 1$ does not hold. There are two separate possibilities, $\alpha_2 > 1$ or $\alpha_2 = 1$. First, we consider the latter case. For fixed $E_1$ and $E_2$, this happens for exactly one fixed value of the constant $\beta_c = 1/kT_c$ and the corresponding temperature $T_c$ is called the critical temperature. The "strong Szegö

limit theorem" does not apply since our generating function is of the form

$$\phi(e^{i\theta}) = \left(\frac{(1-\alpha_1 e^{i\theta})(1-e^{-i\theta})}{(1-\alpha_1 e^{-i\theta})(1-e^{i\theta})}\right)^{1/2} \qquad [16]$$

In 1968, Fisher and Hartwig raised a conjecture about $D_n(\phi)$ for nonsmooth $\phi$ which included the above example. They considered generating functions of the form

$$\phi(e^{i\theta}) = \psi(e^{i\theta}) \prod_{j=1}^{R} \phi_{\alpha_j,\beta_j}(e^{i(\theta-\theta_j)}) \qquad [17]$$

where

$$\phi_{\alpha,\beta}(e^{i\theta}) = (2-2\cos\theta)^{\alpha} e^{i\beta(\theta-\pi)}, \quad 0<\theta<2\pi$$

$\Re\alpha > -1/2$, and $\beta$ is not an integer. The function $\psi$ is assumed to be a smooth function. Using the Fisher–Hartwig notation, the symbol of interest in the Ising model from eqn [16] can be written as

$$\psi(e^{i\theta})\phi_{0,-1/2}(e^{i\theta})$$

where

$$\psi(e^{i\theta}) = \left(\frac{1-\alpha_1 e^{i\theta}}{1-\alpha_1 e^{-i\theta}}\right)^{1/2}$$

The conjecture of Fisher and Hartwig for general symbols of this type stated that

$$D_n(\phi) \sim G(\psi)^n n^p E$$

where

$$p = \sum_{r=1}^{R} (\alpha_r^2 - \beta_r^2)$$

and $E^*$ is a constant whose value they did not identify. The constant was later computed to be

$$\begin{aligned} E^*(\phi) = E(\psi) &\prod_{j=1}^{R} \psi_+(e^{i\theta_j})^{-\alpha_j+\beta_j}\psi_-(e^{i\theta_j})^{-\alpha_j-\beta_j} \\ &\times \prod_{1\le s\ne r\le R} (1-e^{i(\theta_s-\theta_r)})^{-(\alpha_s+\beta_s)(\alpha_r-\beta_r)} \\ &\times \prod_{j=1}^{R} \frac{G(1+\alpha_j+\beta_j)G(1+\alpha_j-\beta_j)}{G(1+2\alpha_j)} \end{aligned}$$

where $G(z)$ is the Barnes $G$-function satisfying

$$G(1+z) = \Gamma(z)G(z)$$

and is defined by

$$\begin{aligned} G(1+z) = {} & (2\pi)^{z/2} e^{-(z+1)z/2-\gamma z^2/2} \\ & \times \prod_{k=1}^{\infty}\left(1+\frac{z}{k}\right)^k e^{-z+z^2/2k} \end{aligned}$$

For the above factors, we normalize $\psi$ so that the geometric mean is 1. Then we may assume that the factors $\psi_+, \psi_-(\psi_-\psi_+ = \psi)$ are 1 at zero and infinity, respectively, and this defines the logarithms for the first product. The $E(\psi)$ term is the constant in Szegö's theorem, and the argument of a term of the form $(1-e^{i(\theta_s-\theta_r)})$ is taken between $-\pi/2$ and $\pi/2$.

In the case where $R=1$, the conjecture is known to hold if $\Re\alpha > -1/2$ and the function $b$ satisfies the conditions of Szegö's theorem and is infinitely differentiable. The theorem also has an extension to the case where $\Re\alpha < -1/2$, with $2\alpha$ not an integer, as long as the Fourier coefficients are defined as the coefficients of a distribution.

If we apply the theorem to the generating function from [16]

$$\psi(e^{i\theta})\phi_{0,-1/2}(e^{i\theta}) = \left(\frac{1-\alpha_1 e^{i\theta}}{1-\alpha_1 e^{-i\theta}}\right)^{1/2} \phi_{0,-1/2}(e^{i\theta})$$

we see that the asymptotic expansion is given by

$$n^{-1/4}\left(\frac{1+\alpha_1}{1-\alpha_1}\right)^{1/4} G(1/2)G(3/2)$$

This last formula shows that, at the critical temperature,

$$\lim_{n\to\infty}\langle\sigma_{0,0}\sigma_{0,n}\rangle = \lim_{n\to\infty} D_n(\phi) = 0$$

thus, $M=0$, and hence there is no correlation between distant lattice points.

It should be remarked here that the diagonal correlation at the critical temperature is also given by a singular Toeplitz determinant,

$$\langle\sigma_{0,0}\sigma_{n,n}\rangle = D_n(\phi_{0,-1/2}) \sim n^{-1/4}G(1/2)G(3/2)$$

and thus this limit is also zero.

The proof of the Fisher–Hartwig conjecture is much more complicated than the proof of the "strong Szegö limit theorem." For an indication of how it is proved, note that if we consider the generating function $\phi_{0,\beta}$, the Fourier coefficients are $(\sin\pi\beta)/[\pi(n-\beta)]$ and hence the matrix is Cauchy and the determinant can be computed exactly. From this the asymptotics can be derived and they yield a special case of the Fisher–Hartwig conjecture. The main idea in extending the result to a symbol of the form

$$\psi(e^{i\theta})\phi_{0,\beta}(e^{i\theta})$$

is to prove that the limit of

$$\frac{D_n(\psi\phi_{0,\beta})}{D_n(\psi)D_n(\phi_{0,\beta})}$$

exists. The proof uses much of the same trace-class approach used in proving the "strong Szegö limit theorem," although the results are more complicated. These ideas are then extended for $R > 1$ and also more general $\beta$ and $\alpha$.

It should be noted that in this article the Fisher–Hartwig conjecture does not always hold. If we consider the function

$$\phi(e^{i\theta}) = \begin{cases} -1, & -\pi < \theta < 0 \\ 1, & 0 < \theta < \pi \end{cases}$$

then

$$\phi_n = \begin{cases} 0, & \text{if } k \text{ is even} \\ -2i/(\pi k), & \text{if } k \text{ is odd} \end{cases}$$

The matrix $T_n(\phi)$ is antisymmetric and, if $n$ is odd, $D_n(\phi) = 0$. If $n$ is even, using elementary row and column operations, the determinant can be put in block form with each block of Cauchy type. The determinant can then be evaluated to find

$$D_n(\phi) \sim (i)^n n^{-1/2} K$$

where $K$ is a certain constant.

It is instructive to note that

$$\begin{aligned}\phi(e^{i\theta}) &= \phi_{0,1/2}(e^{i\theta})\phi_{0,-1/2}(e^{i(\theta-\pi)}) \\ &= \phi_{0,-1/2}(e^{i\theta})\phi_{0,1/2}(e^{i(\theta-\pi)})\end{aligned}$$

and thus that this particular symbol has two representations of the type given in [17] and each would give a different asymptotic expansion of the determinant if the conjecture were true for this set of parameters. Hence, it is clear that the conjecture must fail to hold in this case.

However, this example indicates that there might be a generalization of the original conjecture of Fisher and Hartwig. If

$$\phi_{\alpha,\beta}(e^{i(\theta-\gamma)}) = \phi_{\alpha,\beta,\gamma}$$

then

$$\phi = \psi \prod_{j=1}^{R} \phi_{\alpha_j,\beta_j,\theta_j}$$

it is also the case that

$$\phi = \psi^* \prod_{j=1}^{R} \phi_{\alpha_j,\beta_j+n_j,\theta_j}$$

where

$$\sum_{j=1}^{R} n_j = 0 \quad \text{and} \quad \psi^* = \psi \prod_{j=1}^{R} (-e^{i\theta_j})^{n_j}$$

In the example above, $\beta_1 = 1/2$, $\beta_2 = -1/2$, $\theta_1 = 0$, $\theta_2 = \pi$, $n_1 = -1$, and $n_2 = 1$. The result for the counterexample, combined with what is known for the case of integer values of $\alpha$ and $\beta$, leads to the following generalized conjecture. Suppose

$$\psi(e^{i\theta}) = \phi^k \prod_{j=1}^{R} \phi_{\alpha_j^k,\beta_j^k,\theta_j}$$

for some set of indices $k$. Define $Q(k) = \sum_{j=1}^{R} (\alpha_j^k)^2 - (\beta_j^k)^2$. Let $Q = \max_k \Re(Q(k))$ and

$$\mathcal{K} = \{k \mid \Re(Q(k)) = Q\}$$

The generalized asymptotic formula is conjectured to be

$$D_n(\psi) = \sum_{k \in \mathcal{K}} G(\psi^k) n^{Q(k)} E_k^* + o(|G(\phi)|^n n^Q)$$

It may turn out that there is only one element in $\mathcal{K}$ and for these symbols there is a unique representation that yields the highest power in the exponent of the asymptotic expansion. These are the symbols for which the original Fisher–Hartwig conjecture should be true and it is now confirmed in these cases. For example, the conjecture is known to hold for $R > 1$ when $|\Re\alpha_r| < 1/2$ and $|\Re\beta_r| < 1/2$.

## Symbols with Nonzero Index or $T > T_c$

The last possibility in computing the correlation asymptotics is the case where $\alpha_2 > 1$. Note that, for fixed $E_1$ and $E_2$, there is exactly one value of $\beta = 1/kT$ where

$$\alpha_2 = z_1^{-1}\left(\frac{1 - z_2}{1 + z_2}\right) = 1$$

For values of $T > T_c$, we have that the symbol

$$\left(\frac{(1 - \alpha_1 e^{i\theta})(1 - \alpha_2 e^{-i\theta})}{(1 - \alpha_1 e^{-i\theta})(1 - \alpha_2 e^{i\theta})}\right)^{1/2}$$

is the same as

$$e^{-i\theta}\left(\frac{(1 - \alpha_1 e^{i\theta})(1 - (1/\alpha_2)e^{i\theta})}{(1 - \alpha_1 e^{-i\theta})(1 - (1/\alpha_2)e^{-i\theta})}\right)^{1/2}$$

with the argument chosen so that the symbol is positive at $\pi$. Except for the extra factor of $e^{-i\theta}$, this is the same type of smooth symbol that was considered earlier (see the section "Strong Szegö limit theorem"). However, a factor of $e^{i\theta}$ can change the asymptotics considerably as can be seen by considering the simple example of the $\phi \equiv 1$. Fortunately, a variation of the Szegö theorem, first

considered by Fisher and Hartwig, holds for this case of smooth, nonvanishing index.

**Theorem 2** *Suppose that $\phi = \phi_-\phi_+$ satisfies the condition of the "strong Szegö limit theorem" and in addition is at least once continuously differentiable. Then, if $b = \phi_-\phi_+^{-1}$ and $c = \phi_-^{-1}\phi_+$,*

$$D_n(e^{im\theta}\phi) \sim (-1)^{(n-1+m)m} G(\phi)^n E(\phi) G(c)^m \qquad [18]$$

$$\times \left( \det \begin{pmatrix} b_n & \cdots & b_{n-m+1} \\ \vdots & \ddots & \vdots \\ b_{n-1+m} & \cdots & b_n \end{pmatrix} + O(n^{-3}) \right) \times (1 + O(n^{-1})) \qquad [19]$$

Applying this to the symbol

$$e^{-i\theta}\phi(e^{i\theta}) = e^{-i\theta} \left( \frac{(1-\alpha_1 e^{i\theta})(1-(1/\alpha_2)e^{i\theta})}{(1-\alpha_1 e^{-i\theta})(1-(1/\alpha_2)e^{-i\theta})} \right)^{1/2}$$

we have that $m = 1, G(\phi) = -1, G(c) = -1$, and

$$E(\phi) = \left[ (1-\alpha_1^2)\left(1 - \frac{1}{\alpha_2^2}\right)\left(1 - \frac{\alpha_1}{\alpha_2}\right)^2 \right]^{1/4} \qquad [20]$$

The determinant in the above formula is the constant

$$b_n = \frac{1}{2\pi}\int_0^{2\pi} \left( (1-\alpha_1 e^{i\theta})\left(1 - \frac{1}{\alpha_2}e^{i\theta}\right) \times (1-\alpha_1 e^{-i\theta})\left(1 - \frac{1}{\alpha_2}e^{-i\theta}\right) \right)^{-1/2} e^{-in\theta} d\theta$$

The last integral can be deformed to a segment of the real line and evaluated asymptotically to find that the leading term is

$$-\frac{1}{\sqrt{\pi}\alpha_2^n} \left( \left(1 - \frac{\alpha_1}{\alpha_2}\right)(1-\alpha_1\alpha_2)\left(1 - \frac{1}{\alpha_2^2}\right) \right)^{-1/2} \times \frac{\Gamma(n+1/2)}{\Gamma(n+1)}$$

Putting this together with the above constants, we have, for $T > T_c$,

$$\langle \sigma_{0,0}\sigma_{0,n} \rangle \sim \frac{1}{\sqrt{\pi n}\alpha_2^n} \left[ (1-\alpha_1^2)^{1/4} \left(1 - \frac{1}{\alpha_2^2}\right)^{-1/4} (1-\alpha_1\alpha_2)^{-1/2} \right]$$

This implies that the correlation tends to zero very rapidly as $n \to \infty$.

## Further Remarks

The interaction between statistical mechanics and the theory of Toeplitz determinants has a long history, and much of the motivation to describe the asymptotics of the determinants was spurred by the question of spontaneous magnetization in the two-dimensional Ising model. The previous three sections attempt to show how the very different physical situations – $T < T_c, T = T_c$, and $T > T_c$ – all correspond to very different behavior in the symbols of the generating functions. Critical systems predict qualitatively different Szegö type theorems. For example, the phase transition at $T_c$ predicts that the asymptotics for singular symbols cannot be predicted by the smooth symbols, that is, one cannot use continuous functions to approximate the results for singular symbols.

Onsager (1971) was the first to understand that the correlation function could be expressed as a Toeplitz determinant. This was made explicit by Montroll *et al.* (1963). For more information about the Ising model, the reader is referred to McCoy and Wu (1973), where a clear and complete description of the Ising model (and most of the notation used here in reference to this model) can be found.

Szegö (1915, 1952) had originally proved a weak form of the "limit" theorem and he understood that it was desirable to extend to a second-order term. Szegö first proved the "strong Szegö limit theorem" for positive generating functions and this was later extended to the nonpositive case.

The first to understand that a different asymptotic behavior was expected at the critical temperature was Fisher and this resulted in the conjecture for the class of determinants generated by what is now known as Fisher–Hartwig symbols (Fisher and Hartwig 1968). Progress on the conjecture was made by many authors. Böttcher and Silbermann (1998) have provided general results concerning Toeplitz operators and determinants. Additional information about the conjectures of Fisher and Hartwig can be found in Böttcher and Silbermann (1990, 1998), Ehrhardt (2001), and Ehrhardt and Silbermann (1997).

Toeplitz determinants are also important in many other applications. One more recent area of interest is the connection between random-matrix theory and Toeplitz determinants. Many statistical quantities for the circular unitary ensemble can be described as a Toeplitz determinant. For example, the probability of finding no eigenvalues in an interval can be expressed as a Toeplitz determinant. It is also the case that many of the most interesting

statistics correspond to singular symbols. For basic random-matrix theory information see Mehta (1991), and for connections between the circular unitary ensemble and Toeplitz determinants, see Hughes (2001), Tracy and Widom (1993), and Widom (1994).

# Tomita–Takesaki Modular Theory

**S J Summers**, University of Florida, Gainesville, FL, USA

## Basic Structure

The origins of Tomita–Takesaki modular theory lie in two unpublished papers of M Tomita in 1967 and a slim volume by Takesaki (1970). It has developed into one of the most important tools in the theory of operator algebras and has found many applications in mathematical physics.

Although the modular theory has been formulated in a more general setting, it will be presented in the form in which it most often finds application in mathematical physics (for generalizations, details, and further references concerning the material covered in this article, the reader is referred to the Further Reading section). Let $\mathcal{M}$ be a von Neumann algebra on a Hilbert space $\mathcal{H}$ containing a vector $\Omega$ which is cyclic and separating for $\mathcal{M}$. Define the operator $S_0$ on $\mathcal{H}$ as follows:

$$S_0 A\Omega = A^*\Omega, \quad \text{for all } A \in \mathcal{M}$$

This operator extends to a closed antilinear operator $S$ defined on a dense subset of $\mathcal{H}$. Let $\Delta$ be the unique positive, self-adjoint operator and $J$ the unique antiunitary operator occurring in the polar decomposition

$$S = J\Delta^{1/2} = \Delta^{-1/2}J$$

$\Delta$ is called the modular operator and $J$ the modular conjugation (or modular involution) associated with the pair $(\mathcal{M}, \Omega)$. Note that $J^2$ is the identity operator and $J = J^*$. Moreover, the spectral calculus may be applied to $\Delta$ so that $\Delta^{it}$ is a unitary operator for each $t \in \mathbb{R}$ and $\{\Delta^{it} \mid t \in \mathbb{R}\}$ forms a strongly continuous unitary group. Let $\mathcal{M}'$ denote the set of all bounded linear operators on $\mathcal{H}$ which commute with all elements of $\mathcal{M}$. The modular theory begins with the following remarkable theorem.

**Theorem 1** *Let $\mathcal{M}$ be a von Neumann algebra with a cyclic and separating vector $\Omega$. Then $J\Omega = \Omega = \Delta\Omega$, and the following equalities hold:*

$$J\mathcal{M}J = \mathcal{M}'$$

*and*

$$\Delta^{it}\mathcal{M}\Delta^{-it} = \mathcal{M}, \quad \text{for all } t \in \mathbb{R}$$

Note that if one defines $F_0 A'\Omega = A'^*\Omega$, for all $A' \in \mathcal{M}'$, and takes its closure $F$, then one has the relations

$$\Delta = FS, \quad \Delta^{-1} = SF, \quad F = J\Delta^{-1/2}$$

## Modular Automorphism Group

By Theorem 1, the unitaries $\Delta^{it}, t \in \mathbb{R}$, induce a one-parameter automorphism group $\{\sigma_t\}$ of $\mathcal{M}$ by

$$\sigma_t(A) = \Delta^{it} A \Delta^{-it}, \quad A \in \mathcal{M}, \quad t \in \mathbb{R}$$

This group is called the modular automorphism group of $\mathcal{M}$ (relative to $\Omega$). Let $\omega$ denote the faithful normal state on $\mathcal{M}$ induced by $\Omega$:

$$\omega(A) = \frac{1}{\|\Omega\|^2} \langle \Omega, A\Omega \rangle, \quad A \in \mathcal{M}$$

From Theorem 1 it follows that $\omega$ is invariant under $\{\sigma_t\}$, that is, $\omega(\sigma_t(A)) = \omega(A)$ for all $A \in \mathcal{M}$ and $t \in \mathbb{R}$.

The modular automorphism group contains information about both $\mathcal{M}$ and $\omega$. For example, the modular automorphism group is an inner automorphism on $\mathcal{M}$ if and only if $\mathcal{M}$ is semifinite. It is trivial if and only if $\omega$ is a tracial state on $\mathcal{M}$. Indeed, for any $B \in \mathcal{M}$, one has $\sigma_t(B) = B$ for all $t \in \mathbb{R}$ if and only if $\omega(AB) = \omega(BA)$ for all $A \in \mathcal{M}$. Let $\mathcal{M}^\sigma$ denote the set of all such $B$ in $\mathcal{M}$.

### The KMS Condition

The modular automorphism group satisfies a condition which had already been used in mathematical physics to characterize equilibrium temperature states of quantum systems in statistical mechanics and field theory – the Kubo–Martin–Schwinger (KMS) condition. If $\mathcal{M}$ is a von Neumann algebra and $\{\alpha_t \mid t \in \mathbb{R}\}$ is a $\sigma$-weakly continuous one-parameter group of automorphisms of $\mathcal{M}$, then the state $\phi$ on $\mathcal{M}$ satisfies the KMS condition at (inverse temperature) $\beta$ $(0 < \beta < \infty)$ with respect to $\{\alpha_t\}$ if for any $A,B \in \mathcal{M}$ there exists a complex function $F_{AB}(z)$ which is analytic on the strip $\{z \in \mathbb{C} \mid 0 < \operatorname{Im} z < \beta\}$ and continuous on the closure of this strip such that

$$F_{A,B}(t) = \phi(\alpha_t(A)B)$$
$$F_{A,B}(t + i\beta) = \phi(B\alpha_t(A))$$

for all $t \in \mathbb{R}$. In this case, $\phi(\alpha_{i\beta}(A)B) = \phi(BA)$, for all $A, B$ in a $\sigma$-weakly dense, $\alpha$-invariant $*$-subalgebra of $\mathcal{M}$. Such KMS states are $\alpha$-invariant, that is, $\phi(\alpha_t(A)) = \phi(A)$, for all $A \in \mathcal{M}, t \in \mathbb{R}$, and are stable and passive (cf. Bratteli and Robinson (1981) and Haag (1992)).

Every faithful normal state satisfies the KMS condition at $\beta = 1$ (henceforth called the modular condition) with respect to the corresponding modular automorphism group.

**Theorem 2** *Let $\mathcal{M}$ be a von Neumann algebra with a cyclic and separating vector $\Omega$. Then the induced state $\omega$ on $\mathcal{M}$ satisfies the modular condition with respect to the modular automorphism group $\{\sigma_t \mid t \in \mathbb{R}\}$ associated to the pair $(\mathcal{M}, \Omega)$.*

The modular automorphism group is, therefore, endowed with the analyticity associated with the KMS condition, and this is a powerful tool in many applications of the modular theory to mathematical physics. In addition, the physical properties and interpretations of KMS states are often invoked when applying modular theory to quantum physics.

Note that while the nontriviality of the modular automorphism group gives a measure of the nontracial nature of the state, the KMS condition for the modular automorphism group provides the missing link between the values $\omega(AB)$ and $\omega(BA)$, for all $A,B \in \mathcal{M}$ (hence the use of the term "modular," as in the theory of integration on locally compact groups).

The modular condition is quite restrictive. Only the modular group can satisfy the modular condition for $(\mathcal{M}, \Omega)$, and the modular group for one state can satisfy the modular condition only in states differing from the original state by the action of an element in the center of $\mathcal{M}$.

**Theorem 3** *Let $\mathcal{M}$ be a von Neumann algebra with a cyclic and separating vector $\Omega$, and let $\{\sigma_t\}$ be the corresponding modular automorphism group. If the induced state $\omega$ satisfies the modular condition with respect to a group $\{\alpha_t\}$ of automorphisms of $\mathcal{M}$, then $\{\alpha_t\}$ must coincide with $\{\sigma_t\}$. Moreover, a normal state $\psi$ on $\mathcal{M}$ satisfies the modular condition with respect to $\{\sigma_t\}$ if and only if $\psi(\,\cdot\,) = \omega(h\,\cdot\,) = \omega(h^{1/2} \cdot h^{1/2})$ for some unique positive injective operator $h$ affiliated with the center of $\mathcal{M}$.*

Hence, if $\mathcal{M}$ is a factor, two distinct states cannot share the same modular automorphism group. The relation between the modular automorphism groups for two different states will be described in more detail.

### One Algebra and Two States

Consider a von Neumann algebra $\mathcal{M}$ with two cyclic and separating vectors $\Omega$ and $\Phi$, and denote by $\omega$ and $\phi$, respectively, the induced states on $\mathcal{M}$. Let $\{\sigma_t^\omega\}$ and $\{\sigma_t^\phi\}$ denote the corresponding modular groups. There is a general relation between the modular automorphism groups of these states.

**Theorem 4** *There exists a σ-strongly continuous map* $\mathbb{R} \ni t \mapsto U_t \in \mathcal{M}$ *such that*

(i) $U_t$ *is unitary for all* $t \in \mathbb{R}$;
(ii) $U_{t+s} = U_t \sigma_t^{\omega}(U_s)$ *for all* $s,t \in \mathbb{R}$; *and*
(iii) $\sigma_t^{\phi}(A) = U_t \sigma_t^{\omega}(A) U_t^*$ *for all* $A \in \mathcal{M}$ *and* $t \in \mathbb{R}$.

The 1-cocycle $\{U_t\}$ is commonly called the cocycle derivative of $\phi$ with respect to $\omega$ and one writes $U_t = (D\phi : D\omega)_t$. There is a chain rule for this derivative, as well: If $\phi,\psi$, and $\rho$ are faithful normal states on $\mathcal{M}$, then $(D\psi : D\phi)_t = (D\psi : D\rho)_t (D\rho : D\phi)_t$, for all $t \in \mathbb{R}$. More can be said about the cocycle derivative if the states satisfy any of the conditions in the following theorem.

**Theorem 5** *The following conditions are equivalent*:

(i) $\phi$ *is* $\{\sigma_t^{\omega}\}$*-invariant*;
(ii) $\omega$ *is* $\{\sigma_t^{\phi}\}$*-invariant*;
(iii) *there exists a unique positive injective operator* $h$ *affiliated with* $\mathcal{M}^{\sigma^{\omega}} \cap \mathcal{M}^{\sigma^{\phi}}$ *such that* $\omega(\,\cdot\,) = \phi(h\,\cdot\,) = \phi(h^{1/2}\,\cdot\,h^{1/2})$;
(iv) *there exists a unique positive injective operator* $h'$ *affiliated with* $\mathcal{M}^{\sigma^{\omega}} \cap \mathcal{M}^{\sigma^{\phi}}$ *such that* $\phi(\,\cdot\,) = \omega(h'\,\cdot\,) = \omega(h'^{1/2}\,\cdot\,h'^{1/2})$;
(v) *the norms of the linear functionals* $\omega + \mathrm{i}\phi$ *and* $\omega - \mathrm{i}\phi$ *are equal*; *and*
(vi) $\sigma_t^{\omega}\sigma_s^{\phi} = \sigma_s^{\phi}\sigma_t^{\omega}$, *for all* $s,t \in \mathbb{R}$.

The conditions in Theorem 5 turn out to be equivalent to the cocycle derivative being a representation.

**Theorem 6** *The cocycle* $\{U_t\}$ *intertwining* $\{\sigma_t^{\omega}\}$ *with* $\{\sigma_t^{\phi}\}$ *is a group representation of the additive group of reals if and only if* $\phi$ *and* $\omega$ *satisfy the conditions in* Theorem 5. *In that case*, $U(t) = h^{-\mathrm{i}t}$.

The operator $h' = h^{-1}$ in Theorem 5 is called the Radon–Nikodym derivative of $\phi$ with respect to $\omega$ (often denoted by $\mathrm{d}\phi/\mathrm{d}\omega$), due to the following result, which, if the algebra $\mathcal{M}$ is abelian, *is* the well-known Radon–Nikodym theorem from measure theory.

**Theorem 7** *If* $\phi$ *and* $\omega$ *are normal positive linear functionals on* $\mathcal{M}$ such that $\phi(A) \le \omega(A)$, *for all positive elements* $A \in \mathcal{M}$, *then there exists a unique element* $h^{1/2} \in \mathcal{M}$ *such that* $\phi(\,\cdot\,) = \omega(h^{1/2}\,\cdot\,h^{1/2})$ *and* $0 \le h^{1/2} \le 1$.

The analogies with measure theory are not accidental, although these are not discussed in detail here. Indeed, any normal trace on a (finite) von Neumann algebra $\mathcal{M}$ gives rise to a noncommutative integration theory in a natural manner. Modular theory affords an extension of this theory to the setting of faithful normal functionals $\eta$ on von Neumann algebras $\mathcal{M}$ of any type, enabling the definition of noncommutative $L^p$ spaces, $L^p(\mathcal{M},\eta)$.

## Modular Invariants and the Classification of von Neumann Algebras

As already mentioned, the modular structure carries information about the algebra. This is best evidenced in the structure of type III factors. As this theory is rather involved, only a sketch of some of the results can be given.

If $\mathcal{M}$ is a type III algebra, then its crossed product $\mathcal{N} = \mathcal{M} \rtimes_{\sigma^{\omega}} \mathbb{R}$ relative to the modular automorphism group of any faithful normal state $\omega$ on $\mathcal{M}$ is a type $\mathrm{II}_{\infty}$ algebra with a faithful semifinite normal trace $\tau$ such that $\tau \circ \theta_t = \mathrm{e}^{-t}\tau$, $t \in \mathbb{R}$, where $\theta$ is the dual of $\sigma^{\omega}$ on $\mathcal{N}$. Moreover, the algebra $\mathcal{M}$ is isomorphic to the cross product $\mathcal{N} \rtimes_{\theta} \mathbb{R}$, and this decomposition is unique in a very strong sense. This structure theorem entails the existence of important algebraic invariants for $\mathcal{M}$, which has many consequences, one of which is made explicit here.

If $\omega$ is a faithful normal state of a von Neumann algebra $\mathcal{M}$ induced by $\Omega$, let $\Delta_{\omega}$ denote the modular operator associated to $(\mathcal{M},\Omega)$ and $\mathrm{sp}\,\Delta_{\omega}$ denote the spectrum of $\Delta_{\omega}$. The intersection

$$S'(\mathcal{M}) = \cap\ \mathrm{sp}\,\Delta_{\omega}$$

over all faithful normal states $\omega$ of $\mathcal{M}$ is an algebraic invariant of $\mathcal{M}$.

**Theorem 8** *Let* $\mathcal{M}$ *be a factor acting on a separable Hilbert space. If* $\mathcal{M}$ *is of type* III, *then* $0 \in S'(\mathcal{M})$; *otherwise*, $S'(\mathcal{M}) = \{0,1\}$ *if* $\mathcal{M}$ *is of type* $\mathrm{I}_{\infty}$ *or* $\mathrm{II}_{\infty}$ *and* $S'(\mathcal{M}) = \{1\}$ *if not. Let* $\mathcal{M}$ *now be a factor of type* III.

(i) $\mathcal{M}$ *is of type* $\mathrm{III}_{\lambda}, 0 < \lambda < 1$, *if and only if* $S'(\mathcal{M}) = \{0\} \cup \{\lambda^n \mid n \in \mathbb{Z}\}$.
(ii) $\mathcal{M}$ *is of type* $\mathrm{III}_0$ *if and only if* $S'(\mathcal{M}) = \{0,1\}$.
(iii) $\mathcal{M}$ *is of type* $\mathrm{III}_1$ *if and only if* $S'(\mathcal{M}) = [0,\infty)$.

In certain physically relevant situations, the spectra of the modular operators of all faithful normal states coincide, so that Theorem 8 entails that it suffices to compute the spectrum of any conveniently chosen modular operator in order to determine the type of $\mathcal{M}$. In other such situations, there are distinguished states $\omega$ such that $S'(\mathcal{M}) = \mathrm{sp}\,\Delta_{\omega}$. One such example is provided by asymptotically abelian systems. A von Neumann algebra $\mathcal{M}$ is said to be "asymptotically abelian" if there exists a sequence $\{\alpha_n\}_{n\in\mathbb{N}}$ of automorphisms of $\mathcal{M}$ such that the limit of $\{A\alpha_n(B) - \alpha_n(B)A\}_{n\in\mathbb{N}}$ in

the strong operator topology is zero, for all $A, B \in \mathcal{M}$. If the state $\omega$ is $\alpha_n$-invariant, for all $n \in \mathbb{N}$, then $\mathrm{sp}\,\Delta_\omega$ is contained in $\mathrm{sp}\,\Delta_\phi$, for all faithful normal states $\phi$ on $\mathcal{M}$, so that $S'(\mathcal{M}) = \mathrm{sp}\,\Delta_\omega$. If, moreover, $\mathrm{sp}\,\Delta_\omega = [0, \infty)$, then $\mathrm{sp}\,\Delta_\omega = \mathrm{sp}\,\Delta_\phi$, for all $\phi$ as described.

## Self-Dual Cones

Let $j : \mathcal{M} \to \mathcal{M}'$ denote the antilinear $*$-isomorphism defined by $j(A) = JAJ, A \in \mathcal{M}$. The natural positive cone $\mathcal{P}^\natural$ associated with the pair $(\mathcal{M}, \Omega)$ is defined as the closure, in $\mathcal{H}$, of the set of vectors

$$\{Aj(A)\Omega \mid A \in \mathcal{M}\}$$

Let $\mathcal{M}_+$ denote the set of all positive elements of $\mathcal{M}$. The following theorem collects the main attributes of the natural cone.

**Theorem 9**

(i) *$\mathcal{P}^\natural$ coincides with the closure in $\mathcal{H}$ of the set $\{\Delta^{1/4} A\Omega \mid A \in \mathcal{M}_+\}$.*
(ii) *$\Delta^{it}\mathcal{P}^\natural = \mathcal{P}^\natural$ for all $t \in \mathbb{R}$.*
(iii) *$J\Phi = \Phi$ for all $\Phi \in \mathcal{P}^\natural$.*
(iv) *$Aj(A)\mathcal{P}^\natural \subset \mathcal{P}^\natural$ for all $A \in \mathcal{M}$.*
(v) *$\mathcal{P}^\natural$ is a pointed, self-dual cone whose linear span coincides with $\mathcal{H}$.*
(vi) *If $\Phi \in \mathcal{P}^\natural$, then $\Phi$ is cyclic for $\mathcal{M}$ if and only if $\Phi$ is separating for $\mathcal{M}$.*
(vii) *If $\Phi \in \mathcal{P}^\natural$ is cyclic, and hence separating, for $\mathcal{M}$, then the modular conjugation and the natural cone associated with the pair $(\mathcal{M}, \Phi)$ coincide with $J$ and $\mathcal{P}^\natural$, respectively.*
(viii) *For every normal positive linear functional $\phi$ on $\mathcal{M}$, there exists a unique vector $\Phi_\phi \in \mathcal{P}^\natural$ such that $\phi(A) = \langle \Phi_\phi, A\Phi_\phi \rangle$ for all $A \in \mathcal{M}$.*

In fact, the algebras $\mathcal{M}$ and $\mathcal{M}'$ are uniquely characterized by the natural cone $\mathcal{P}^\natural$ [4]. In light of (viii), if $\alpha$ is an automorphism of $\mathcal{M}$, then

$$V(\alpha)\Phi_\phi = \Phi_{\phi \circ \alpha^{-1}}$$

defines an isometric operator on $\mathcal{P}^\natural$, which by (v) extends to a unitary operator on $\mathcal{H}$. The map $\alpha \mapsto V(\alpha)$ defines a unitary representation of the group of automorphisms $\mathrm{Aut}(\mathcal{M})$ on $\mathcal{M}$ in such a manner that $V(\alpha)AV(\alpha)^{-1} = \alpha(A)$ for all $A \in \mathcal{M}$ and $\alpha \in \mathrm{Aut}(\mathcal{M})$. Indeed, one has the following:

**Theorem 10** *Let $\mathcal{M}$ be a von Neumann algebra with a cyclic and separating vector $\Omega$. The group $\mathcal{V}$ of all unitaries $V$ satisfying*

$$V\mathcal{M}V^* = \mathcal{M}, \quad VJV^* = J, \quad V\mathcal{P}^\natural = \mathcal{P}^\natural$$

*is isomorphic to* $\mathrm{Aut}(\mathcal{M})$ *under the above map $\alpha \mapsto V(\alpha)$, which is called the "standard implementation" of* $\mathrm{Aut}(\mathcal{M})$.

Often of particular physical interest are (anti-)automorphisms of $\mathcal{M}$ leaving $\omega$ invariant. They can only be implemented by (anti)unitaries which leave the pair $(\mathcal{M}, \Omega)$ invariant. In fact, if $U$ is a unitary or antiunitary operator satisfying $U\Omega = \Omega$ and $U\mathcal{M}U^* = \mathcal{M}$, then $U$ commutes with both $J$ and $\Delta$.

## Two Algebras and One State

Motivated by applications to quantum field theory, the study of the modular structures associated with one state and more than one von Neumann algebra has begun (see Borchers (2000) for references and details). Let $\mathcal{N} \subset \mathcal{M}$ be von Neumann algebras with a common cyclic and separating vector $\Omega$, and $\Delta_\mathcal{N}$, $J_\mathcal{N}$ and $\Delta_\mathcal{M}, J_\mathcal{M}$ denote the corresponding modular objects. The structure $(\mathcal{M}, \mathcal{N}, \Omega)$ is called a $\pm$-half-sided modular inclusion if $\Delta_\mathcal{M}^{it}\mathcal{N}\Delta_\mathcal{M}^{-it} \subset \mathcal{N}$, for all $\pm t \geq 0$.

**Theorem 11** *Let $\mathcal{M}$ be a von Neumann algebra with cyclic and separating vector $\Omega$. The following are equivalent:*

(i) *There exists a proper subalgebra $\mathcal{N} \subset \mathcal{M}$ such that $(\mathcal{M}, \mathcal{N}, \Omega)$ is a $\mp$-half-sided modular inclusion.*
(ii) *There exists a unitary group $\{U(t)\}$ with positive generator such that*

$$U(t)\mathcal{M}U(t)^{-1} \subset \mathcal{M}, \quad \text{for all} \pm t \geq 0,$$
$$U(t)\Omega = \Omega, \quad \text{for all } t \in \mathbb{R}$$

*Moreover, if these conditions are satisfied, then the following relations must hold:*

$$\Delta_\mathcal{M}^{it}U(s)\Delta_\mathcal{M}^{-it} = \Delta_\mathcal{N}^{it}U(s)\Delta_\mathcal{N}^{-it} = U(\mathrm{e}^{\mp 2\pi t}s)$$

*and*

$$J_\mathcal{M}U(s)J_\mathcal{M} = J_\mathcal{N}U(s)J_\mathcal{N} = U(-s)$$

*for all $s,t \in \mathbb{R}$. In addition, $\mathcal{N} = U(\pm 1)\mathcal{M}U(\pm 1)^{-1}$, and if $\mathcal{M}$ is a factor, it must be type* $\mathrm{III}_1$.

The richness of this structure is further suggested by the next theorem.

**Theorem 12**

(i) *Let $(\mathcal{M}, \mathcal{N}_1, \Omega)$ and $(\mathcal{M}, \mathcal{N}_2, \Omega)$ be $-$-half-sided, resp. $+$-half-sided, modular inclusions satisfying the condition $J_{\mathcal{N}_1}J_{\mathcal{N}_2} = J_\mathcal{M}J_{\mathcal{N}_2}J_{\mathcal{N}_1}J_\mathcal{M}$. Then the modular unitaries $\Delta_\mathcal{M}^{it}, \Delta_{\mathcal{N}_1}^{is}, \Delta_{\mathcal{N}_2}^{iu}, s, t, u \in \mathbb{R}$, generate a faithful continuous unitary representation of the identity component of the*

*group of isometries of two-dimensional Minkowski space.*

(ii) *Let $\mathcal{M}, \mathcal{N}, \mathcal{N} \cap \mathcal{M}$ be von Neumann algebras with a common cyclic and separating vector $\Omega$. If $(\mathcal{M}, \mathcal{M} \cap \mathcal{N}, \Omega)$ and $(\mathcal{N}, \mathcal{M} \cap \mathcal{N}, \Omega)$ are $-$-half-sided, resp. $+$-half-sided, modular inclusions such that $J_{\mathcal{N}} \mathcal{M} J_{\mathcal{N}} = \mathcal{M}$, then the modular unitaries $\Delta^{it}_{\mathcal{M}}, \Delta^{is}_{\mathcal{N}}, \Delta^{iu}_{\mathcal{N} \cap \mathcal{M}}, s, t, u \in \mathbb{R}$, generate a faithful continuous unitary representation of* SL $(2, \mathbb{R})/\mathbb{Z}_2$.

This has led to a further useful notion. If $\mathcal{N} \subset \mathcal{M}$ and $\Omega$ is cyclic for $\mathcal{N} \cap \mathcal{M}$, then $(\mathcal{M}, \mathcal{N}, \Omega)$ is said to be a "$\pm$-modular intersection" if both $(\mathcal{M}, \mathcal{M} \cap \mathcal{N}, \Omega)$ and $(\mathcal{N}, \mathcal{M} \cap \mathcal{N}, \Omega)$ are $\pm$-half-sided modular inclusions and

$$J_{\mathcal{N}} \left[ \lim_{t \to \mp\infty} \Delta^{it}_{\mathcal{N}} \Delta^{-it}_{\mathcal{M}} \right] J_{\mathcal{N}} = \lim_{t \to \mp\infty} \Delta^{it}_{\mathcal{M}} \Delta^{-it}_{\mathcal{N}}$$

where the existence of the strong operator limits is assured by the preceding assumptions. An example of the utility of this structure is the following theorem.

**Theorem 13** *Let $\mathcal{N}, \mathcal{M}, \mathcal{L}$ be von Neumann algebras with a common cyclic and separating vector $\Omega$. If $(\mathcal{M}, \mathcal{N}, \Omega)$ and $(\mathcal{N}', \mathcal{L}, \Omega)$ are $-$-modular intersections and $(\mathcal{M}, \mathcal{L}, \Omega)$ is a $+$-modular intersection, then the unitaries $\Delta^{it}_{\mathcal{M}}, \Delta^{is}_{\mathcal{N}}, \Delta^{iu}_{\mathcal{L}}, s, t, u \in \mathbb{R}$, generate a faithful continuous unitary representation of* $\mathrm{SO}^{\uparrow}(1, 2)$.

These results and their extensions to larger numbers of algebras were developed for application in algebraic quantum field theory, but one may anticipate that half-sided modular inclusions will find wider use. Modular theory has also been applied fruitfully in the theory of inclusions $\mathcal{N} \subset \mathcal{M}$ of properly infinite algebras with finite or infinite index.

## Applications in Quantum Theory

The Tomita–Takesaki theory has found many applications in quantum field theory and quantum statistical mechanics. As mentioned earlier, the modular automorphism group satisfies the KMS condition, a property of physical significance in the quantum theory of many-particle systems, which includes quantum statistical mechanics and quantum field theory. In such settings, for a suitable algebra of observables $\mathcal{M}$ and state $\omega$, an automorphism group $\{\sigma_{\beta t}\}$ representing the time evolution of the system satisfies the modular condition. Hence, on the one hand, $\{\sigma_{\beta t}\}$ is the modular automorphism group of the pair $(\mathcal{M}, \Omega)$, and, on the other, $\omega$ is an equilibrium state at inverse temperature $\beta$, with all the consequences which both of these facts have.

But it has become increasingly clear that the modular objects $\Delta^{it}$, $J$, of certain algebras of observables and states encode additional physical information. In 1975, it was discovered that if one considers the algebras of observables associated with a finite-component quantum field theory satisfying the Wightman axioms, then the modular objects associated with the vacuum state and algebras of observables localized in certain wedge-shaped regions in Minkowski space have geometric content. In fact, the unitary group $\{\Delta^{it}\}$ implements the group of Lorentz boosts leaving the wedge region invariant (this property is now called modular covariance), and the modular involution $J$ implements the space-time reflection about the edge of the wedge, along with a charge conjugation. This discovery caused some intense research activity (see Baumgartel and Wollenberg 1992, Borchers 2000, Haag 1992).

### Positive Energy

In quantum physics the time development of the system is often represented by a strongly continuous group $\{U(t) = e^{itH} \mid t \in \mathbb{R}\}$ of unitary operators, and the generator $H$ is interpreted as the total energy of the system. There is a link between modular structure and positive energy, which has found many applications in quantum field theory. This result was crucial in the development of Theorem 11 and was motivated by the 1975 discovery mentioned above, now commonly called the Bisognano–Wichmann theorem.

**Theorem 14** *Let $\mathcal{M}$ be a von Neumann algebra with a cyclic and separating vector $\Omega$, and let $\{U(t)\}$ be a continuous unitary group satisfying $U(t)\mathcal{M}U(-t) \subset \mathcal{M}$, for all $t \geq 0$. Then any two of the following conditions imply the third*:

(i) $U(t) = e^{itH}$, *with* $H \geq 0$;
(ii) $U(t)\Omega = \Omega$, *for all* $t \in \mathbb{R}$; *and*
(iii) $\Delta^{it} U(s) \Delta^{-it} = U(e^{-2\pi t} s)$ *and* $JU(s)J = U(-s)$, *for all* $s, t \in \mathbb{R}$.

### Modular Nuclearity and Phase Space Properties

Modular theory can be used to express physically meaningful properties of quantum "phase spaces" by a condition of compactness or nuclearity of certain maps. In its initial form, the condition was formulated in terms of the Hamiltonian, the global energy operator of theories in Minkowski space. The above indications that the modular operators carry information about the energy of the system were reinforced when it was shown that a

formulation in terms of modular operators was essentially equivalent.

Let $\mathcal{O}_1 \subset \mathcal{O}_2$ be nonempty bounded open subregions of Minkowski space with corresponding algebras of observables $\mathcal{A}(\mathcal{O}_1) \subset \mathcal{A}(\mathcal{O}_2)$ in a vacuum representation with vacuum vector $\Omega$, and let $\Delta$ be the modular operator associated with $(\mathcal{A}(\mathcal{O}_2), \Omega)$ (by the Reeh–Schlieder theorem, $\Omega$ is cyclic and separating for $\mathcal{A}(\mathcal{O}_2)$). For each $\lambda \in (0, 1/2)$ define the mapping $\Xi_\lambda : \mathcal{A}(\mathcal{O}_1) \to \mathcal{H}$ by $\Xi_\lambda(A) = \Delta^\lambda A\Omega$. The compactness of any one of these mappings implies the compactness of all of the others. Moreover, the $l^p$ (nuclear) norms of these mappings are interrelated and provide a measure of the number of local degrees of freedom of the system. Suitable conditions on the maps in terms of these norms entail the strong statistical independence condition called the split property. Conversely, the split property implies the compactness of all of these maps. Moreover, the existence of equilibrium temperature states on the global algebra of observables can be derived from suitable conditions on these norms in the vacuum sector.

The conceptual advantage of the modular compactness and nuclearity conditions compared to their original Hamiltonian form lies in the fact that they are meaningful also for quantum systems in curved spacetimes, where global energy operators (i.e., generators corresponding to global timelike Killing vector fields) need not exist.

## Modular Position and Quantum Field Theory

The characterization of the relative "geometric" position of algebras based on the notions of modular inclusion and modular intersection was directly motivated by the Bisognano–Wichmann theorem. Observable algebras associated with suitably chosen wedge regions in Minkowski space provided examples whose essential structure could be abstracted for more general application, resulting in the notions presented in the preceding sections.

Theorem 12(ii) has been used to construct, from two algebras and the indicated half-sided modular inclusions, a conformal quantum field theory on the circle (compactified light ray) with positive energy. Since the chiral part of a conformal quantum field model in two spacetime dimensions naturally yields such half-sided modular inclusions, studying the inclusions in Theorem 12(ii) is equivalent to studying such field theories. Theorems 12(i) and 13 and their generalizations to inclusions involving up to six algebras have been employed to construct Poincaré-covariant nets of observable algebras (the algebraic form of quantum field theories) satisfying the spectrum condition on $(d+1)$-dimensional Minkowski space for $d = 1, 2, 3$. Conversely, such quantum field theories naturally yield such systems of algebras.

This intimate relation would seem to open up the possibility of constructing interacting quantum field theories from a limited number of modular inclusions/intersections.

## Geometric Modular Action

The fact that the modular objects in quantum field theory associated with wedge-shaped regions and the vacuum state in Minkowski space have geometric significance ("geometric modular action") was originally discovered in the framework of the Wightman axioms. As an algebraic quantum field theory (AQFT) does not rely on the concept of Wightman fields, it was natural to ask (i) when does geometric modular action hold in AQFT and (ii) which physically relevant consequences follow from this feature?

There are two approaches to the study of geometric modular action. In the first, attention is focused on modular covariance, expressed in terms of the modular groups associated with wedge algebras and the vacuum state in Minkowski space. Modular covariance has been proven to obtain in conformally invariant AQFT, in any massive theory satisfying asymptotic completeness, and also in the presence of other, physically natural assumptions. To mention only three of its consequences, both the spin–statistics theorem and the PCT theorem, as well as the existence of a continuous unitary representation of the Poincaré group acting covariantly upon the observable algebras and satisfying the spectrum condition follow from modular covariance.

In a second approach to geometric modular action, the modular involutions are the primary focus. Here, no *a priori* connection between the modular objects and isometries of the spacetime is assumed. The central assumption, given the state vector $\Omega$ and the von Neumann algebras of localized observables $\{\mathcal{A}(\mathcal{O})\}$ on the spacetime, is that there exists a family $\mathcal{W}$ of subsets of the spacetime such that $J_{W_1}\mathcal{R}(W_2)J_{W_1} \in \{\mathcal{R}(W) \mid W \in \mathcal{W}\}$, for every $W_1, W_2 \in \mathcal{W}$. This condition makes no explicit appeal to isometries or other special attributes and is thus applicable, in principle, to quantum field theories on general curved spacetimes.

It has been shown for certain spacetimes, including Minkowski space, that under certain additional technical assumptions, the modular involutions encode enough information to determine the dynamics of the theory, the isometry group of the spacetime, and a continuous unitary representation of the isometry group which acts covariantly upon the observables and leaves the state invariant. In certain

cases including Minkowski space, it is even possible to derive the spacetime itself from the group $\mathcal{J}$ generated by the modular involutions $\{J_W \mid W \in \mathcal{W}\}$.

The modular unitaries $\Delta_W^{it}$ enter in this approach through a condition which is designed to assure the stability of the theory, namely that $\Delta_W^{it} \in \mathcal{J}$, for all $t \in \mathbb{R}$ and $W \in \mathcal{W}$. In Minkowski space, this additional condition entails that the derived representation of the Poincaré group satisfies the spectrum condition.

### Further Applications

As previously observed, through the close connection to the KMS condition, modular theory enters naturally into the equilibrium thermodynamics of many-body systems. But in recent work on the theory of nonequilibrium thermodynamics it also plays a role in making mathematical sense of the notion of quantum systems in local thermodynamic equilibrium. Modular theory has also proved to be of utility in recent developments in the theory of superselection rules and their attendant sectors, charges and charge-carrying fields.

# Topological Defects and Their Homotopy Classification

**T W B Kibble**, Imperial College, London, UK

## Introduction

Symmetry-breaking phase transitions occur in a wide variety of systems – from condensed matter to the early universe. One of the common features of such transitions is the appearance, in the broken-symmetry phase, of topological defects, trapped regions in which the symmetry is restored, or at least changed. Examples are vortices in superfluids, domain walls in ferromagnets, and disclination lines in liquid crystals. Often these defects are stable for topological reasons, and play an important role in the dynamics of the system. An astonishingly rich variety of defects can be found in various systems. They can usefully be classified using the tools of homotopy theory.

## Spontaneous Symmetry Breaking

Let us consider a quantum-mechanical system with a symmetry group $G$. This means that each $g \in G$ is represented on the Hilbert space of quantum states by a unitary operator $\hat{U}(g)$, which commutes with the Hamiltonian. Spontaneous symmetry breaking occurs if this symmetry is not shared by the ground state or vacuum state $|0\rangle$ of the system. In other words, for some $g \in G, \hat{U}(g)|0\rangle \neq |0\rangle$. Then the ground state is necessarily degenerate: $\hat{U}(g)|0\rangle$ must have the same energy as $|0\rangle$.

Spontaneous symmetry breaking is usually describable in terms of an order-parameter field, which vanishes above the transition and is nonzero below it. We can find a scalar field $\hat{\phi}(\boldsymbol{r})$, or multiplet of fields $\hat{\phi} = (\hat{\phi}_i, i = 1, \ldots, n)$ transforming according to some representation $D$ of $G$ (assumed not to contain the trivial representation), whose expectation value in the ground state is nonzero:

$$\langle 0|\hat{\phi}(\boldsymbol{r})|0\rangle = \phi_0 \neq 0 \qquad [1]$$

This is the order parameter. Since

$$\langle 0|\hat{U}^\dagger(g)\hat{\phi}(\boldsymbol{r})\hat{U}(g)|0\rangle = D(g)\phi_0 \qquad [2]$$

it follows that the only elements of $G$ that can be symmetries of the ground state are those in the

stability subgroup $H$ of $\phi_0$ (the group of unbroken symmetries in this ground state):

$$H = \{g \in G:\ D(g)\phi_0 = \phi_0\} \qquad [3]$$

In terms of this subgroup, we can find a useful characterization of the manifold $\mathcal{M}$ of degenerate ground states. As noted above, for each $g \in G$, $\hat{U}(g)|0\rangle$ is also a ground state. However, these are not all distinct, because clearly $\hat{U}(gh)|0\rangle = \hat{U}(g)|0\rangle$ for all $h \in H$. Hence, the distinct ground states are in one-to-one correspondence with the left cosets $gH$ of $H$ in $G$, and $\mathcal{M}$ may be identified with the quotient space $G/H$, the space of left cosets.

For example, suppose $G$ is the rotation group SO(3), and $\hat{\boldsymbol{\phi}}$ belongs to the three-dimensional vector representation. If $\boldsymbol{\phi} \neq \mathbf{0}$ in the ground state, we may choose $\boldsymbol{\phi}_0 = (0, 0, v)$. Then, clearly, $H = \mathrm{SO}(2)$, the group of rotations about the $z$-axis, and $\mathcal{M} = \mathrm{SO}(3)/\mathrm{SO}(2) = S^2$, the 2-sphere. It is useful to think of $\mathcal{M}$ as the subset of the order-parameter space comprising the possible expectation values $\boldsymbol{\phi} = \langle\hat{\phi}\rangle$ for the various degenerate ground states. For example, in this case, $\mathcal{M} = \{\boldsymbol{\phi}\text{: } \boldsymbol{\phi}^2 = v^2\}$.

## Defect Formation

It is often possible to characterize the dynamics at finite temperature in terms of a function of the order parameter, the effective potential $V(\phi)$, which is necessarily invariant under $G$, and whose minima define the equilibrium states. At low temperatures, it has a form like $V = \lambda(\boldsymbol{\phi}^2 - v^2)^2$, whose minima occur at nonzero values of $\boldsymbol{\phi}$. But above the critical temperature $T_c$, the only minimum is at $\boldsymbol{\phi} = \mathbf{0}$, so the equilibrium state is symmetric under $G$. In the high-temperature phase, there may be large fluctuations in $\hat{\boldsymbol{\phi}}$, but its mean value will be zero.

Now, when the system is cooled through the phase tränsition, $\hat{\phi}$ will acquire a nonzero expectation value, gradually approaching one of the degenerate ground states characterized by a point of $\mathcal{M}$. But the choice of which one is unpredictable; the symmetry breaking is spontaneous. Moreover, in a large system, there is no reason why the same choice should be made everywhere. For example, a ferromagnet cooling through its Curie point may acquire a spontaneous magnetization in different directions in different parts of the sample.

Of course, there is an energetic penalty to having a spatially varying order parameter, so it will tend to become more uniform as the temperature is lowered. But the question arises whether there may be any topological obstruction to this process. It can happen that if we choose points on $\mathcal{M}$ in a continuous manner everywhere around the periphery of some region, it is topologically impossible to complete the process throughout its interior. Continuity may require that there are points where $\phi$ leaves the surface $\mathcal{M}$. For example, if our ferromagnet has two opposite possible directions of easy magnetization, described by $\boldsymbol{\phi}_0$ and $-\boldsymbol{\phi}_0$, then $\mathcal{M}$ consists essentially of these two points. Regions where $\boldsymbol{\phi} \approx \boldsymbol{\phi}_0$ and where $\boldsymbol{\phi} \approx -\boldsymbol{\phi}_0$ must be separated by domain walls across which $\boldsymbol{\phi}$ varies smoothly from one to the other.

## Homotopy Groups

To classify the various possible types of defect, we need to consider the homotopy groups of the manifold $\mathcal{M}$ of degenerate ground states. In this section, we briefly review the necessary definitions.

A path in $\mathcal{M}$ is a map $\phi: I \rightarrow \mathcal{M}$ from the unit interval $I = [0, 1] \subset \mathbb{R}$. We choose a base point $m_0 \in \mathcal{M}$ (which may be identified with $\phi_0$), and consider loops in $\mathcal{M}$, paths such that $\phi(0) = \phi(1) = m_0$. We say that two loops are homotopic, and write $\phi \sim \psi$, if one can be continuously deformed into the other within $\mathcal{M}$, that is, if there exists a map $\chi: I^2 \rightarrow \mathcal{M}$ such that

$$\chi(0, t) = \phi(t) \quad \text{and} \quad \chi(1, t) = \psi(t) \qquad [4]$$

for all $t$, and

$$\chi(s, 0) = \chi(s, 1) = m_0 \qquad [5]$$

for all $s$. This is an equivalence relation. The set $\pi_1(\mathcal{M})$ is the set of equivalence classes $[\phi]$ of loops under this relation.

On the set of loops, we may define a product $\phi\psi$, comprising the loop $\phi$ followed by $\psi$ (see Figure 1). Explicitly,

$$(\phi\psi)(t) = \begin{cases} \phi(2t), & 0 \leq t \leq \frac{1}{2} \\ \psi(2t-1), & \frac{1}{2} < t \leq 1 \end{cases} \qquad [6]$$

It is easy to show that if $\phi \sim \phi'$ and $\psi \sim \psi'$, then $\phi\psi \sim \phi'\psi'$. Hence, this defines a product on $\pi_1(\mathcal{M})$, by $[\phi][\psi] = [\phi\psi]$. So equipped, $\pi_1(\mathcal{M})$ becomes the

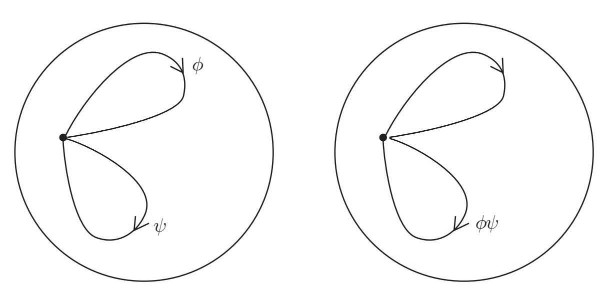

**Figure 1** The product of loops.

fundamental group or first homotopy group of $\mathcal{M}$. Note that the identity is the equivalence class $[\phi_0]$ of the trivial loop with $\phi_0(t) \equiv m_0$, while the inverse is $[\phi]^{-1} = [\tilde{\phi}]$, where the map $\tilde{\phi}$ is the reverse of $\phi$: $\tilde{\phi}(t) = \phi(1-t)$.

Strictly speaking, we should write $\pi_1(\mathcal{M}, m_0)$ in place of $\pi_1(\mathcal{M})$. However, for any path-connected space, the groups $\pi_1(\mathcal{M}, m_0)$ and $\pi_1(\mathcal{M}, m_0')$ are always isomorphic, and, more importantly, the same is true for any coset space $\mathcal{M} = G/H$, where $G$ is a Lie group and $H$ a closed subgroup. For a general manifold $\mathcal{M}, \pi_1(\mathcal{M})$ is not necessarily abelian, but it is so if $\mathcal{M}$ is a Lie group, or more generally a Riemannian symmetric space. The space $\mathcal{M}$ is said to be simply connected if $\pi_1(\mathcal{M}) = 0$, the group comprising only the identity element, $0 = \{[\phi_0]\}$. (Although $\pi_1(\mathcal{M})$ is not always abelian, it is conventional for homotopy groups to use an additive notation and represent the trivial group by 0 rather than 1.)

The $n$th homotopy group $\pi_n(\mathcal{M})$ may be defined similarly, as a set of equivalence classes of maps $\phi: I^n \to \mathcal{M}$ such that $\phi$ maps the entire boundary $\partial I^n$ to the base point $m_0$. Two such maps are homotopic ($\phi \sim \psi$) if there exists a map $\chi: I^{n+1} \to \mathcal{M}$ such that

$$\chi(0, t) = \phi(t) \quad \text{and} \quad \chi(1, t) = \psi(t) \qquad [7]$$

for all $t = (t_1, \ldots, t_n)$, and, for each $s \in I, \chi(s, t) = m_0$ for all $t \in \partial I^n$. The product $\phi\psi$ is defined by

$$(\phi\psi)(t_1, \ldots, t_n) = \begin{cases} \phi(2t_1, t_2, \ldots, t_n), & 0 \le t_1 \le \frac{1}{2} \\ \psi(2t_1 - 1, t_2, \ldots, t_n), & \frac{1}{2} < t_1 \le 1 \end{cases} \qquad [8]$$

The choice of $t_1$ rather than any other $t_j$ is arbitrary; all choices yield homotopic product maps. The product again defines a product on $\pi_n(\mathcal{M})$, which thereby becomes a group, the $n$th homotopy group. One new feature is that, for all $n > 1, \pi_n(\mathcal{M})$ is always abelian.

Note that since the entire boundary of $I_n$ is mapped to a single point, it is possible to collapse it, and talk instead about maps from the $n$-sphere $S^n$ to $\mathcal{M}$, taking one designated point to $m_0$. The fact that $\pi_n(\mathcal{M})$ is nontrivial indicates the existence in $\mathcal{M}$ of closed $n$-surfaces that cannot be smoothly shrunk to a point. In particular, it is worth noting that, for any $n$, $\pi_n(S^n) = \mathbb{Z}$, the additive group of integers, while $\pi_m(S^n) = 0$ for all $m < n$.

A special case is $n = 0$. Here, $S^0$ comprises two points only, and since one of them is always mapped to $m_0$, we really have to consider maps from a single point to $\mathcal{M}$, that is, points in $\mathcal{M}$. Two points are homotopic if they can be joined by a path in $\mathcal{M}$. Thus, $\pi_0(\mathcal{M})$ may be identified with the set of path-connected components of $\mathcal{M}$. Note, however, that in general no product can be defined on $\pi_0(\mathcal{M})$, so $\pi_0(\mathcal{M})$ should be called the zeroth homotopy set (not group). There is an important exception, however: if $G$ is a Lie group, and $G_0$ its connected subgroup (the subset of elements joined by paths to the identity $e$), then $\pi_0(\mathcal{M})$ may be identified with the quotient group $G/G_0$. Note, however, that this group $\pi_0(\mathcal{M}) = G/G_0$ is not necessarily abelian.

## Classification of Defects

We now turn to the classification of defects by means of homotopy groups. It will be useful to start with simple specific examples in three-dimensional space, $\mathbb{R}^3$.

First, suppose again that $\boldsymbol{\phi}$ belongs to the vector representation of $G = \mathrm{SO}(3)$. Then $\mathcal{M} = \mathrm{SO}(3)/\mathrm{SO}(2) = S^2$ may be identified with the sphere $\mathcal{M} = \{\boldsymbol{\phi}: \boldsymbol{\phi}^2 = v^2\}$ in $\phi$ space. Consider a closed surface $\mathcal{S}$, an embedding of a 2-sphere $S^2$ in $\mathbb{R}^3$. Assume that everywhere on $\mathcal{S}$ the field $\boldsymbol{\phi}(\boldsymbol{r})$ has one of the ground-state values. In other words, we have a map $\boldsymbol{\phi}: \mathcal{S} \to \mathcal{M}$, from one 2-sphere to another. The map $\boldsymbol{\phi}$ can be extended to a map from the interior of $\mathcal{S}$ to $\mathcal{M}$ only if it belongs to the trivial homotopy class $[\boldsymbol{\phi}_0] \in \pi_2(\mathcal{M})$, where $\phi_0: I^2 \to \mathcal{M}: (t_1, t_2) \mapsto m_0 = eH$. In all other cases, there must be at least one point where $\boldsymbol{\phi}(\boldsymbol{r}) = \boldsymbol{0}$; this is a point defect. The second homotopy group in this case is $\pi_2(S^2) = \mathbb{Z}$, so the possible point defects, or monopoles, are labeled by an integer $n \in \mathbb{Z}$, the winding number. (An example of a map with winding number $n$ is (in spherical polars) $(r, \theta, \varphi) \mapsto (v, \theta, n\varphi)$.)

More generally, point defects in $\mathbb{R}^d$ are classified by $\pi_{d-1}(\mathcal{M})$. A map $\phi$ from a closed $(d-1)$-dimensional surface $\mathcal{S} \subset \mathbb{R}^d$ to $\mathcal{M}$ can be extended to the interior of $\mathcal{S}$ if and only if it belongs to the trivial homotopy class $[\phi_0] \in \pi_{d-1}(\mathcal{M})$. If this is not the case, there must be at least one point around which $\phi(\boldsymbol{r})$ leaves the surface $\mathcal{M}$, although in general it is not required to vanish anywhere.

Second, take the case where $\phi$ is a single complex field, and $G$ is the phase symmetry group U(1). In this case, $H$ is the subgroup $\mathbf{1} = \{1\} \subset G$. Thus, $\mathcal{M} = \mathrm{U}(1)/\mathbf{1} = S^1$; this manifold may be identified with the circle $\{\phi: |\phi| = v\}$ in the order-parameter space. Now consider a closed loop $\mathcal{C}$ in space, an embedding of $S^1$ in $\mathbb{R}^3$ (see Figure 2). Suppose that on $\mathcal{C}, \phi(\boldsymbol{r})$ takes one of the ground-state values, say $\phi(\boldsymbol{r}) = v \exp[i\alpha(\boldsymbol{r})]$. If $\mathcal{S}$ is some surface with boundary $\mathcal{C}$, then the map $\phi: \mathcal{C} \to \mathcal{M}$ can be extended to a map $\phi: \mathcal{S} \to \mathcal{M}$ if and only if it belongs to the trivial homotopy class $[\phi_0] \in \pi_1(\mathcal{M})$. If it does not, then there must be at least one point on $\mathcal{S}$ within $\mathcal{C}$ where $\phi = 0$. Moreover, this

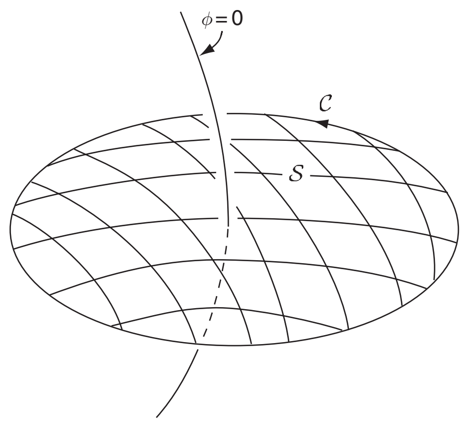

**Figure 2** A linear defect.

must be true of every surface $\mathcal{S}$ spanning $\mathcal{C}$, so there must be a curve passing through $\mathcal{C}$ along which $\phi = 0$. This is a linear defect, a string or vortex line. In this case, the first homotopy group is $\pi_1(S^1) = \mathbb{Z}$, so we see that the possible linear defects are classified by an integer, the winding number $n$. An example of a map with winding number $n$ is $\varphi \mapsto v e^{ni\varphi}$.

Again, this result can easily be generalized. Linear defects in $\mathbb{R}^d$ are classified by $\pi_{d-2}(\mathcal{M})$. If, on a $(d-2)$-dimensional surface $\mathcal{C}, \phi(\boldsymbol{r})$ takes values in $\mathcal{M}$, and if it does not belong to the trivial homotopy class, there must be a linear defect threading through $\mathcal{C}$, around which $\phi$ leaves the surface $\mathcal{M}$ – although again it need not necessarily vanish.

More generally yet, in the $d$-dimensional space $\mathbb{R}^d$, defects of dimension $p$ are classified by the homotopy group $\pi_{d-p-1}(\mathcal{M})$. For example, in three dimensions, planar defects – domain walls – are classified by $\pi_0(\mathcal{M})$.

## The Exact Sequence

There are mathematical theorems that greatly facilitate the computation of the homotopy group of homogeneous spaces, of the form $\mathcal{M} = G/H$.

We begin with the maps relating these spaces to each other. There is a canonical injective homomorphism $i: H \to G: h \mapsto h$, and a canonical projection associating each element of $G$ with its coset: $p: G \to \mathcal{M}: g \mapsto gH$. Moreover, it is clear that the image of $i$, namely the subgroup $H$, is also the kernel of $p$, the inverse image $p^{-1}m_0$ of the distinguished element $m_0 = eH$ of $\mathcal{M}$. These statements can be summarized by saying that

$$\mathbf{1} \to H \xrightarrow{i} G \xrightarrow{p} \mathcal{M} \to \mathbf{1}$$

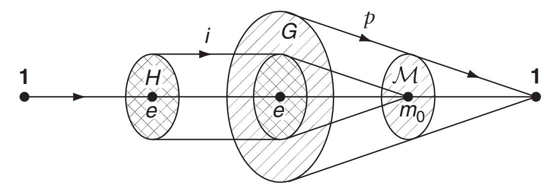

**Figure 3** An exact sequence.

is an exact sequence: the image of each map is the kernel of the following one (see Figure 3).

Next, we note that since any closed loops (or $n$-surfaces) in $H$ belonging to the same homotopy class are also homotopic as loops (or $n$-surfaces) in $G$, there is an induced homomorphism $i_*: \pi_n(H) \to \pi_n(G)$. Similarly, homotopic loops or $n$-surfaces in $G$ project to homotopic loops or $n$-surfaces in $\mathcal{M}$, so there is an induced homomorphism $p_*: \pi_n(G) \to \pi_n(\mathcal{M})$. Moreover, it is easy to see that although $i_*$ is not necessarily injective and $p_*$ not necessarily projective, it is true that the image of $i_*$ is the kernel of $p_*$. For example, any loop in $G$ will be mapped to a homotopically trivial loop in $\mathcal{M}$ if and only if it is homotopic to the image of a loop in $H$.

In addition, there is a boundary map that relates homotopy groups of different dimension: $\partial: \pi_{n+1}(\mathcal{M}) \to \pi_n(H)$. To see this, it is useful to think of $G$ as a fiber bundle with base space $\mathcal{M}$ and fiber $H$. Now consider a map $\phi: (I^{n+1}, \partial I^{n+1}) \to (\mathcal{M}, m_0)$. Since $p$ is a projection, $\phi$ can always be lifted to a map $\hat{\phi}: (I^{n+1}, \partial I^{n+1}) \to (G, H)$, that is, we can find a (nonunique) map $\hat{\phi}$ such that $\phi = p \circ \hat{\phi}$ (see Figure 4). However, $\hat{\phi}$ does not necessarily map the boundary to a single point; what is true is that $\hat{\phi}$ must map the boundary to a subset of $H$, and since topologically $\partial I^{n+1} \simeq S^n$, this defines a map $\tilde{\phi}: S^n \to H$. If we allow $\phi$ to vary over some homotopy class of maps, and $\hat{\phi}$ to vary continuously, then $\tilde{\phi}$ will

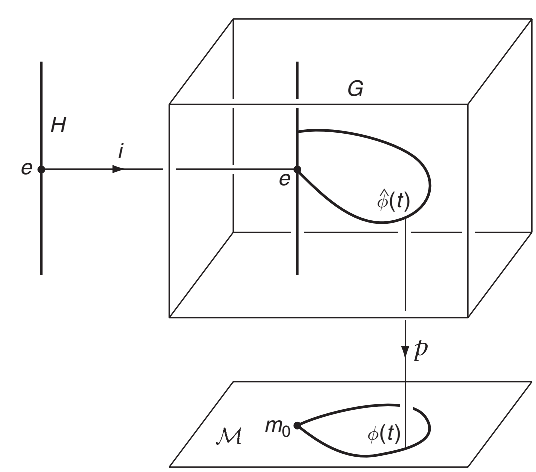

**Figure 4** Lift of a loop.

also remain in one homotopy class. Thus, we have defined a map $\partial : \pi_{n+1}(\mathcal{M}) \to \pi_n(H) : [\phi] \mapsto [\tilde{\phi}]$.

It is also easy to see that the image of $\partial : \pi_{n+1}(\mathcal{M}) \to \pi_n(H)$ is the kernel of $i_* : \pi_n(H) \to \pi_n(G)$, because the $n$-surface in $H$ defined by $\tilde{\phi}$ is necessarily homotopically trivial in $G$. Similarly, one can see that the image of $p_* : \pi_{n+1}(G) \to \pi_{n+1}(\mathcal{M})$ is the kernel of $\partial : \pi_{n+1}(\mathcal{M}) \to \pi_n(H)$.

Putting all these results together, we see that there is a (semi-infinite) exact sequence connecting all the homotopy groups:

$$\cdots \xrightarrow{p_*} \pi_{n+1}(\mathcal{M}) \xrightarrow{\partial} \pi_n(H) \xrightarrow{i_*} \pi_n(G) \xrightarrow{p_*} \pi_n(\mathcal{M})$$
$$\xrightarrow{\partial} \pi_{n-1}(H) \xrightarrow{i_*} \cdots \pi_1(G) \xrightarrow{p_*} \pi_1(\mathcal{M}) \xrightarrow{\partial} \pi_0(H) \quad [9]$$
$$\xrightarrow{i_*} \pi_0(G) \xrightarrow{p_*} \pi_0(\mathcal{M})$$

This sequence makes it easy to compute most of the low-dimensional homotopy groups of $\mathcal{M}$. Let us begin with $\pi_0(\mathcal{M})$, which merely labels its disconnected components. As noted earlier, for the Lie group $G, \pi_0(G)$ is the quotient group $\pi_0(G) = G/G_0$, where $G_0$ is the connected subgroup of $G$. Now the image of $\pi_0(H)$ under $i_*$ is clearly the set of connected components of $G$ that contain elements of $H$, so if $G$ has $m$ connected components, and $n$ of them contain elements of $H$, then $\pi_0(\mathcal{M})$ has $m/n$ elements (see Figure 5).

Next, we note that, for all the higher homotopy groups, disconnected pieces are irrelevant. Since a loop, for example, starting at $m_0$ must remain within its connected component $\mathcal{M}_0 \subset \mathcal{M}$, it follows that $\pi_1(\mathcal{M}) = \pi_1(\mathcal{M}_0)$, and similarly $\pi_n(\mathcal{M}) = \pi_n(\mathcal{M}_0)$ for all $n > 1$. So one can ignore any disconnected parts of the symmetry group $G$, and assume from now on that $\pi_0(G) = 0$. Moreover, it is always possible to replace $G$ by its simply connected covering group, replacing SO(3), for

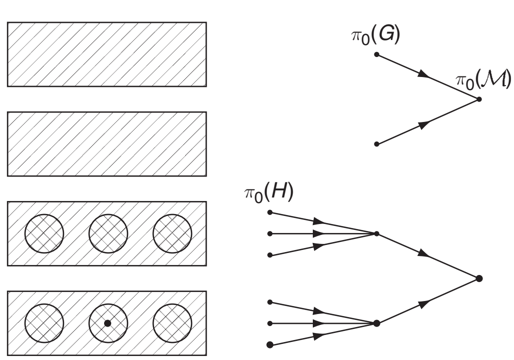

**Figure 5** The disconnected components of $G$ are shaded, those of $H$ are cross-hatched. Here $\pi_0(\mathcal{M})$ has two elements.

example, by SU(2). Thus, we may also assume that $\pi_1(G) = 0$. Then the section of the exact sequence in the second line of [9] becomes

$$0 \xrightarrow{p_*} \pi_1(\mathcal{M}) \xrightarrow{\partial} \pi_0(H) \xrightarrow{i_*} 0$$

which implies that the two groups in the center are isomorphic:

$$\pi_1(\mathcal{M}) = \pi_0(H) \quad [10]$$

For example, if the symmetry group $G = \mathrm{SO}(3)$ is completely broken, so that $H = \mathbf{1}$, then replacing $G$ by $\tilde{G} = \mathrm{SU}(2)$ requires replacing $H$ by $\tilde{H} = \{+1, -1\} \simeq \mathbb{Z}_2$, hence also $\pi_1(\mathcal{M}) = \pi_0(\tilde{H}) = \mathbb{Z}_2$; there is only one nontrivial class of linear defects in this model.

To find $\pi_2(\mathcal{M})$, we need a standard theorem about Lie groups, namely that the second homotopy group of any Lie group is trivial: for any $G, \pi_2(G) = 0$. (No details of the proof are given here. It derives from the fact that a generic element $g \in G$ belongs to a unique one-parameter subgroup $\{\exp(tX), t \in \mathbb{R}\} \subset G$, where $X$ is an element of the Lie algebra of $G$. Thus, all the points on a surface in $G$ may be joined by these paths to the identity, and the surface may then be shrunk along the resulting cone. There are exceptional elements for which this is not true, but it can be shown that in a $d$-dimensional group they lie on $(d-3)$-dimensional surfaces, so any 2-surface can be smoothly deformed to avoid them.)

It follows from this theorem that another section of the exact sequence is

$$0 \xrightarrow{p_*} \pi_2(\mathcal{M}) \xrightarrow{\partial} \pi_1(H) \xrightarrow{i_*} 0$$

which again implies an isomorphism:

$$\pi_2(\mathcal{M}) = \pi_1(H) \quad [11]$$

For example, if $G = \mathrm{SO}(3)$ and $H = \mathrm{SO}(2)$, or equivalently $\tilde{G} = \mathrm{SU}(2)$ and $\tilde{H} = \mathrm{U}(1)$ (a double cover of the SO(2)), then $\pi_2(\mathcal{M}) = \pi_1(\tilde{H}) = \mathbb{Z}$, so point defects in this theory are labeled by an integer winding number.

## Examples

The simplest continuous symmetry is the U(1) phase symmetry $\hat{\phi} \mapsto \hat{\phi}e^{i\alpha}$ of a complex field. In a weakly interacting Bose gas, below the Bose–Einstein condensation temperature, or in superfluid helium-4, a macroscopic fraction of the atoms occupies a single quantum state, and $\hat{\phi}$ acquires a nonzero expectation value, $\langle\hat{\phi}\rangle = \phi$, whose phase is arbitrary, so the symmetry is completely broken to $H = \mathbf{1}$. Thus, $\mathcal{M} = S^1$; we have a circle of equivalent degenerate ground states. (This corresponds to

spontaneous breaking of the particle-number symmetry. It is possible to describe the system in a U(1)-invariant way, by projecting out a state of definite particle number, a uniform superposition of all the states in $\mathcal{M}$, but it is generally less convenient to do so.) In this case, the only nontrivial homotopy group is $\pi_1(\mathcal{M}) = \mathbb{Z}$, so the only defects are linear defects classified by a winding number $n \in \mathbb{Z}$. The defects with $n = \pm 1$ are stable vortices. Those with $|n| > 1$ are in general unstable and tend to break up into $|n|$ single-quantum vortices.

Low-temperature superconductors also have a U(1) symmetry, although there are important differences. This is not a global symmetry but a local, gauge symmetry, with coupling to the electromagnetic field. Moreover, it is not single atoms that condense but Cooper pairs, pairs of electrons of equal and opposite momentum and spin. These systems too exhibit linear defects, magnetic flux tubes carrying a magnetic flux $4\pi n\hbar/e$.

A less trivial example is a nematic liquid crystal. These materials are composed of rod-shaped molecules that tend, at low temperatures, to line up parallel to one another. The nematic state is characterized by a preferred orientation, described by a unit vector $\boldsymbol{n}$, the director. (Note that $\boldsymbol{n}$ and $-\boldsymbol{n}$ are physically equivalent.) There is long-range orientational order, with molecules preferentially lining up parallel to $\boldsymbol{n}$, but unlike a solid crystal there is no long-range translational order – the molecules move freely past each other as in a normal liquid.

A convenient order parameter here is the mean mass quadrupole tensor $\Phi$ of a molecule. In the nematic state, $\Phi$ is proportional to $(3\boldsymbol{nn} - \mathbf{1})$; for example, if $\boldsymbol{n} = (0, 0, 1)$, then $\Phi$ is diagonal with diagonal elements proportional to $(-1, -1, 2)$. In this case, the symmetry group is SO(3) (or, more precisely, O(3); but the inversion symmetry is not broken, so we can restrict our attention to the connected part of the group). The subgroup $H$ that leaves this $\Phi$ invariant is a semidirect product, $H = \mathrm{SO}(2) \ltimes \mathbb{Z}_2$ (isomorphic to O(2)), composed of rotations about the $z$-axis and rotations through $\pi$ about axes in the $x$–$y$ plane. (If we enlarge $G$ to its simply connected covering group $\tilde{G} = \mathrm{SU}(2)$, then $H$ becomes $\tilde{H} = [\mathrm{U}(1) \ltimes \mathbb{Z}_4]/\mathbb{Z}_2$, where U(1) is generated as before by $J_z$. The essential difference is that the square of any of the elements in the disconnected piece of $\tilde{H}$ is not now the identity but the element $\mathrm{e}^{2\pi \mathrm{i} J_z} = -1 \in \mathrm{U}(1)$.) The manifold $\mathcal{M}$ of degenerate ground states in this case is the projective space $\mathbb{R}P^2$ (obtained by identifying opposite points of $S^2$).

Since $\tilde{H}$ has disconnected pieces, we have $\pi_1(\mathcal{M}) = \pi_0(\tilde{H}) = \mathbb{Z}_2$. Thus, there can be topologically stable linear defects, here called disclination lines, around which the director $\boldsymbol{n}$ rotates by $\pi$ (see Figure 6). The fact that these defects are classified by $\mathbb{Z}_2$ rather than $\mathbb{Z}$ means that a line around which $\boldsymbol{n}$ rotates by $2\pi$ is topologically trivial; indeed, $\boldsymbol{n}$ can be smoothly rotated near the line to run parallel to it, leaving a configuration with no defect.

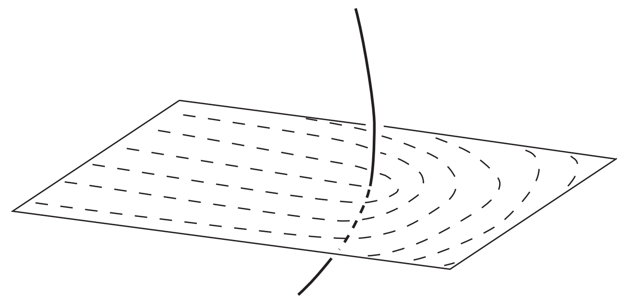

**Figure 6** Orientation of molecules around a disclination line.

There are also point defects; since $\pi_2(\mathcal{M}) = \pi_1(\tilde{H}) = \mathbb{Z}$, they are labeled by an integer winding number $n$. In a defect with $n = 1$, the vector $\boldsymbol{n}$ points radially outwards all round the defect position.

## Helium-3

Finally, let us turn to helium-3, one of the most fascinating and complex examples of spontaneous symmetry breaking, which becomes a superfluid at a temperature of a few millikelvin. Unlike helium-4, this is, of course, a Fermi liquid, so it is not the atoms that condense, but bound pairs of atoms, analogous to Cooper pairs. In this case, however, the most attractive channel is not the $^1$S, but the $^3$P, so the pairs have both orbital and spin angular momentum, $L = S = 1$. Therefore, the order parameter is not a single complex scalar field but a $3 \times 3$ complex matrix $\Phi_{jk}$, where the two indices label the orbital and spin angular momentum states.

To a good approximation, the system is invariant under separate rotations of $\boldsymbol{L}$ and $\boldsymbol{S}$ (the effects of the small spin–orbit coupling will be discussed later), so the symmetry group is

$$G = \mathrm{U}(1)_Y \times \mathrm{SO}(3)_L \times \mathrm{SO}(3)_S \qquad [12]$$

where the subscripts denote the generators and $\mathrm{U}(1)_Y$ represents multiplication by an overall phase factor, $\mathrm{e}^{\mathrm{i}\alpha Y} : \Phi_{jk} \mapsto \Phi_{jk}\mathrm{e}^{\mathrm{i}\alpha}$. This complicated symmetry allows much scope for a large variety of defects. There are, in fact, two distinct superfluid phases, $A$ and $B$, with different symmetries (and indeed in the presence of a magnetic field there is a third, $A1$).

In the $^3$He-$A$ phase, the order parameter has the form $\Phi_{jk} \propto (m_j + \mathrm{i}n_j)d_k$, where $\boldsymbol{m}$, $\boldsymbol{n}$, $\boldsymbol{d}$ are unit vectors, with $\boldsymbol{m} \perp \boldsymbol{n}$; if we set $\boldsymbol{l} = \boldsymbol{m} \wedge \boldsymbol{n}$, then

$\boldsymbol{l}$ defines the orbital angular momentum state by $\boldsymbol{l} \cdot \boldsymbol{L} = 1$, while $\boldsymbol{d}$ defines the spin quantization axis, such that $\boldsymbol{d} \cdot \boldsymbol{S} = 0$. The manifold $\mathcal{M}_A$ for this phase is

$$\mathcal{M}_A = [\mathrm{SO}(3) \times S^2]/\mathbb{Z}_2 \qquad [13]$$

where the $\mathbb{Z}_2$ is present because ($\boldsymbol{m}$, $\boldsymbol{n}$, $\boldsymbol{d}$) and ($-\boldsymbol{m}$, $-\boldsymbol{n}$, $-\boldsymbol{d}$) represent the same state. If, for example, we take $\boldsymbol{l}$ and $\boldsymbol{d}$ in the $z$-direction, the unbroken symmetry subgroup is

$$H_A = \mathrm{SO}(2)_{L_z+Y} \times [\mathrm{SO}(2)_{S_z} \ltimes \mathbb{Z}_2] \qquad [14]$$

where the nontrivial element of $\mathbb{Z}_2$ may be taken to be $e^{i\pi(S_x+L_z)}$. The covering group of $G$ is, of course,

$$\tilde{G} = \mathbb{R}_Y \times \mathrm{SU}(2)_L \times \mathrm{SU}(2)_S \qquad [15]$$

Correspondingly,

$$\tilde{H}_A = \mathbb{R}_{L_z+Y} \times [\mathrm{U}(1)_{S_z} \ltimes \mathbb{Z}_4] \qquad [16]$$

It follows that the homotopy groups are

$$\pi_0(\mathcal{M}_A) = 0, \quad \pi_1(\mathcal{M}_A) = \mathbb{Z}_4, \quad \pi_2(\mathcal{M}_A) = \mathbb{Z} \qquad [17]$$

There are linear defects labeled by a mod-4 quantum number and point defects labeled by an integer.

For the $^3$He-$B$ phase, by contrast, the order parameter is of the form

$$\Phi_{jk} \propto R_{jk} e^{i\theta} \qquad [18]$$

where $R$ is a rotation matrix, $R \in \mathrm{SO}(3)$. Here then,

$$\mathcal{M}_B = \mathrm{SO}(3) \times S^1 \qquad [19]$$

with homotopy groups

$$\pi_0(\mathcal{M}_B) = 0, \quad \pi_1(\mathcal{M}_B) = \mathbb{Z}_2 \times \mathbb{Z}, \quad \pi_2(\mathcal{M}_B) = 0 \qquad [20]$$

In this phase, there are two distinct types of linear defect, the mass vortices with an integer label, and the spin vortices with a mod-2 label. (One can also have a "spin–mass vortex" carrying both quantum numbers.)

## Composite Defects

There are several cases, including in particular helium-3, that exhibit symmetry breaking with multiple length or energy scales. For example, there may be two order parameters, say $\phi, \psi$, with $|\phi| \gg |\psi|$. If $|\psi|$ is negligible, the symmetry $G$ is broken by $\phi$ to $H$, and the manifold of degenerate ground states is $\mathcal{M} = G/H$. However, these states are not all exactly degenerate: $\psi$ breaks the symmetry further to $K \subset H$, so the precisely degenerate ground states form a submanifold $\mathcal{M}' = G/K$.

The case of helium-3 is slightly different. Here it is the small spin–orbit coupling, arising from long-range dipole–dipole interactions, that introduces the second scale. Its effect is only significant over large distances.

In the $^3$He-$A$ phase, at short range the $\boldsymbol{l}$ and $\boldsymbol{d}$ vectors are uncorrelated but, over large distances, they tend to be aligned parallel or antiparallel. We can use the $\mathbb{Z}_2$ symmetry mentioned earlier to choose $\boldsymbol{l} = \boldsymbol{d}$. Hence, the manifold $\mathcal{M}'_A$ of true ground states is only a submanifold of $\mathcal{M}_A$, namely $\mathcal{M}'_A = \mathrm{SO}(3)$, whose homotopy groups are

$$\pi_0(\mathcal{M}'_A) = 0, \quad \pi_1(\mathcal{M}'_A) = \mathbb{Z}_2, \quad \pi_2(\mathcal{M}'_A) = 0 \qquad [21]$$

Because of different behavior on different scales, "composite" defects can arise. For example, because $\pi_2(\mathcal{M}_A) = \mathbb{Z}$, there are short-range monopole configurations. For the $n = 1$ monopole, we have a configuration with uniform $\boldsymbol{l}$, and with $\boldsymbol{d}$ pointing outwards from the center. But, eventually the misalignment of $\boldsymbol{d}$ with $\boldsymbol{l}$ is energetically disfavored, and at large distances $\boldsymbol{d}$ tends to rotate to align with $\boldsymbol{l}$ except around one particular direction where it is oppositely aligned (see Figure 7). We have a composite defect: a small monopole coupled to a relatively fat string.

To see how the small- and large-scale structures fit together, one has to look also at the relative homotopy groups $\pi_n(\mathcal{M}, \mathcal{M}')$, whose elements are homotopy classes of maps from $I^n$ to $\mathcal{M}$ such that one face of the boundary is mapped into $\mathcal{M}'$, and the remainder to the chosen base point $m_0$. For example, $\pi_1(\mathcal{M}, \mathcal{M}')$ classifies paths that terminate at $m_0$ while beginning at any point of $\mathcal{M}'$. There is, in fact, a long exact sequence, similar to [9], relating these homotopy groups, of which a typical segment is

$$\cdots \xrightarrow{\partial} \pi_n(\mathcal{M}') \xrightarrow{i_*} \pi_n(\mathcal{M}) \xrightarrow{p_*} \pi_n(\mathcal{M}, \mathcal{M}') \xrightarrow{\partial} \pi_{n-1}(\mathcal{M}') \xrightarrow{i_*} \cdots \qquad [22]$$

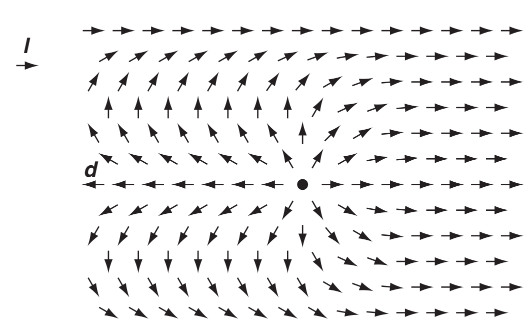

**Figure 7** Cross-section of a short-range monopole attached to a fat string.

The relevant groups in the present case are

$$\pi_1(\mathcal{M}_A, \mathcal{M}'_A) = \mathbb{Z}_2, \quad \pi_2(\mathcal{M}_A, \mathcal{M}'_A) = \mathbb{Z} \qquad [23]$$

Because $\pi_1(\mathcal{M}_A) = \mathbb{Z}_4$, there are three distinct classes of linear defects at small scales, but only those with quantum number $n = 2 \,(\mathrm{mod}\, 4)$ survive unchanged to large scales; they correspond to the nontrivial element of $\pi_1(\mathcal{M}'_A) = \mathbb{Z}_2$. On the other hand, the homotopy classes $n = \pm 1 \,(\mathrm{mod}\, 4)$ are mapped to nontrivial elements of $\pi_1(\mathcal{M}_A, \mathcal{M}'_A) = \mathbb{Z}_2$, which indicates that the corresponding linear defects are coupled at long range to fat domain walls, across which $\boldsymbol{d}$ rotates through $\pi$ with a compensating rotation through $\pi$ about $\boldsymbol{l}$. Similarly, the nontrivial elements of $\pi_2(\mathcal{M}_A) = \mathbb{Z}$ are mapped to nontrivial elements of $\pi_2(\mathcal{M}_A, \mathcal{M}'_A)$, confirming that these short-range monopoles are coupled to fat strings, as in Figure 7.

For $^3$He-$B$, the effect of the spin–orbit coupling is to make the most energetically favorable configurations those in which the rotation matrix $R$ in [18] represents a rotation about an arbitrary axis $\boldsymbol{n}$ through the Leggett angle $\theta_L = \arccos(-1/4) = 104°$: $R = \exp(-\mathrm{i}\theta_L \boldsymbol{n} \cdot \boldsymbol{J})$.

Consequently,

$$\mathcal{M}'_B = S^2 \times S^1 \qquad [24]$$

and so

$$\pi_0(\mathcal{M}'_B) = 0, \quad \pi_1(\mathcal{M}'_B) = \mathbb{Z}, \quad \pi_2(\mathcal{M}'_B) = \mathbb{Z} \qquad [25]$$

The relative homotopy groups are

$$\pi_1(\mathcal{M}_B, \mathcal{M}'_B) = \mathbb{Z}_2, \quad \pi_2(\mathcal{M}_B, \mathcal{M}'_B) = 0 \qquad [26]$$

Here the mass vortex persists at long range, but the configuration around the spin vortex deforms so that they become attached to fat domain walls. The "monopole" configurations corresponding to nontrivial elements of $\pi_2(\mathcal{M}'_B)$ have no short-range singularity at all.

**T Eguchi**, University of Tokyo, Tokyo, Japan

## Introduction

It is well known that large-$N$ Hermitian matrix models generate Feynman diagrams which represent the triangulation of Riemann surfaces. For instance, if we consider the integral of an $N \times N$ Hermitian matrix $H$

$$Z = \int \mathrm{d}H \exp\left(-N\left[\frac{1}{2}\mathrm{tr}\, H^2 + \frac{\lambda}{4}\mathrm{tr}\, H^4\right]\right) \qquad [1]$$

we find that the free energy $F = \log Z$ has the $1/N$ expansion

$$F = \sum_{g=0}^{\infty} N^{2-2g} F_g(\lambda) \qquad [2]$$

Inspection of the Feynman diagrams shows that $F_g$ reproduces the sum over the triangulations of genus $g$ Riemann surfaces. The theory [1] is obviously well defined for $\lambda \geq 0$. In the large-$N$ expansion, the theory continues to exist also at negative values of $\lambda$ down to the critical point $\lambda_c = -1/12$.

The double scaling limit of large-$N$ matrix models (Brézin and Kazakov 1990, Douglas and

Shenker 1990, Gross and Migdal 1990) is given by adjusting the coupling $\lambda$ to $\lambda_c$ and at the same time taking the limit $N \to \infty$. In this limit, contributions of all genera survive, and the theory describes the dynamics of fluctuating surfaces of arbitrary topologies. Results obtained in this way do not, in fact, depend on the detailed choice of the potential ($\phi^4$ type in [1]) and have a high degree of universality. Thus, it provides an interesting model of two-dimensional (2D) quantum gravity.

Soon after the discovery of double scaling limit of matrix models, Witten observed that the correlation functions of the 2D gravity theory may be given a geometrical interpretation as topological invariants of the moduli space of Riemann surfaces $\mathcal{M}$, and that the 2D gravity theory may be reformulated as a topological field theory (Witten 1990). This reformulation of the results of the 2D gravity theory is called "2D topological gravity."

In fact, 2D gravity theories come in a family parametrized by a pair of integers $(p, q)$. The double scaling limit of [1] gives the simplest example $(p=2, q=1)$. Models with a chain of $p-1$ Hermitian matrices give the $(p, q)$ 2D gravity theories. The label $q$ stands for the order of criticality of the model, and higher values of $q$ are achieved by fine-tuning the parameters of the potential. At $q=1$, 2D gravity theories possess a topological interpretation. The most basic case $(p=2, q=1)$ is called pure topological gravity, and in theories at higher values of $p$, topological gravity is coupled to a matter system, that is, topological minimal models. Topological minimal models are obtained by twisting $\mathcal{N}=2$ superconformal field theories.

Let us first consider the case of pure gravity $(p=2, 1)$. Let $\mathcal{O}_n$ denote the observables in the theory and $t_n$ the coupling constants to these operators. The correlation functions of topological gravity are given by

$$\langle \mathcal{O}_{n_1}\mathcal{O}_{n_2}\ldots\mathcal{O}_{n_s}\rangle_g, \quad n_i = 1, 2, \ldots \qquad [3]$$

where $\langle\cdots\rangle_g$ denotes the expectation value on a surface with $g$ handles. The precise significance of eqn [3] as the intersection number on the moduli space is discussed below. The string partition function $\tau(t)$ is defined as the generating function of all possible correlation functions

$$\tau(t) = \exp\sum_{g=0}^{\infty}\left\langle \exp\sum t_n\mathcal{O}_n\right\rangle_g \qquad [4]$$

The most striking aspect of topological gravity is the connection of the intersection theory on $\mathcal{M}$ to the theory of completely integrable systems, that is, Korteveg–de Vries (KdV) and KP hierarchies. Witten conjectured that the generating function of intersection numbers on moduli space $\tau(t)$ is the $\tau$-function of KdV hierarchy. KdV hierarchy is obtained by generalizing the well-known KdV equation

$$\frac{\partial u}{\partial t} = \frac{3}{2}u\frac{\partial u}{\partial x} + \frac{1}{4}\frac{\partial^3 u}{\partial x^3} \qquad [5]$$

Identification of the KdV equation with topological gravity is given by $u=2\langle\mathcal{O}_1\mathcal{O}_1\rangle, x=t_1, t=t_3$. Witten's conjecture was verified by Kontsevich (1991) by an explicit construction of a new type of matrix model which generates the triangulation of the moduli space of Riemann surfaces.

In the general case of $(p, 1)$ topological gravity, the partition function of the theory obeys the equations of $p$th generalized KdV hierarchy ($p$ reduction of KP hierarchy).

## Intersection Theory

We now present some basic features of intersection theory on the moduli space of Riemann surfaces. It is known that 2D oriented surfaces $\Sigma$ with $g$ handles and $s$ marked points $x_i$ $(i=1,\ldots,s)$ possess a finite number of inequivalent complex structures (complex structures are identified when they differ only by diffeomorphism). The space of inequivalent complex structures is called the moduli space $\mathcal{M}_{g,s}$ of the Riemann surface $\Sigma$. Its dimension is given by

$$\dim\mathcal{M}_{g,s} = 3g-3+s \qquad [6]$$

For a mathematically rigorous treatment, we have to consider a compactification $\bar{\mathcal{M}}_{g,s}$ of moduli space $\mathcal{M}_{g,s}$ by adding suitable boundary components which arise due to various types of degenerations of Riemann surfaces. In the Deligne–Mumford or stable compactification, one considers the following three classes of singular Riemann surfaces $\Sigma$:

1. Two points, $x_i$ and $x_j$, on $\Sigma$ come close together. In this case, an extra 2-sphere is pinched off from the surface by forming a thin neck. The sphere contains points $x_i$ and $x_j$ and also the point $x_l$ at the end of the neck (see Figure 1a). Since the original surface now has one point less and the 2-sphere with three points has no moduli, the degenerate surface has $3g-4+s$ parameters and forms a boundary divisor of the moduli space $\bar{\mathcal{M}}_{g,s}$.
2. If a cycle of nontrivial homology class shrinks to a point, we have a surface with one less genus and two extra marked points. Singular surface has $3(g-1)-3+s+2$ number of moduli and this is again a complex codimension-1 component (see Figure 1b).

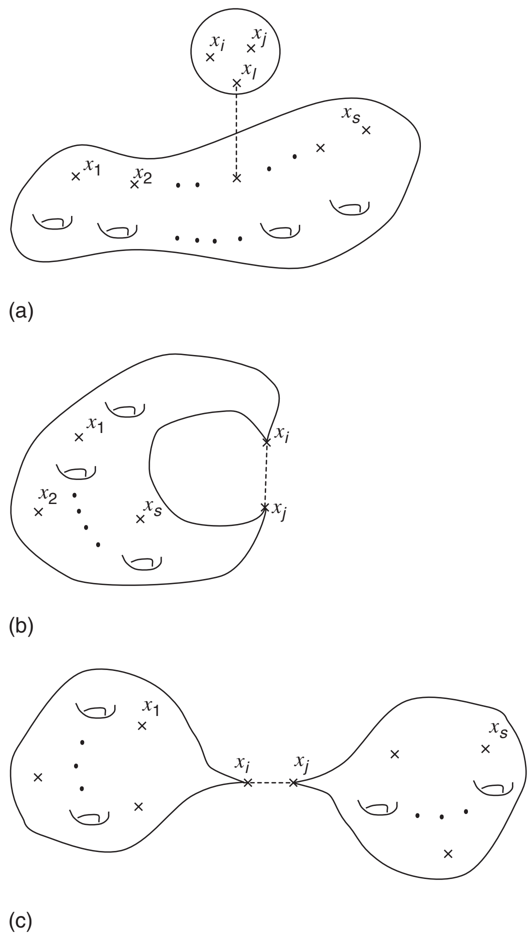

**Figure 1** Degenerate Riemann surface obtained when (a) the points $x_i$ and $x_j$ coincide; (b) a nontrivial cycle collapses, two new points $x_i$ and $x_j$ are created; (c) a pinching cycle collapses, two new points $x_i$ and $x_j$ are created.

3. Similarly, if a dividing cycle pinches, one obtains two disconnected surfaces of genus $g_i$ with $s_i+1$ marked points $(i=1,2; g_1+g_2=g, s_1+s_2=s)$. This type of degeneration also has the same number of parameters $\sum(3g_i-3)+\sum(s_1+1)=3g-4+s$ (see Figure 1c).

It is known that $\bar{\mathcal{M}}_{g,s}$ is a compact and smooth orbifold space, and observables of topological gravity are given by the cohomology classes on $\bar{\mathcal{M}}_{g,s}$. There exist special cohomology classes introduced by Mumford and Morita, which are defined as follows: There are natural line bundles $\mathcal{L}_1,\ldots,\mathcal{L}_s$ on the moduli space $\bar{\mathcal{M}}_{g,s}$. The fiber of the bundle $\mathcal{L}_i$ at a point $\Sigma\in\bar{\mathcal{M}}_{g,s}$ is the cotangent space $T^*_{x_i}\Sigma$ to the point $x_i$ on the surface $\Sigma$. These line bundles have the first Chern classes $c_1(\mathcal{L}_i)$ and by taking their exterior power we can define $2n$-dimensional classes

$$\sigma_n(i)=c_1(\mathcal{L}_i)^n\in H^{2n}(\bar{\mathcal{M}}_{g,s}) \qquad [7]$$

Correlation functions are defined by integrating these classes over the moduli space:

$$\langle\sigma_{n_1}\cdots\sigma_{n_s}\rangle_g\equiv\int_{\bar{\mathcal{M}}_{g,s}}c_1(\mathcal{L}_1)^{n_1}\wedge\cdots\wedge c_1(\mathcal{L}_s)^{n_s} \qquad [8]$$

These integrals are topological invariants of $\bar{\mathcal{M}}_{g,s}$ and are nonzero only when the degree of the cohomology classes adds up to the dimension of the moduli space

$$\sum_{i=1}^{s}n_i=3g-3+s \qquad [9]$$

$\sigma_n(i)$ is known as the $n$th descendant of the puncture operator $\sigma_0(i)$, since it is associated with the marked point $x_i$.

The above correlation functions are evaluated using various recursion relations. First, one has the puncture equation

$$\langle\sigma_0\sigma_{n_1}\cdots\sigma_{n_s}\rangle_g=\sum_{i=1,n_i\neq 0}^{s}\langle\sigma_{n_1}\cdots\sigma_{n_i-1}\cdots\sigma_{n_s}\rangle_g \qquad [10]$$

which can be derived by considering a map $\pi:\bar{\mathcal{M}}_{g,s+1}\to\bar{\mathcal{M}}_{g,s}$ where one forgets the position of an extra point. Contributions arise when the forgotten point coincides with the other points. This relation can be used to eliminate $\sigma_0$'s from correlation functions when they are well defined. At $g=0$, less than three insertions are ill-defined and one has

$$\langle\sigma_0\sigma_0\sigma_0\rangle_0=1 \qquad [11]$$

Another basic relation is the dilaton equation for the operator $\sigma_1$:

$$\langle\sigma_1\sigma_{n_1}\cdots\sigma_{n_s}\rangle_g=(2g-2+s)\langle\sigma_{n_1}\cdots\sigma_{n_s}\rangle_g \qquad [12]$$

The dilaton equation follows from the fact that since $\sigma_1$ is the first Chern class $c_1(\mathcal{L})$, it calculates the degree of the canonical line bundle of genus $g$ surface with $s$ punctures. At $g=1$, one insertion is required and one has

$$\langle\sigma_1\rangle_1=\tfrac{1}{24} \qquad [13]$$

By combining these recursion relations, one can evaluate the correlation functions. For instance, at $g=0$ one finds

$$\langle\sigma_{n_1}\cdots\sigma_{n_s}\rangle_0=\frac{(n_1+\cdots+n_s)!}{n_1!\cdots n_s!} \qquad [14]$$

A powerful way of computing correlation functions is given by the KdV hierarchies and Virasoro conditions as discussed below. In the context of integrable systems, it is convenient to redefine the observables as

$$\mathcal{O}_{2n+1}=(2n+1)!!\cdot\sigma_n,\quad n\geq 0 \qquad [15]$$

## Topological Minimal Models

Standard intersection theory applies to the case of pure topological gravity, $p=2$. At higher values of $p$, the theory is generalized as follows: one introduces the coupling of topological gravity to the topological matter sector which is obtained by twisting the $\mathcal{N}=2$ superconformal theories.

We recall that $\mathcal{N}=2$ superconformal symmetry is generated by the operators, stress tensor $T(z)$, U(1) current $J(z)$, and two types of supersymmetry generators $G(z)^{\pm}$. (In the holomorphic sector of the theory these operators depend on the holomorphic coordinate $z$ of the Riemann surface. In the antiholomorphic sector they depend on the antiholomorphic variable $\bar{z}$.) Mode expansion of the stress tensor and U(1) current is given by

$$T(z) = \sum_n L_n z^{-n-2}, \qquad J(z) = \sum_n J_n z^{-n-1} \qquad [16]$$

$L_n$ generates the Virasoro algebra

$$[L_m, L_n] = (m-n)L_{m+n} + \frac{c}{12} m(m^2-1)\delta_{m+n,0} \quad [17]$$

where $c$ denotes the central charge of the theory. Commutators of $J_n$ and $L_n$ are given by

$$[J_m, J_n] = \frac{c}{3} m\delta_{m+n,0}, \qquad [L_m, J_n] = -nJ_{m+n} \qquad [18]$$

It is known that there is a continuum of unitary $\mathcal{N}=2$ conformal theories in the range $c \geq 3$; however, only discrete values of the central charge $c = 3k/(k+2), k = 1, 2, \ldots$ are allowed in the region $3 \geq c \geq 1$. These are the $\mathcal{N}=2$ minimal models labeled by the level $k$. Only a finite number of primary fields exist in these theories.

In $\mathcal{N}=2$ theory, primary fields $\phi_\alpha$ are characterized by their conformal dimension and U(1) charge:

$$L_0|\phi_\alpha\rangle = h|\phi_\alpha\rangle, \qquad J_0|\phi_\alpha\rangle = q|\phi_\alpha\rangle \qquad [19]$$

There exists a special set of primary operators, chiral primary fields $\phi_\ell$ ($\ell = 0, \ldots, k$), which are annihilated by the supercharge operator $G^+$:

$$\oint dz G^+(z)|\phi_\ell\rangle = 0 \qquad [20]$$

$\phi_\ell$ has the dimension and U(1) charge

$$q(\phi_\ell) = \frac{\ell}{k+2}, \quad h(\phi_\ell) = \tfrac{1}{2}q(\phi_\ell), \quad \ell = 0, 1, \ldots, k \quad [21]$$

By considering primary fields annihilated by $G^-$, we can also define antichiral fields. Antichiral fields have U(1) charge opposite to those of chiral fields.

If one defines the twisted stress tensor by

$$T'(z) = T(z) + \tfrac{1}{2}\partial J(z) \qquad [22]$$

then $T'(z)$ has a vanishing central charge. Furthermore, the conformal dimensions of the supersymmetry operators $G^{\pm}$ become shifted from 3/2 to $h(G^+) = 1$ and $h(G^-) = 2$. It is then possible to integrate $G^+$ on the Riemann surface and define a fermionic scalar operator $G_0^+ = \oint dz G^+(z)$. From the $\mathcal{N}=2$ algebra, one has

$$(G_0^+)^2 = 0, \qquad \{G_0^+, G^-(z)\} = 2\,T'(z) \qquad [23]$$

If we identify $G_0^+$ as the Becchi–Rouet–Stora–Tyupin (BRST) operator of the theory, then the twisted stress tensor becomes BRST trivial, which is the characteristic feature of topological field theory. Thus, we obtain a topological field theory by twisting $\mathcal{N}=2$ conformal theory (Eguchi and Yang 1990). These are topological minimal models. BRST-invariant observables are given by the chiral primary fields [20]. (To be precise, when we take account of the antiholomorphic sector, we may define either $Q = G_0^+ + \bar{G}_0^+$ or $Q = G_0^+ + \bar{G}_0^-$ as the BRST operator. Thus, in general, we obtain two different topological field theories. This is the origin of the mirror symmetry. In the context of topological gravity, one takes the convention $Q = G_0^+ + \bar{G}_0^+$.)

Now, we consider the coupling of topological gravity to topological minimal models. We identify $k = p-2$. Making use of chiral fields $\phi_\ell$ ($\ell = 0, \ldots, p-2$), observables are constructed:

$$\sigma_{n,\ell} = \sigma_n \otimes \phi_\ell \qquad [24]$$

$\mathcal{N}=2$U(1) charge is identified as the degree of differential form of the moduli space. Thus, the degree of $\sigma_{n,\ell}$ is $n + \ell/p$. Correlation functions $\langle \prod_{i=1}^s \sigma_{n_i,\ell_i} \rangle_g$ are nonzero if the selection rule

$$\sum_{i=1}^s \left(n_i + \frac{\ell_i}{p}\right) = \left(3 - \frac{p-2}{p}\right)(g-1) + s \qquad [25]$$

is obeyed.

We may assemble $\sigma_{n,\ell}$ into operators with one index $\mathcal{O}_m$ as

$$\mathcal{O}_{np+\ell+1} = \prod_{r=0}^{n}(rp + \ell + 1) \cdot \sigma_{n,\ell} \qquad [26]$$

where one introduces a convenient normalization factor. Note that the operators $\mathcal{O}_m$ do not exist when $m \equiv 0 \bmod p$ and the corresponding paramters $t_m$ are absent. This is a characteristic feature of $p$ reduced KP hierarchy.

The puncture and dilaton equations for $(p, 1)$ theories read

$$\langle\sigma_{0,0}\sigma_{n_1,k_1}\cdots\sigma_{n_s,k_s}\rangle_g = \sum_{i=1,n_i\neq 0}^{s}\langle\sigma_{n_1,k_1}\cdots\sigma_{n_i-1,k_i}\cdots\sigma_{n_s,k_s}\rangle_g \quad [27]$$

$$\langle\sigma_{1,0}\sigma_{n_1,k_1}\cdots\sigma_{n_s,k_s}\rangle_g = (2g-2+s)\langle\sigma_{n_1,k_1}\cdots\sigma_{n_s,k_s}\rangle_g \quad [28]$$

The special terms at $g=0$ and $g=1$ are given by

$$\langle\sigma_{0,0}\sigma_{0,i}\sigma_{0,p-i-2}\rangle_0 = 1, \qquad \langle\sigma_{1,0}\rangle_1 = \frac{p-1}{24} \quad [29]$$

## Integrable Hierarchy

We now summarize some basic facts about the integrable hierarchy (see for instance eqn [5]). We introduce a $p$th order differential operator:

$$L = D^p + \sum_{i=0}^{p-2} u_i(x)D^i, \quad D \equiv \frac{\partial}{\partial x} \quad [30]$$

where the coefficient functions $u_i$ are arbitrary functions of $x$. This Lax operator describes the $p$th generalized KdV hierarchy. We consider the time evolution of the operator $L$ by an infinite set of commuting Hamiltonians:

$$\frac{\partial L}{\partial t_n} = [H_n, L], \quad n = 1, 2, \ldots \quad [31]$$

where $H_n$ is given by

$$H_n = \left(L^{n/p}\right)_+ \quad [32]$$

Here "+" denotes the non-negative part of a pseudodifferential operator and is defined as

$$A = \sum_{i=-\infty}^{n} f_i(x)D^i, \qquad A_+ = \sum_{i=0}^{n} f_i(x)D^i \quad [33]$$

We also use the notation

$$\operatorname{res} A = f_{-1}(x), \qquad A_- = \sum_{i=-\infty}^{-1} f_i(x)D^i \quad [34]$$

Note that $x$ is identified as the first time variable $t_1$, that is, $x = t_1$.

It is a basic result of the calculus of pseudodifferential operators that the above Hamiltonians satisfy the zero-curvature condition

$$\frac{\partial H_m}{\partial t_n} - \frac{\partial H_n}{\partial t_m} + [H_m, H_n] = 0 \quad [35]$$

Note that when $m$ is a multiple of $p$, $H_m$ becomes a power of $L$ and trivially commutes with $L$. Thus, the time variables $t_m$ are absent for $n \equiv 0 \bmod p$. In the simple case of $p = 2$, one has

$$L = D^2 + u(x) \quad [36]$$

and $H_3 = D^3 + (3/2)uD + (3/4)u'$. One finds

$$\frac{\partial L}{\partial t_3} = \frac{\partial u}{\partial t_3} = [H_3, L] = \frac{3}{2}u\frac{\partial u}{\partial x} + \frac{1}{4}\frac{\partial^3 u}{\partial x^3} \quad [37]$$

which is the standard KdV equation.

In the case of KP hierarchy, one starts with a pseudodifferential operator

$$Q = D + \sum_{i=1}^{\infty} a_i D^{-i} \quad [38]$$

and considers the time evolution equations

$$\frac{\partial Q}{\partial t_n} = [H_n, Q], \quad H_n = (Q^n)_+ \quad [39]$$

$p$-reduced KP hierarchy is obtained if one has

$$Q^p{}_- = 0 \quad [40]$$

By introducing a pseudodifferential operator $K$, one may bring $Q$ to the simple derivative operator $D$ as

$$Q = KDK^{-1} \quad [41]$$

$K$ has an expansion of the form

$$K = 1 + \sum_{i=1}^{\infty} a_i D^{-i} \quad [42]$$

After time evolution, the coefficient functions $u_i(x)$ of the Lax operator depend also on the variables $t_2, t_3, \ldots$ and become functions of $t \equiv \{t_1, t_2, \ldots\}$. These functions are expressed by the $\tau$-function $\tau(t)$ of the hierarchy in the following manner:

$$\operatorname{res} K = -\frac{\partial}{\partial x}\log\tau(t) \quad [43]$$

$$\operatorname{res} L^{i/p} = \frac{\partial^2}{\partial x \partial t_i}\log\tau(t) \quad [44]$$

These residues are expressed in terms of $\{u_i\}$ and their derivatives in $x$, and one can determine them in terms of the $\tau$-function.

In the case $p=2$, one has

$$[H_k, L] = 2D\,\mathrm{res}(L^{k/2}) = DR_k, \quad k = \text{odd} \qquad [45]$$

Here $\{R_k\}$ are the Gelfand–Dikii potentials

$$\begin{aligned} R_1 &= u, \qquad R_3 = \tfrac{1}{4}(3u^2 + u'') \\ R_5 &= \tfrac{1}{16}(10u^3 + 5u'^2 + 10uu'' + u'''') \\ &\vdots \end{aligned} \qquad [46]$$

and obey the recursion relation

$$DR_{k+2} = \tfrac{1}{4}\left(D^3 + 2(Du + uD)\right)R_k \qquad [47]$$

If one uses the relation [44], Gelfand–Dikii potentials are identified as

$$R_k = 2\langle \mathcal{O}_1 \mathcal{O}_k \rangle \qquad [48]$$

By setting $k=1$, we note $u=2\langle \mathcal{O}_1\mathcal{O}_1\rangle$ and find that the evolution equations [31] are all satisfied as

$$\begin{aligned} \frac{\partial L}{\partial t_k} &= \frac{\partial u}{\partial t_k} = 2\frac{\partial}{\partial t_k}\langle \mathcal{O}_1\mathcal{O}_1\rangle = 2D\langle \mathcal{O}_1\mathcal{O}_k\rangle \\ &= DR_k = [H_k, L] \end{aligned} \qquad [49]$$

Now it is possible to identify the initial condition for the Lax operator in the case of topological $(p, 1)$ gravity. By using the definition

$$\log \tau(t) = \sum_{g=0}^{\infty} \left\langle \exp \sum_n t_n \mathcal{O}_n \right\rangle_g \qquad [50]$$

one has

$$\mathrm{res}\, L^{i/p}(0) = \langle \mathcal{O}_1 \mathcal{O}_i \rangle, \quad i = 1, \ldots, p-1 \qquad [51]$$

From [29] one finds

$$\mathrm{res} L^{i/p}(0) = \mathrm{i}x \cdot \delta_{i,p-1} \qquad [52]$$

This gives the initial value of the Lax operator:

$$L(0) = D^p + px \qquad [53]$$

Thus, only the lowest term $u_0(x)=px$ is nonzero and higher coefficients all vanish at $t=0$. This is the special simplification which takes place in the topological gravity theory.

We note a relation

$$\left[\frac{1}{p}D, L(0)\right] = 1 \qquad [54]$$

This is the so-called "string equation" (at $t=0$). At nonzero values of $t$, the string equation takes the form

$$\begin{aligned} &[P, L] = 1 \\ &P = \frac{1}{p}\left( (L^{1/p})_+ - \sum_{k=p+1} kt_k (L^{(k-p)/p})_+ \right) \end{aligned} \qquad [55]$$

From [55], we see that $(p, 1)$ theory corresponds to the background value of the coupling $t_{p+1} = -1/(p+1)$. In the case of $(p, q)$ theory, background value is given by $t_{pq+1} = -1/(pq+1)$.

## Virasoro Conditions

A powerful algebraic machinery controlling the structure of 2D gravity is the so-called "Virasoro conditions." One introduces differential operators

$$L_{-1} = -\frac{\partial}{\partial t_1} + \sum_{k=p+1}^{\infty} kt_k \frac{\partial}{\partial t_{k-p}} + \frac{1}{2}\sum_{i+j=p} ijt_it_j \qquad [56]$$

$$L_0 = -\frac{\partial}{\partial t_{p+1}} + \sum_{k=1}^{\infty} kt_k \frac{\partial}{\partial t_k} + \frac{p^2-1}{24} \qquad [57]$$

By using the fact that derivative in $t_n$ brings down the operator $\mathcal{O}_n$ when acting on the $\tau$-function, it is easy to show that

$$L_{-1} \cdot \tau = 0 \qquad [58]$$

$$L_0 \cdot \tau = 0 \qquad [59]$$

reproduce the puncture [27] and dilaton equation [28], respectively. It is possible to show that the $L_{-1}$-condition, $L_{-1} \cdot \tau = 0$, is equivalent to the string equation [55].

Together with the operators $(n \geq 1)$

$$L_n = -\frac{\partial}{\partial t_{1+(n+1)p}} + \sum_{k=1}^{\infty} kt_k \frac{\partial}{\partial t_{k+np}} + \frac{1}{2}\sum_{i+j=np} \frac{\partial^2}{\partial t_i \partial t_j}$$

they generate Virasoro algebra $(L'_n \equiv (1/p)L_n)$

$$[L'_m, L'_n] = (m-n)L'_{m+n}, \quad n, m \geq -1 \qquad [60]$$

It is possible to show that the $(p, 1)$ model obeys the Virasoro conditions [6]

$$L_n \cdot \tau = 0, \quad n \geq -1 \qquad [61]$$

It is known that $(p, 1)$ models with $p > 2$ also obey constraints of $W$-algebra.

The relationship of the Virasoro conditions to KdV hierarchy is summarized as

string equation + KdV hierarchy
$\Longleftrightarrow$ Virasoro and $W$-algebra constraints

## Topological $\sigma$-Model

It is known that when the target space of a supersymmetric nonlinear $\sigma$-model is a Kahler manifold $K$, the theory acquires an enhanced $\mathcal{N}=2$

supersymmetry. Then we can twist the theory and converted into a topological field theory. This is the topological $\sigma$-model [7]. The partition function of the theory consists of a sum over world-sheet instantons, that is, holomorphic maps from the Riemann surface to the target space $K$. Due to supersymmetry, functional determinants around instantons cancel and the theory simply counts the number of holomorphic curves inside the Kahler manifold $K$. Thus, the topological $\sigma$-model has a close relationship with enumerative problems in algebraic geometry, that is, Gromov–Witten invariants and quantum cohomology theory.

When the topological $\sigma$-model is coupled to topological gravity, the BRST-invariant observables are given by $\sigma_n(\Phi_i) \equiv \sigma_n \otimes \Phi_i$, where $\Phi_i$ are cohomology classes of $K$. Correlation functions are defined as

$$\left\langle \prod_{i=1}^{s} \sigma_{n_i}(\Phi_i) \right\rangle_{g,d} = \int_{\bar{\mathcal{M}}(K;d)_{g,s}} \prod_{i=1}^{s} c_i(\mathcal{L}_i)^{n_i} \wedge e_i^*(\Phi_i) \quad [62]$$

Here $\bar{\mathcal{M}}_{g,s}(K;d)$ denotes the (stable compactification of) moduli space of degree $d$ holomorphic maps to $K$ from genus $g$ Riemann surfaces $\Sigma$. $e_i^*$ is the pullback of the evaluation map $e_i : (f; x_1, \ldots, x_s) \in \bar{\mathcal{M}}_{g,s}(K;d) \to f(x_i) \in K$ by $f$ where $f$ is a holomorphic map. Correlation functions [62] give topological (symplectic) invariants of the manifold $K$. In the cases $n_i = 0\,(i = 1, \ldots, s)$, they are known as Gromov–Witten invariants.

Equation [62] is nonvanishing if the selection rule

$$\begin{aligned} \sum_{i=1}^{s}(n_i + q_i) &= \dim \mathcal{M}_{g,s}(K;d) \\ &= c_1(K)d + (3 - \dim K)(g-1) + s \end{aligned} \quad [63]$$

is obeyed, where $q_i$ is the degree of cohomology class $\Phi_i$ and $c_1(K)$ is the first Chern class of the tangent bundle of $K$.

We see that there is a close parallel between the topological $\sigma$-model and ($p$, 1) topological gravity. If we formally set $q_i = \ell_i/p, c_1(K) = 0$, and $\dim K = (p-2)/p$, eqn [63] agrees with eqn [25]. Based on this analogy, Eguchi, Hori, and Xiong proposed the Virasoro conjecture [8], that is, generating functions of the number of holomorphic maps to arbitrary Kahler manifolds are annihilated by the Virasoro operators which are constructed by taking an analogy with those of $(p, 1)$ gravity. The Virasoro conjecture is a natural generalization of Witten's conjecture, and has recently been rigorously proved in the case of curves and projective spaces.

Excellent reviews on the theory of 2D topological gravity are given in Witten (1991) and Dijkgraaf (1991).

# Topological Knot Theory and Macroscopic Physics

**L Boi**, EHESS and LUTH, Paris, France

## Introduction to the Physical and Mathematical Contexts and Issues

One of the most exciting developments of mathematical physics in the last three decades has been the discovery of numerous intimate relationships between the topology and the geometry of knot theory and the dynamics of many domains of "classical" and "new" macroscopic physics. Indeed, complex systems of knotted and entangled filamentary structures are ubiquitous in nature and arise in such disparate contexts as electrodynamics, magnetohydrodynamics, fluid dynamics (vortex structures), superfluidity, dynamical systems, plasma physics, cosmic string theory, chaos of magnetic flows and nonlinear phenomena, turbulence, polymer physics, and molecular biology. In the recent years, mathematical tools have been developed to identify and analyze the geometrical and topological complex structures and behaviors of such systems and relate this information to energy levels and stable states.

The influence of geometry and topology on macroscopic physics has been especially fruitful in the study and comprehension of the following topics.

1. *Knots and braids in dynamical systems.* It is now clear that the chaotic behavior of the Hénon–Heiles system and other nonlinear systems is driven and controlled by topological properties. For example, it has been found that trajectories in the phase space form hyperbolic knots. The finding of knots in the Lorenz equations is another important theme closely related to the previous. By varying the Rayleigh number $r$, a parameter in the Lorenz equations, both chaotic and periodic behavior is observed. In the recent years, the knots (notably several torus knots) corresponding to the different periodic solutions of the system have been found and classified. By finding hyperbolic knots and in particular hyperbolic figure-8 knot as a solution to the Lorenz equations the suspicion that there exists a new route to chaos would be strengthened.

2. *Topological structures of electromagnetic fields.* Progress in the field of space physics, astronomy, and astrophysics over the last decade, increasingly reveals the significance of topological magnetic fields in these areas. In particular, the interaction of plasma and magnetic field can create an astonishing variety of structures, which often exhibit linked and knotted forms of magnetic flux. In these complex structures of the fields, huge amounts of magnetic energy can be stored. It is, however, a typical property of astrophysical plasmas, that the dynamics of magnetic fields is alternating between an ideal motion, where all forms of knottedness and linkage of the field are conserved (topology conservation), and a kind of disruption of the magnetic structure, the so-called magnetic reconnection. In the latter, the magnetic structure breaks up and reconnects, a process often accompanied by explosive eruptions, where enormous amounts of energy are set free. Magnetic reconnection is in close analogy to splitting of knots, which makes us confident that the global dynamics of magnetic and electromagnetic fields can be characterized with the help of such topological quantities as well.

3. *Knotting and unknotting of phase singularities.* It has long been known that dislocation lines can be closed, and recently it was shown that they can be knotted and linked. Moreover, Berry and Dennis (2001) constructed exact solutions of the Helmhotz equation representing torus knots and links; in fact, a straightforward application of this idea led to knotted and linked dislocation lines in stationary states of electrons in hydrogen. As a parameter, called $\alpha$, is varied, the topology of dislocation lines can change, leading to the creation of knots and links from initially simple dislocation loops, and the reverse process of unknotting and unlinking. The main purpose here is to elucidate the mechanism of these changes of topology. All waves are solutions of monochromatic wave equations, that is, stationary waves, and $\alpha$ is an external parameter that could be manipulated experimentally. However, $\alpha$ could represent time, and then the analogous solutions of time-dependent wave equations would describe knotting and linking events in the history of waves. The methods of Berry and Dennis are based on exact stationary solutions of wave equations, and lead to knots and links threaded by multistranded helices.

## The Origins of Topological Vortex Dynamics Ideas

The intimate relationship between three-dimensional vortex dynamics and topology was recognized as early as 1869 by W Thomson (Lord Kelvin) who tried to elaborate a theory of matter in which atoms were thought to be tiny vortex filaments embedded in an elastic-like fluid medium, called ether. Accordingly, the infinite variety of possible chemical compounds was given by the endless family of topological

combinations of linked and knotted vortices. Kelvin was inspired by the work of Gauss, who in an attempt to describe topologically the behavior of two inseparably closed linked circuits carrying electric current, found a relationship between the magnetic action induced by the currents and a pure number that depends only on the type of link, and not on the geometry: this number is the first topological invariant now known as the linking number.

In modern mathematical terms, Gauss introduced an invariant of a link consisting of two simple closed curves $\gamma_1, \gamma_2$ in $R^3$, namely the signed number of turns of one of the curves around the other, the linking coefficient $\{\gamma_1, \gamma_2\}$ of the link. His formula for this is

$$N = \{\gamma_1, \gamma_2\} = \frac{1}{4\pi}\int_{\gamma_1}\int_{\gamma_2} ([\mathrm{d}\gamma_1(t), \mathrm{d}\gamma_2(t)], \gamma_1 - \gamma_2)/ |\gamma_1(t) - \gamma_2(t)|^3 \qquad [1]$$

where [ , ] denotes the vector (or cross) product of vectors in $R^3$ and ( , ) the Euclidean scalar product. Thus, this integral always has an integer value $N$. If we take one of the curves to be the $z$-axis in $R^3$ and the other to lie in the $(x, y)$-plane, then the formula [1] gives the net number of turns of the plane curve around the $z$-axis. It is interesting to note that the linking coefficient [1] may be zero even though the curves are nontrivially linked. Thus, its having nonzero value represents only a sufficient condition for nontrivial linkage of the loops. This last consideration leads naturally to the mathematical concepts of knots and links whose most striking properties have been investigated in our introductory article (*see* Mathematical Knot Theory).

The other source of inspiration of Kelvin's theory of matter was the Helmholtz's laws of vortex motion, which state that in an ideal fluid (where there is no viscosity) vortex lives forever: two closed vortex rings, once linked, will always be linked. The classical results obtained by Helmholtz are basic to understanding the dynamics of Euler motions. The vorticity of a velocity field is its curl and is denoted $\omega_t(z) := \mathrm{curl}(X(z,t))$. In two dimensions, the vorticity is a real-valued function and $\omega_t = -\Delta\Psi$, where $\Psi$ is the stream function of $X(z, t)$. Recall that the push-forward of a scalar field (0-form) $s$ under a diffeomorphism $f$ is $f_* s = s \circ f^{-1}$. These results, in modern terms, can be stated as follows:

**Theorem** (Helmholtz–Kelvin). *An incompressible fluid motion* $(M_t, \phi_t)$ *with velocity field* $X$ *and vorticity* $\omega_t$ *is Euler if and only if its vorticity is passively transported,*

$$\phi_{t^*}\omega_0 = \omega_t$$

*and circulation around all smooth simple closed curves C are preserved under the flow,*

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{\phi_t(C)} X \cdot \mathrm{d}\boldsymbol{r} = 0$$

One knows that in three dimensions, the Helmholtz–Kelvin theorem says that the vorticity (now a vector field) is transported. Thus, with generic initial vorticity a 3D time-periodic Euler fluid motion preserves a nontrivial vector field. One very interesting question that remains to be elucidated is the following: are there any chaotic, time-periodic Euler flows with stationary boundaries?

## The Connection between Topological and Numerical Invariants of Knots and the Physical Helicity of Vector Fields

The writhing number of a curve in Euclidean three-dimensional space is the standard measure of the extent to which the curve wraps and coils around itself; it has proved its importance for electrodynamics and fluid mechanics in the study of the knotted structures of magnetic vortices and dynamics flows, and for molecular biologists in the study of knotted duplex DNA and the enzymes which affect it. The helicity of a divergenceless vector field defined on a domain in Euclidean 3-space, introduced by Woltjer in 1958 in an astrophysical context and coined by Moffat in 1969 in the study of its topological meaning, is the standard measure of the extent to which the field lines wrap and coil around one another; it plays important roles in fluid mechanics, magnetohydrodynamics, and plasma physics. The "Biot–Savart operator" associates with each current distribution on a given domain the restriction of its magnetic field to the domain. When the domain is simply connected, the divergence-free fields which are tangent to the boundary and which minimize energy for given helicity provide models for stable force-free magnetic fields in space and laboratory plasmas; these fields appear mathematically as the extreme eigenfields for an appropriate modification of the Biot–Savart operator. Information about these fields can be converted into bounds on the writhing number of a given piece of DNA.

Recent researches (Cantarella *et al.* 2001) obtained rough upper bounds for the writhing number of a knot or link in terms of its length and thickness, and rough upper bounds for the helicity of a vector field in terms of its energy and the geometry of its domain. It was also showed that in the case of classical electrodynamics in vacuum, the

natural helicity invariant, called the electromagnetic helicity, has an important particle meaning: the difference between the numbers of right- and left-handed photons. Recently, a topological model of classical electrodynamics has been proposed in which the helicity is topologically quantized, in a relation that connects the wave and particle aspects of the fields (Trueba and Rañada 2000).

Consider two disjoint closed space curves, $C$ and $C'$, and the Gauss' integral formula for their linking number

$$\mathrm{Lk}(C, C') = \frac{1}{4\pi}\int_{C\times C'} (\mathrm{d}x/\mathrm{d}s \times \mathrm{d}y/\mathrm{d}t) \times x - y/|x-y|\,\mathrm{d}s\,\mathrm{d}t \qquad [2]$$

The curves $C$ and $C'$ are assumed to be smooth and to be parametrized by arclength. Now the question is to know what happens to this integral when the two space curves $C$ and $C'$ come together and coalesce as one curve $C$. At first glance, the integrand looks like it might blow up along the diagonal of $C \times C'$, but a careful calculation shows that in fact the integrand approaches zero on the diagonal, and so the integral converges. Its value is the writhing number $\mathrm{Wr}(C)$ of $C$ defined above:

$$\mathrm{Wr}(C) = \frac{1}{4\pi}\int_{C\times C} (\mathrm{d}x/\mathrm{d}s \times \mathrm{d}y/\mathrm{d}t) \times x - y/|x-y|\,\mathrm{d}s\,\mathrm{d}t \qquad [3]$$

Here is the very useful result, due to Fuller (1978). The writhing number of a knot $K$ is the average linking number of $K$ with its slight perturbations in every possible direction:

$$\mathrm{Wr}(K) = \frac{1}{4\pi}\int_{W\in S^2} \mathrm{Lk}(K, K+\varepsilon W)\,\mathrm{d(area)} \qquad [4]$$

This is helpful for getting a quick approximation to the writhing number of a knot which almost lies in a plane; in the example of a trefoil knot, $\mathrm{Wr}(K) \approx 3$.

Here, a very important result must be recalled, a "bridge theorem," proved by Berger and Field (1984), see also Ricca and Moffatt (1992), which connects helicity of vector fields to writhing of knots and links, and which can be used to convert upper bounds on helicity into upper bounds on writhing.

**Proposition** (Berger and Field). *Let $K$ be a smooth knot or link in 3-space and $\Omega = N(K, R)$ a tubular neighborhood of radius $R$ about $K$. Let $V$ be a vector field defined in $\Omega$, orthogonal to the cross-sectional disks, with length depending only on distance from $K$. This makes $V$ divergence-free and tangent to the boundary of $\Omega$. Then the writhing number $\mathrm{Wr}(K)$ of $K$ and the helicity $H(V)$ of the vector field $V$ are related by the formula*

$$H(V) = \mathrm{Flux}(V)^2\,\mathrm{Wr}(K)$$

In the formula, $\mathrm{Flux}(V)$ denotes the flux of $V$ through any of the cross-sectional disks $D$,

$$\mathrm{Flux}(V) = \int_D V\cdot n\,\mathrm{d(area)}$$

where $n$ is a unit normal vector field to $D$.

A key feature of this formula is that the helicity of $V$ depends on the writhing number of $K$, but not any further on its geometry; in particular, such quantities as the curvature and torsion of $K$ do not enter into the formula. Berger and Field actually showed that the helicity $H(V)$ is a sum of two terms: a "kink helicity," which is given by the right-hand side of the above formula, and a "twist helicity," which is easily shown in our case to be zero. Their proof assumes $K$ is a knot, but it is straightforward to extend it to cover links.

Let $\Omega$ be a compact domain in 3-space with smooth boundary $\partial\Omega$; we allow both $\Omega$ and $\partial\Omega$ to be disconnected. Let $V$ be a smooth vector field (where "smooth" means of class $C^\infty$), defined on the domain $\Omega$. The helicity $H(V)$ of the vector field $V$ is defined by the formula

$$H(V) = \frac{1}{4\pi}\int_{\Omega\times\Omega} V(x)\times V(y)\cdot x - y/|x-y|^3 \times \mathrm{d(vol)}_x\,\mathrm{d(vol)}_y \qquad [5]$$

Clearly, helicity for vector fields is the analog of writhing number for knots. Both formulas are variants of Gauss' integral formula for the linking number of two disjoint closed space curves.

In order to understand this formula for helicity, think of $V$ as a distribution of electric current, and use the Biot–Savart law of electrodynamics to compute its magnetic field:

$$\mathrm{BS}(V)(y) = \frac{1}{4\pi}\int_\Omega V(x)\times y - x/|y-x|^3\,\mathrm{d(vol)}_x \qquad [6]$$

Then the helicity of $V$ can be expressed as an integrated dot product of $V$ with its magnetic field $\mathrm{BS}(V)$:

$$\begin{aligned}H(V) &= \frac{1}{4\pi}\int_{\Omega\times\Omega} V(x)\times V(y)\cdot x - y/|y-x|^3 \times \mathrm{d(vol)}_x\,\mathrm{d(vol)}_y\\ &= \int_\Omega V(g)\cdot\left[\frac{1}{4\pi}\int_\Omega V(x)\times y - x/|x-y|^3\,\mathrm{d(vol)}_x\right] \times \mathrm{d(vol)}_y\\ &= \int_\Omega V(y)\cdot \mathrm{BS}(V)(y)\,\mathrm{d(vol)}_y\\ &= \int_\Omega V\cdot\mathrm{BS}(V)\,\mathrm{d(vol)}\end{aligned}$$

Cantarella *et al.* (2001) found two very interesting results.

**Theorem 1** *Let K be a smooth knot or link in 3-space, with length L and with an embedded tubular neighborhood of radius R. Then the writhing number* Wr(*K*) *of K is bounded by*

$$|\mathrm{Wr}(K)| < 1/4(L/R)^{4/3}$$

For the proof, see Cantarella *et al.* (2001).

**Theorem 2** *The helicity of a unit vector field V defined on the compact domain Ω is bounded by*

$$|H(V)| < 1/2\,\mathrm{vol}(\Omega)^{4/3}$$

Let us now give a brief overview of the methods used to find sharp upper bounds for the helicity of vector fields defined on a given domain Ω in 3-space. As usual, Ω will denote a compact domain with smooth boundary in 3-space. Let $K(\Omega)$ denotes the set of all smooth divergence-free vector fields defined on Ω and tangent to its boundary. These vector fields, sometimes called "fluid knots," are prominent for several reasons: (1) They are natural vector fields to study in a "fluid dynamics approach" to geometric knot theory. (2) They correspond to incompressible fluid flows inside a fixed container. (3) They are vector fields most often studied in plasma physics. (4) For given energy (equivalently minimize energy for given helicity), they provide models for stable force-free magnetic fields in gaseous nebulaes and laboratory plasmas. (5) The search for these helicity-maximizing fields can be converted to the task of solving a system of partial differential equations. (6) The fluid knots can reveal some fundamental and still unknown mechanisms, which characterize the phenomenon of phase transition, and in particular the transition from chaotic (unstable) phases and behaviors of matter to ordered (stable) ones.

## Knots and Fluid Mechanics (Vortex Lines, Magnetic Helicity, and Turbulence)

The Kelvin's theory of explaining atoms as knotted vortices in fluid ether was seminal in the development of topological fluid mechanics. The recent revival (starting in the 1970s) is mainly due to the work of Moffat, on topological interpretation of helicity, and Arnol'd, on asymptotic linking number of space-filling curves. Modern developments have been influenced by recent progress in the theory of knots and links.

### Influence of Geometry and Topology on Fluid Flows

Ideal topological fluid mechanics deals essentially with the study of fluid structures that are continuously deformed from one configuration to another by ambient isotopies. Since the fluid flow map $\varphi$ is both continuous and invertible, then $\varphi_{t_1}(K)$ and $\varphi_{t_2}(K)$ generate isotopies of a fluid structure $K$ (e.g., a vortex filament) for any $\{t_1, t_2\} \in I$. Isotopic flows generate equivalence classes of (linked and knotted) fluid structures. In the case of (vortex or magnetic) fluid flux tubes, fluid actions induce continuous deformations in $D$. One of the simplest deformations is local stretching of the tube. From a mathematical viewpoint, this deformation corresponds to a time-dependent, continuous reparametrization of the tube centerline. This reparametrization (via homotopy classes) generates ambient isotopies of the flux tube, with a continuous deformation of the integral curves.

Moreover, in the context of the Euler equations, the Reidemeister moves (or isotopic plane deformations), whose changes conserves the knot topology, are performed quite naturally by the action of local flows on flux tube strands. If the fluid in $(D - K)$ is irrotational, then these fluid flows (with velocity $\boldsymbol{u}$) must satisfy the Dirichlet problem for the Laplacian of the stream function $\varphi$, that is,

$$\begin{aligned} \boldsymbol{u} &= \nabla\varphi \quad \text{in } (D-K) \\ \nabla^2\varphi &= 0 \end{aligned} \qquad [7]$$

with normal component of the velocity to the tube boundary $\boldsymbol{u}_\perp$ given. Equations [7] admit a unique solution in terms of local flows, and these flows are interpretable in terms of Reidemeister's moves performed on the tube strands. Note that boundary conditions prescribe only $\boldsymbol{u}_\perp$, whereas no condition is imposed on the tangential component of the velocity. This is consistent with the fact that tangential effects do not alter the topology of the physical knot (or link). The three type of Reidemeister's moves are therefore performed by local fluid flows, which are solutions to [7], up to arbitrary tangential actions.

### Knotted and Linked Tubes of Magnetic Flux

Let $\boldsymbol{T}$ be the standard solid torus in $\boldsymbol{R}^3$ given by

$$((2 + \varepsilon\cos\theta)\cos\varphi,\ (2 + \varepsilon\cos\theta)\sin\varphi,\ \varepsilon\sin\theta)) \qquad [8]$$

where $0 \le \theta, \varphi < 2\pi$, and $0 \le \varepsilon < 1$. For relatively prime integers $p$ and $q$, let $F_{p,q}$ denote the foliation

of $\boldsymbol{T}$ by the curves $\gamma_{\varepsilon,\theta}$ (where $0 \leq \varepsilon \leq 1$ and $0 \leq \theta < 2\pi$) given by

$$\gamma_{\varepsilon,\theta}(s) = (2 + \varepsilon\cos(\theta + qs))\cos(ps), \\ (2 + \varepsilon\cos(\theta + qs))\sin(ps), \varepsilon\sin(\theta + qs) \qquad [9]$$

where $0 \leq s < 2\pi$.

**Definition** A magnetic tubular link (or magnetic link) is a smooth immersion into $\boldsymbol{R}^3$ of finitely many disjoint standard solid tori $\cup_{i=1}^{n}\boldsymbol{T}_i$

$$L : \cup_{i=1}^{n}\boldsymbol{T}_i \to \boldsymbol{R}^3$$

and a smooth magnetic field $\boldsymbol{B}$ on $\boldsymbol{R}^3$ such that

(i) $L$ is an imbedding when restricted to the interior of $\cup_{i=1}^{n}\boldsymbol{T}_i$,
(ii) the bounding surface of $\cup_i L(\boldsymbol{T}_i)$, that is, $\cup_i L(\partial\boldsymbol{T}_i)$ is a magnetic surface, and
(iii) for each component $L\boldsymbol{T}_i$, there exist relatively prime nonzero integers $p_i$ and $q_i$ such that $L$ maps the foliation $F_{p_i,q_i}$ of $\boldsymbol{T}_i$ onto the integral curves of $\boldsymbol{B}$ in $L\boldsymbol{T}_i$.

**Remark** Thus, for every fixed $i$ and $j$, the linking number between an arbitrary field line in $L\boldsymbol{T}_i$ and an arbitrary field line in $L\boldsymbol{T}_j$ is the same regardless of which integral curves are chosen from $L\boldsymbol{T}_i$ and $L\boldsymbol{T}_j$, respectively. This is true even when $i = j$.

It follows that a magnetic link $\cup_i L\boldsymbol{T}_i$ remains a magnetic link under the action of the fluid flow, that is, $\cup_i g_t L\boldsymbol{T}_i$ is a magnetic link for $t \geq 0$.

Keeping that the magnetic field $\boldsymbol{B}$ is frozen in the fluid, we can now find and study those properties of magnetic links that are invariant under the action of fluid flow. One obvious invariant is the volume $V_i$ of each flux tube $g_t L\boldsymbol{T}_i$, that is,

$$V_i = \mathrm{Vol}(L\boldsymbol{T}_i) = \mathrm{Vol}(g_t L\boldsymbol{T}_i) = \iiint_{g_t L T_i} \mathrm{d(vol)} \qquad [10]$$

which remains unchanged because of incompressibility.

Another invariant of fluid flow is defined as follows:

**Definition** Let $L$ be a magnetic link. For each solid torus $\boldsymbol{T}_i$, choose a meridional disk $D_i$. The magnetic flux $\Phi_i = \Phi(L\boldsymbol{T}_i)$ in the $i$th component is the surface integral defined as

$$\Phi_i = \Phi(L\boldsymbol{T}_i) : \iint_{LD_i} \boldsymbol{B}\cdot\boldsymbol{U}\,\mathrm{d(area)}$$

where $\boldsymbol{U}$ denotes the normal to the surface $LD_i$ pointing in the positive direction induced by the $\boldsymbol{B}$ field.

It can be shown that $\Phi_i$ is independent of the chosen meridional disk. It also can be shown that each $\Phi_i$ is a fluid flow invariant, that is,

$$\Phi_i(g_t L\boldsymbol{T}_i) = \iint_{g_t LD_i} \boldsymbol{B}\cdot\boldsymbol{U}\,\mathrm{d(area)} \qquad [11]$$

is independent of $t$.

One more fluid invariant that will play a central role in the energy minimization of magnetic links is given by the following definition.

**Definition** The helicity of a magnetic link $L$ is defined as

$$H(L) = \iiint_{\cup_i LT_i} \boldsymbol{A}\cdot\boldsymbol{B}\,\mathrm{d(vol)}$$

The term helicity was first introduced in a fluid context by Moffat, and it was previously used in particle physics for the scalar product of the momentum and spin of a particle. In another connection, note that the helicity $H(L)$ is the same as the Chern–Simons action:

$$H(L) = \int \boldsymbol{A}\wedge \mathrm{d}\boldsymbol{A} \\ = \int \mathrm{tr}(\boldsymbol{A}\wedge \mathrm{d}\boldsymbol{A} + \tfrac{2}{3}\boldsymbol{A}\wedge\boldsymbol{A}\wedge\boldsymbol{A}) \qquad [12]$$

where $\boldsymbol{A}$ now denotes the magnetic vector potential as a 1-form.

It can be shown that $H(L)$ is gauge invariant, and hence well defined.

**Theorem** (Moffat). *The helicity is invariant under fluid flow, that is,*

$$\frac{\mathrm{d}}{\mathrm{d}t}H(g_t L) = 0$$

Arnol'd (1998) defines the helicity in a more abstract setting and shows that it is invariant under the group $S(\mathrm{Diff})$ of volume-preserving diffeomorphisms.

The following theorem summarizes the many results due to Moffat, Ricca, Berger, Lomonaco, Hornig, Kauffman, and others, relating the helicity of magnetic links to linking and to magnetic flux.

**Theorem** *Let $L$ be a magnetic link. Then*

$$H(L) = \sum_{1\leq i\leq n} \Phi^2{}_i \mathrm{SL}_{F_i} + 2\sum_{1\leq i<j\leq n} \Phi_i\Phi_j \mathrm{LK}_{ij}$$

*where $\mathrm{SL}_{F_i}$ denotes the self-linking number of the axis curve of the tube $L\boldsymbol{T}_i$ with respect to the framing $F_i$ induced by the integral curves of the magnetic field $\boldsymbol{B}$ within $L\boldsymbol{T}_i$, and $\mathrm{LK}_{ij}$ denotes the linking number between any integral curve of*

*the magnetic field* $\boldsymbol{B}$ *in* $LT_i$ *with any integral curve of the magnetic field* $\boldsymbol{B}$ *in* $LT_j$.

**Remark** In fact, $\mathrm{SL}_{F_i}$ is the same as the linking number between any two integral curves of the magnetic field $\boldsymbol{B}$ within the tube $LT_i$.

Thus, as many authors have showed, the helicity does reflect the topology and the geometry of the magnetic lines of force within a magnetic link. If, for example, $L$ has only one component, that is, $L$ is a magnetic knot, then

$$H(L) = \Phi^2 \mathrm{SL}_F(C) \qquad [13]$$

where $\mathrm{SL}_F(C)$ is the self-linking number of the axis curve $C$ of the knotted tube with respect to the framing $F$ induced by the integral curves of the magnetic field $\boldsymbol{B}$ within the magnetic knot. If, for example, the tube is knotted in the form of a trefoil and if the magnetic lines of force appear to be parallel to the axis curve when the trefoil is placed on a plane flat surface, then $\mathrm{SL} = \pm 3$ and

$$H = \pm 3\Phi^2 \qquad [14]$$

On the other hand, if for example, the magnetic lines of force induce the trivial framing in each component, then

$$H(L) = 2 \sum_{1 \le i < j \le n} \Phi_i \Phi_j LK_{ij} \qquad [15]$$

Thus, if $L$ is a magnetic two-component Hopf link with no twisting of the integral curves of the magnetic field within the components of $L$, then

$$H(L) = \pm 2\Phi_1 \Phi_2 \qquad [16]$$

because the self-linking number based on the $\boldsymbol{B}$-field framing is zero for each component, and the linking number between the two components is ±1.

### Energy of Magnetic Knots and Links

Let us conclude this section with the definition of the energy of a magnetic link.

**Definition** The magnetic energy $E_{\mathrm{M}}(L)$ of a magnetic link $L$ is defined by the classical formula

$$E_{\mathrm{M}}(L) = \frac{1}{8\pi} \iiint_{\cup_i LT_i} |\mathbf{B}|^2 \, \mathrm{d(vol)} \ \text{(Gaussian units)}$$

Although the energy $E_{\mathrm{M}}$ is not flow invariant, it will play a central role in magnetic relaxation of knots and minimum energy magnetic links.

Consider a magnetic link $L$ in a perfectly conducting, incompressible, viscous fluid. As a result of dissipative frictional fluid forces, the magnetic energy $E_{\mathrm{M}}(g_t L)$ of $g_t L$ will decrease with time $t$. In losing energy, the magnetic lines of force will contract. On the other hand, since this is a volume-preserving process, the cross sections of the flux tubes of $g_t L$ will at the same time expand. These changes of topology occur while the flux $\Phi$, volume $V$, and helicity of $g_t L$ will remain the same. In other words, knotted magnetic flux tubes left free to evolve in such a fluid will do so by conserving their magnetic flux $\Phi$ and volume $V$, but converting their magnetic energy into kinetic energy, which in turn dissipates by internal friction. Magnetic links and knots evolve from high to low magnetic energy levels, conserving topology; and because of the induced shortening of field lines under conservation of volume, they become fatter and fatter, with an increase of the average tube cross section.

This process cannot continue indefinitely. Eventually, the magnetic flux tubes of $g_t L$ must make contact with each other. In other words, the topology of the magnetic link $g_t L$, as expressed in knotting and linking, creates a barrier to the full dissipation of the magnetic link's energy, that is, $E_{\mathrm{M}}(g_t L)$ has a positive lower bound that results from the topology of $g_t L$. That means, in other words, that relaxation is obstructed by the knottedness and entanglement of the field lines, and a minimum magnetic energy is reached. Thus, the magnetic link will reach a nontrivial stable and invariant energy state, much as Kelvin conjectured his atomic vortices would.

Various estimates of magnetomechanical energy in terms of topological quantities have been put forward in recent years (see Freedmann and He (1994)). These relations give lower bounds for the energy levels attainable by knot or link types by taking into account the effects that linking numbers and number of crossings have on the energy of the relaxed state. These bounds are expressed by relationship of the kind

$$E_{\min} \ge \phi(C_{\min}, \Phi, V, N) \qquad [17]$$

where $E_{\min}$ is the equilibrium energy and $\phi$ gives the relationship between physical quantities – such as total flux $\Phi$, number of tubes $N$, magnetic volume $V$ – and topology, given here by the minimal possible number of crossing $C_{\min}$. These relations offer numerous advantages due to the explicit dependence on qualitative properties of the flow field. A simple example is provided by the analysis of three braids, which shows that magnetic energy grows quadratically in time due to random braiding. This means that the least possible amount of magnetic energy that can be attained by the physical knot or link is determined purely by its topology. If topological information sets the levels of minimum energy accessible to the knot or link, geometric properties

may also influence the relaxation process. Considerations of helicity and linking numbers, for example, demonstrate that internal rearrangement of magnetic field geometry leads to a spectrum of different asymptotic endstates with the same topology. Moreover, magnetic knots have a natural tendency to get rid of excessive torsion of field lines and *S*-shaped tube geometries, and this may influence the relaxation process.

Since the helicity $H(g_t L)$ is both an invariant of fluid flow and an expression of the magnetic link $g_t L$'s topology, the following theorem, first stated by Moffat, is a mathematical expression of this topological bounds.

**Theorem** *Let L be a magnetic link. Then*

$$E_{\mathrm{M}}(L) \geq q_0 |H(L)|$$

*where $q_0$ is a nonzero constant that is independent of the magnetic link.*

Freedman and He (1991) obtain more subtle and tighter topological bounds on the minimum energy of magnetic links. For example, for a magnetic knot $K$, they prove that

$$E_{\mathrm{M}}(K) \geq \frac{1}{4\pi^{5/4}} \frac{\Phi(K)^{3/2}\ \mathrm{ac}(K)^{3/4}}{V(K)^{1/3}} \geq \frac{1}{4\pi^{5/4}} \frac{\Phi(K)^{3/2}(2g(K)-1)}{V(K)^{1/3}} \quad \text{(Gaussian units)} \qquad [18]$$

where $V(K)$ denotes the volume of the magnetic knot $K$, $\Phi(K)$ denotes the flux in $K$, $\mathrm{ac}(K)$ is the asymptotic crossing number, and $g(K)$ is the genus of the knot $K$. Freedman and He conjecture that $\mathrm{ac}(K) = \mathrm{c}(K)$, where $\mathrm{c}(K)$ is the crossing number, that is, the minimum number of crossings among all plane diagrams representing the knot $K$. Besides, Moffat (1990) suggests that the minimum energy spectrum of a magnetic knot can be used to construct new knot invariants.

## Topological Changes, Dissipation, and Reconnection in Fluid Patterns

As we saw above, topological changes do occur when dissipative effects become predominant over the coherency of structures. When this happens, there is a dramatic change of fluid patterns, often on small timescales compared to evolution. The change occurs through the formation and disappearance of physical reconnections in the fluid pattern. In real fluids, for example, vortex and magnetic tubes do interact and reconnect freely. From a dynamical system viewpoint, reconnections take place when the vector field lines (streamlines, vortex lines, or magnetic lines) cross each other. If two field lines meet, the point of crossing is a true nodal point, like a bifurcation in a path. Dissipative effects allow the reconnection to proceed through such points.

In dissipative fluids, mathematical and physical properties are no longer conserved, and during the process we lose part of the original information. However, some of the invariants are rather robust and may only degrade slowly. One of them is magnetic helicity, the magnetic analog of the kinetic helicity. Its dissipation during reconnection can be modest; in particular, if the reconnection timescale is small compared to classical dissipation times, then helicity loss will be negligible. The robustness of magnetic helicity plays a central role in fusion plasma physics and in many astrophysical contexts. On the other hand, large changes in kinetic helicity are intimately related to qualitative changes in the topology of vortex flows.

Under Euler's equations, the helicity of a vortex tube of vorticity $\omega$ and velocity $\boldsymbol{u}$ is defined by $H = \int \boldsymbol{u} \cdot \omega \, \mathrm{d}V$. The integral is taken over the tube volume $V$ occupied by $\omega$. Now, for $n$ knotted and linked vortex tubes, each of (constant) strength (total vorticity) $\Phi_i (1 \leq i \leq N)$, the helicity of the whole system can be expressed in terms of linking numbers $\mathrm{Lk}_{ij}$ as

$$H = \sum_{ij} \mathrm{Lk}_{ij} \Phi_i \Phi_j \cdot \mathrm{Lk}_{ij}$$

which is equal to $\mathrm{Lk}_{ji}$; this is a topological invariant whose value does not change under continuous deformation of the fluid structure. Since helicity and flux-tube strength are measurable conserved quantities, the above equation provides useful information about the topology of the flow field and flow structures. In addition, by direct measurements of helicity and application of conservation of topology, one can estimate average geometric quantities, such as the mean twist of field lines, and their contribution to the total energy.

## Brief Conclusion

In this article, we have made an attempt to indicate how "classical" field theories, which have been successfully used to describe physics of fundamental structures and forces of nature, can also be used to study geometry and topology of low-dimensional manifolds. These developments not only provide new insights into old problems of topology of these manifolds but also have been responsible for profoundly interesting new mathematics (fluid mechanics, dynamical flows, and polymer biophysics

are maybe the most significant examples in the last years). In particular fluid dynamics, a topological macroscopic field theory, provides a powerful framework for modern theory of knots and links in 3-manifolds. Moreover, as we saw here, it provides a physical interpretation of the link, self-linking, and writhing number of knots and links. The present article was essentially aimed to illustrate such a relationship. Thus, the most fundamental result we reported here is the relation (formula) connecting the helicity of vector (magnetic) fields to the writhing number of knots: $H(V) = \text{Flux}(V)^2\ \text{Wr}(K)$. So, writhing number for knots is the analog of helicity for vector fields. Both expressions of these invariants are variants of the (Gaussian) integral formula for the linking number of two disjoint closed space curves. Further investigations of these invariants and their mathematical properties might throw new light on the interfaces between many different areas of macroscopic and quantum physics.

# Topological Quantum Field Theory: Overview

**J M F Labastida**, CSIC, Madrid, Spain
**C Lozano**, INTA, Torrejón de Ardoz, Spain

## Introduction

Topological quantum field theory (TQFT) constitutes one of the most successful fields of mathematical physics since it originated in the 1980s. It possesses an inherent property which makes it unique: TQFT provides predictions in mathematics which open new fields of research. A well-known example is the prediction of Seiberg–Witten invariants as building blocks of Donaldson invariants. However, there are others such as the recent proposal for the coefficients of the HOMFLY polynomial invariants for knots as quantities related to enumerative geometry. These developments have drawn the attention of mathematicians and physicists into TQFT since the 1980s, a very fruitful period in which both communities have benefited from each other.

Topology has always been present in mathematical physics, in particular when dealing with aspects of

quantum physics. Global effects play an important role in quantum-mechanical models and topology becomes an essential ingredient in their description. TQFT itself appeared in the winter of 1987 after Witten's work (Witten 1988a) on Donaldson theory (Donaldson 1990), but a series of papers during the 1980s which dealt with topological aspects of field and string theory anticipated its existence. Two of these correspond to Witten's works on supersymmetric quantum mechanics and supersymmetric sigma models (Witten 1982) that led to a generalization of Morse theory. This generalization was considered by Floer (1987) in a new context that constituted the key element in Witten's construction of TQFT. These developments were certainly influenced by Atiyah (1988). TQFT was born as a result of the interplay between physics and mathematics. This has been a constant feature all along its development.

Soon after the formulation of the TQFT addressing Donaldson theory, now known as Donaldson–Witten theory, Witten formulated a new TQFT which focuses on knot invariants such as the Jones polynomial and its generalizations (Jones 1985). Witten (1989) constructed Chern–Simons gauge theory and proved its relation to the theory of knot and link invariants. This theory possesses different features than Donaldson–Witten theory, and in fact it turns out that these two theories fall into two different general types of TQFTs as will be explained in the following section. Anyhow, despite their formal differences, both Donaldson–Witten and Chern–Simons gauge theory emerged as a novel way to express topological invariants in terms of quantum field theory quantities as well as to generalize their previous formulation. But there was much more to them than it seemed in their beginnings. Once these topological invariants were formulated in field theory language, one had a huge machinery to study them from different points of view. Theoretical physicists have developed many useful tools to study quantum field theory. The use of these tools led to new frameworks for these topological invariants.

In this overview we are going to provide the basics of TQFT and briefly describe two examples – Donaldson–Witten theory and Chern–Simons gauge theory – to explain how the general features are implemented. Some excellent reviews on the subject (Birmingham *et al.* 1991, Cordes *et al.* 1996, Labastida and Mariño 2004) are available. The organization of this work is as follows. In the following section we present a general introduction to TQFT from a functional integral point of view. Next, we touch upon the twisting of extended supersymmetry as a general constructive approach to TQFT. This is followed by a section on Donaldson–Witten theory where we discuss the computation of its observables from a perturbative approach, showing their relation to the Donaldson invariants. Next, we introduce Chern–Simons gauge theory as a theory of knot and link invariants. The penultimate section deals with advanced developments in TQFT. Finally, we end up with some concluding remarks.

## Topological Quantum Field Theory

We will start our overview by presenting the most general structure of a TQFT from a functional integral point of view which, though not rigorously defined, is the approach that has led to the most important developments. As in conventional quantum field theory, axiomatic approaches to TQFT do exist, but we will not follow that route here.

Let us consider an $n$-dimensional Riemannian manifold $X$ endowed with a metric $g_{\mu\nu}$ and a quantum field theory on it. We will say that this theory is "topological" if there exist operators in the theory such that their correlation functions do not depend on the metric. If we denote these operators by $\mathcal{O}_i$ (where $i$ is a generic label), then

$$\frac{\delta}{\delta g_{\mu\nu}}\langle \mathcal{O}_{i_1}\cdots\mathcal{O}_{i_n}\rangle = 0 \qquad [1]$$

where $\langle\cdots\rangle$ denotes a vacuum expectation value. The operators that satisfy this equation are called "topological observables."

The simplest way to achieve metric independence is to consider a theory whose action and operators do not depend on the metric. In this situation, if no anomalous metric dependence is generated upon quantization, the correlation functions of these operators satisfy [1] and lead to topological invariants on $X$. Theories of this sort are collectively referred to as Schwarz-type TQFTs, and well-known examples are Chern–Simons gauge theory and BF theories. However, Schwarz-type theories are too restrictive. One would like to have a theory satisfying property [1] with a weaker condition on the action. This can be achieved with the help of a symmetry. The resulting TQFTs are called of Witten or cohomological type, the main examples being Donaldson–Witten theory and topological sigma models (Witten 1988b).

For TQFTs of Witten type, the action may depend on the metric. However, the theory has an underlying scalar symmetry $\delta$ acting on the fields $\phi_i$. Since $\delta$ is a symmetry, the action of the theory satisfies $\delta S(\phi_i) = 0$. In these theories, metric independence of the correlation functions is achieved as follows. Let $T_{\mu\nu} = (\delta/\delta g^{\mu\nu})S(\phi_i)$ be the energy–momentum tensor of

the theory. It turns out that the energy–momentum tensor is $\delta$-exact:

$$T_{\mu\nu} = -\mathrm{i}\delta G_{\mu\nu} \qquad [2]$$

$G_{\mu\nu}$ being some tensor. Indeed, if [2] is satisfied, it follows that for any set of operators $\mathcal{O}_i$ which are $\delta$-invariant,

$$\begin{aligned}\frac{\delta}{\delta g^{\mu\nu}}\langle \mathcal{O}_{i_1}\mathcal{O}_{i_2}\cdots\mathcal{O}_{i_n}\rangle &= \langle \mathcal{O}_{i_1}\mathcal{O}_{i_2}\cdots\mathcal{O}_{i_n}T_{\mu\nu}\rangle \\ &= -\mathrm{i}\langle \mathcal{O}_{i_1}\mathcal{O}_{i_2}\cdots\mathcal{O}_{i_n}\delta G_{\mu\nu}\rangle \\ &= \pm\mathrm{i}\langle \delta(\mathcal{O}_{i_1}\mathcal{O}_{i_2}\cdots\mathcal{O}_{i_n}G_{\mu\nu})\rangle \\ &= 0 \end{aligned} \qquad [3]$$

In this computation we have assumed that the symmetry $\delta$ is not anomalous and that there are no contributions coming from boundary terms since we have integrated by parts in field space. This is not always the case and in fact the situations in which one of these two properties fails lead to rich phenomena. In those cases, for example, in Donaldson–Witten theory on manifolds with $b_2^+ = 1$, the correlation functions fail to be topological invariants in a controlled manner which unveils many interesting properties.

We will now describe Witten-type theories in a general context. The general structure of Schwarz-type theories is much simpler and will be illustrated in the example presented below. In Witten-type theories the observables are the $\delta$-invariant operators. It is simple to prove that $\delta$-exact operators decouple from the theory. Indeed, if $\mathcal{O}_a$ is $\delta$-exact, $\mathcal{O}_a = \delta\hat{\mathcal{O}}_a$, then

$$\begin{aligned}\langle \mathcal{O}_a\mathcal{O}_{i_1}\mathcal{O}_{i_2}\cdots\mathcal{O}_{i_n}\rangle &= \langle \delta\hat{\mathcal{O}}_a\mathcal{O}_{i_1}\mathcal{O}_{i_2}\cdots\mathcal{O}_{i_n}\rangle \\ &= \langle \delta(\hat{\mathcal{O}}_a\mathcal{O}_{i_1}\mathcal{O}_{i_2}\cdots\mathcal{O}_{i_n})\rangle = 0\end{aligned} \qquad [4]$$

Thus, one can restrict the set of observables to the cohomology of $\delta$:

$$\mathcal{O} \in \frac{\operatorname{Ker}\delta}{\operatorname{Im}\delta} \qquad [5]$$

There is no reason *a priori* why the $\delta$-symmetry should be a scalar Grassmannian symmetry, but in all known models of Witten-type TQFTs this turns out to be the case. Thus, these theories violate the spin-statistics theorem. In all these models the algebra of the $\delta$ symmetry has the form

$$\delta^2 = Z \qquad [6]$$

where $Z$ is a symmetry transformation (typically a gauge symmetry of some sort). This property forces to consider $Z$-invariant observables and to work in the context of "equivariant cohomology."

The observables of Witten-type theories fit into a general pattern that we describe now. The key ingredient is a map between the homology of $X$ and the equivariant cohomology of $\delta$. Given an operator $\phi^{(0)}$ in the equivariant cohomology of $\delta$, let us consider the following set of equations:

$$\mathrm{d}\phi^{(n)} = \delta\phi^{(n+1)}, \quad n \geq 0 \qquad [7]$$

where the operators $\phi^{(n)}(n = 1, \ldots, \dim X)$ are differential forms of degree $n$ on $X$ and d is the de Rham differential. These differential equations are called "descent equations" and their solutions $\phi^{(n)}(n \geq 0)$ "topological descendants" of $\phi^{(0)}$. We will show how to construct a solution to these equations on general grounds.

The topological descendants lead to the construction of a set of elements of the equivariant cohomology of $\delta$. Let $\gamma_n$ be an $n$-cycle on $X$, $\gamma_n \in H_n(X)$, and let us consider the following operator:

$$W_{\phi^{(0)}}^{(\gamma_n)} = \int_{\gamma_n} \phi^{(n)} \qquad [8]$$

This operator is $\delta$-invariant,

$$\delta W_{\phi^{(0)}}^{(\gamma_n)} = \int_{\gamma_n} \delta\phi^{(n)} = \int_{\gamma_n} \mathrm{d}\phi^{(n-1)} = \int_{\partial\gamma_n} \phi^{(n-1)} = 0 \qquad [9]$$

since $\partial\gamma_n = 0$. On the other hand, if $\gamma_n$ were trivial in homology, that is, if $\gamma_n = \partial\gamma_{n+1}$, we would have that $W_{\phi^{(0)}}^{(\gamma_n)}$ is $\delta$-exact:

$$W_{\phi^{(0)}}^{(\gamma_n)} = \int_{\partial\gamma_{n+1}} \phi^{(n)} = \int_{\gamma_{n+1}} \mathrm{d}\phi^{(n)} = \delta\int_{\gamma_{n+1}} \phi^{(n+1)} \qquad [10]$$

Thus, given the operator $\phi^{(0)}$, we have constructed a map between the homology of $X$ and the equivariant cohomology of $\delta$. There are as many maps as basic operators $\phi^{(0)}$ one finds in the theory.

To actually construct these maps, we need to find a solution of the descent equations [7]. As announced before, there is a general solution to those equations in Witten-type theories. Since in this type of theories [2] holds, there exists an operator

$$G_\mu \equiv G_{0\mu} \qquad [11]$$

that satisfies

$$P_\mu = T_{0\mu} = -\mathrm{i}\delta G_\mu \qquad [12]$$

Notice that $G_\mu$ is an anticommuting operator and a 1-form in spacetime. With the aid of this operator, one constructs the following solution to the descent equations [7]:

$$\phi^{(n)} = \frac{1}{n!}\phi^{(n)}_{\mu_1\mu_2\ldots\mu_n}\,\mathrm{d}x^{\mu_1} \wedge \cdots \wedge \mathrm{d}x^{\mu_n} \qquad [13]$$

where

$$\phi^{(n)}_{\mu_1\mu_2\ldots\mu_n}(x) = G_{\mu_1}G_{\mu_2}\cdots G_{\mu_n}\phi^{(0)}(x), \quad n = 1, \ldots, \dim X \qquad [14]$$

One can easily check using [12] and the $\delta$-invariance of $\phi^{(0)}$ that the operators [13] do satisfy the descent equations [7].

We have seen that Witten-type TQFTs are characterized by property [2]. It would be desirable to have at hand a systematic procedure to build theories satisfying that property. It has been found that extended supersymmetry provides a very helpful starting point to build those theories. Although supersymmetry guarantees from first principles only the weaker condition [12] instead of [2], all TQFTs that have been constructed from extended supersymmetry actually satisfy [2]. To build a TQFT from a theory with extended supersymmetry, one needs to go through the twisting procedure that we now describe.

## Twisting of Extended Supersymmetry

All known Witten-type theories are related to an underlying extended supersymmetric quantum field theory. The topological theory is a modified version of the supersymmetric theory in which the Lorentz transformation properties (spins) of some of the fields have been modified. This modification of spin assignments is known as twisting, and it can be carried out on any theory with extended supersymmetry in any spacetime dimension. We will not consider the procedure in such a general setting but instead we will illustrate it by considering the case of $\mathcal{N}=2$ supersymmetry in four dimensions. We will begin with a general description and then we will apply it to a specific example: Donaldson–Witten theory.

Let us consider the Euclidean version of the $\mathcal{N}=2$ supersymmetry algebra with no central charges. Central charges can be included without much ado but we will not consider them for simplicity. The total symmetry group of the theory is $\mathcal{H}=\mathrm{SU}(2)_+\times \mathrm{SU}(2)_-\times \mathrm{SU}(2)_R \times \mathrm{U}(1)_R$, $\mathcal{K}=\mathrm{SU}(2)_+\times \mathrm{SU}(2)_-$ being the rotation group, and $\mathrm{SU}(2)_R\times \mathrm{U}(1)_R$ the internal symmetry group of the $\mathcal{N}=2$ supersymmetry algebra. The generator algebra takes the following form:

$$
\begin{aligned}
&\{Q_{\alpha v},\overline{Q}_{\dot\beta w}\} = 2\epsilon_{vw}\sigma^{\mu}_{\alpha\dot\beta}P_\mu, && \{Q_{\alpha v},Q_{\beta w}\}=0\\
&[P_\mu,Q_{\alpha v}]=0, && [P_\mu,\overline{Q}_{\dot\alpha v}]=0\\
&[M_{\alpha\beta},Q_{\delta v}]=\epsilon_{\delta(\alpha}Q_{\beta)v}, && [M_{\alpha\beta},\overline{Q}_{\dot\alpha v}]=0\\
&[\overline{M}_{\dot\alpha\dot\beta},Q_{\delta v}]=0, && [\overline{M}_{\dot\alpha\dot\beta},\overline{Q}_{\dot\delta v}]=\epsilon_{\dot\delta(\dot\alpha}\overline{Q}_{\dot\beta)v}\\
&[B^{vw},Q^{u}_{\alpha}]=\epsilon^{u(v}Q^{w)}_{\alpha}, && [B^{vw},\overline{Q}^{u}_{\dot\alpha}]=-\epsilon^{u(v}\overline{Q}^{w)}_{\dot\alpha}\\
&[Q_{\alpha v},R]=Q_{\alpha v}, && [\overline{Q}_{\dot\alpha v},R]=-\overline{Q}_{\dot\alpha v}
\end{aligned}
\qquad [15]
$$

In these relations $v,w\in\{1,2\}$ are $\mathrm{SU}(2)_R$ indices and $\alpha$ and $\dot\alpha$ denote spinorial indices of $\mathrm{SU}(2)_-$ and $\mathrm{SU}(2)_+$, respectively. The supersymmetry generators $Q_{\alpha v}$ and $\overline{Q}_{\dot\alpha v}$ transform under $\mathcal{H}$ as $(\mathbf{0},\mathbf{2},\mathbf{2})^1$ and $(\mathbf{2},\mathbf{0},\mathbf{2})^{-1}$, respectively. $\overline{M}_{\dot\alpha\dot\beta}$ and $M_{\alpha\beta}$ are the generators of $\mathrm{SU}(2)_+$ and $\mathrm{SU}(2)_-$, respectively, while $B^{vw}$ and $R$ generate $\mathrm{SU}(2)_R$ and $\mathrm{U}(1)_R$, respectively.

The twisting of a supersymmetric theory involves a modification of the couplings of the theory to a background metric on the space where the theory is defined. This modification is carried out redefining the Lorentz transformation properties of the different fields making use of the internal symmetry $\mathrm{SU}(2)_R$. In particular, we will redefine the couplings of the fields to the $\mathrm{SU}(2)_+$ spin connection according to the way they transform under $\mathrm{SU}(2)_R$. This is easily done by identifying the $\mathrm{SU}(2)_R$ indices $v$ with the $\mathrm{SU}(2)_+$ indices $\dot\alpha$. The procedure involves a redefinition of the rotation group into $\mathcal{K}'=\mathrm{SU}'(2)_+\otimes \mathrm{SU}(2)_-$, where $\mathrm{SU}'(2)_+$ is generated by

$$M'_{\dot\alpha\dot\beta}=M_{\dot\alpha\dot\beta}-B_{\dot\alpha\dot\beta} \qquad [16]$$

The supersymmetry generators $Q_{\alpha v}$ and $\overline{Q}_{\dot\alpha v}$ get transformed in the following way:

$$
\begin{aligned}
\overline{Q}_{\dot\alpha v} &\to \overline{Q}_{\dot\alpha\dot\beta}\\
Q_{\alpha v} &\to Q_{\alpha\dot\beta}
\end{aligned}
\qquad [17]
$$

which allows us to define the "topological supercharge":

$$\overline{\mathcal{Q}}\equiv \epsilon^{\dot\alpha\dot\beta}\overline{Q}_{\dot\alpha\dot\beta} \qquad [18]$$

It is simple to prove using [15] and [16] that this quantity is a scalar under the new rotation group $\mathcal{K}'$: $[M_{\alpha\beta},\overline{\mathcal{Q}}]=0$ and $[M'_{\dot\alpha\dot\beta},\overline{\mathcal{Q}}]=0$. In addition, from [15], it follows that $\overline{\mathcal{Q}}$ is nilpotent (in the absence of central charges):

$$\overline{\mathcal{Q}}^2=0 \qquad [19]$$

The scalar generator $\overline{\mathcal{Q}}$ leads to the topological symmetry $\delta$ of the previous section. Actually, the twisting procedure provides also the operator $G_\mu$ in [12]. Defining

$$G_\mu=\frac{\mathrm{i}}{4}(\overline{\sigma}_\mu)^{\dot\alpha\gamma}Q_{\gamma\dot\alpha} \qquad [20]$$

one easily finds, after using [15] and [18],

$$\{\overline{\mathcal{Q}},G_\mu\}=\partial_\mu \qquad [21]$$

which is indeed equivalent to [12]. On general grounds we cannot prove that twisted supersymmetric theories lead to theories which satisfy [12]. However relation [12], which is weaker, is guaranteed. It turns out that in all the models originated from extended supersymmetry which have been studied, [2] is satisfied and thus the resulting theories are TQFTs of Witten type.

## Donaldson–Witten Theory

One of the greatest successes of TQFT has been the discovery of Seiberg–Witten invariants as building blocks of Donaldson invariants. This was achieved in two main steps. First, Donaldson theory was reformulated in field-theoretical terms, using perturbative methods. Second, the resulting TQFT was solved using nonperturbative methods. In this section we are going to describe in some detail the first step. The second one will be briefly addressed later and is the main object of a separate article in the encyclopedia (*see* Seiberg–Witten Theory).

Let us consider $\mathcal{N}=2$ supersymmetric Yang–Mills theory in four dimensions. The field content of the theory is the following: a gauge field $A_\mu$, two spinors $\lambda_{v\alpha}$, and a complex scalar $\phi$, all of them in the adjoint representation of a gauge group $\mathcal{G}$. In addition, the theory possesses the auxiliary fields $D_{vw}$ in the **3** of the internal $\mathrm{SU}(2)_R$. The theory has the following action:

$$\int \mathrm{d}^4x\,\mathrm{tr}\Big(\nabla_\mu\phi^\dagger\nabla^\mu\phi - \mathrm{i}\lambda_v\sigma^\mu\nabla_\mu\overline{\lambda}^v - \frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \frac{1}{4}D_{vw}D^{vw} - \frac{1}{2}[\phi,\phi^\dagger]^2 - \frac{\mathrm{i}}{\sqrt{2}}\epsilon^{vw}\lambda_v{}^\alpha[\phi^\dagger,\lambda_{w\alpha}] - \frac{\mathrm{i}}{\sqrt{2}}\epsilon_{vw}\overline{\lambda}^v{}_{\dot\alpha}[\overline{\lambda}^{w\dot\alpha},\phi]\Big) \qquad [22]$$

This action is invariant under the following $\mathcal{N}=2$ supersymmetric transformations:

$$\begin{aligned}
\delta\phi &= \sqrt{2}\epsilon^{vw}\xi_v\lambda_w\\
\delta A_\mu &= \mathrm{i}\xi_v\sigma_\mu\overline{\lambda}^v - \mathrm{i}\lambda_v\sigma_\mu\overline{\xi}^v\\
\delta\lambda_{v\alpha} &= D_v{}^w\xi_{w\alpha} - \mathrm{i}\xi_{v\alpha}[\phi,\phi^\dagger] - \mathrm{i}\sigma^{\mu\nu}{}_\alpha{}^\beta\xi_{v\beta}F_{\mu\nu}\\
&\quad + \mathrm{i}\sqrt{2}\epsilon_{vw}\sigma^\mu_{\alpha\dot\alpha}\overline{\xi}^{w\dot\alpha}\nabla_\mu\phi\\
\delta D^{vw} &= 2\mathrm{i}\overline{\xi}^{(v}\overline{\sigma}^\mu\nabla_\mu\lambda^{w)} + 2\mathrm{i}\nabla_\mu\overline{\lambda}^{(v}\overline{\sigma}^\mu\xi^{w)}\\
&\quad + 2\mathrm{i}\sqrt{2}\xi^{(v}[\lambda^{w)},\phi^\dagger] + 2\mathrm{i}\sqrt{2}\overline{\xi}^{(v}[\overline{\lambda}^{w)},\phi]
\end{aligned} \qquad [23]$$

$\xi_v$ being spinorial $\mathcal{N}=2$ supersymmetric parameters.

We can now twist the above theory following the procedure explained in the previous section. Upon twisting, the fields of the theory change their spin content as follows:

$$\begin{aligned}
A_\mu(\mathbf{2},\mathbf{2},\mathbf{0})^0 &\to A_\mu(\mathbf{2},\mathbf{2})^0\\
\lambda_{\alpha v}(\mathbf{2},\mathbf{0},\mathbf{2})^1 &\to \psi_{\alpha\dot\beta}(\mathbf{2},\mathbf{2})^1\\
\overline{\lambda}_{\dot\alpha v}(\mathbf{0},\mathbf{2},\mathbf{2})^{-1} &\to \eta(\mathbf{0},\mathbf{0})^{-1},\chi_{\dot\alpha\dot\beta}(\mathbf{3},\mathbf{0})^{-1}\\
\phi(\mathbf{0},\mathbf{0},\mathbf{0})^2 &\to \phi(\mathbf{0},\mathbf{0})^2\\
\phi^\dagger(\mathbf{0},\mathbf{0},\mathbf{0})^{-2} &\to \phi^\dagger(\mathbf{0},\mathbf{0})^{-2}\\
D_{vw}(\mathbf{0},\mathbf{0},\mathbf{3})^0 &\to D_{\dot\alpha\dot\beta}(\mathbf{0},\mathbf{0})^0
\end{aligned} \qquad [24]$$

In this table the representations of the respective rotation groups carried by the fields have been indicated. The superindices refer to the $\mathrm{U}(1)_R$ charge which is also called "ghost number" in the context of TQFT. The fields $\eta$ and $\chi$ are given by the antisymmetric and symmetric pieces of $\bar\lambda_{\dot\alpha\dot\beta}: \chi_{\dot\alpha\dot\beta} = \bar\lambda_{(\dot\alpha\dot\beta)}$ and $\eta = (1/2)\epsilon^{\dot\alpha\dot\beta}\bar\lambda_{\dot\alpha\dot\beta}$.

Notice that the twisted fields in [24] are differential forms on $X$; therefore, the twisted theory makes sense globally on any arbitrary Riemannian 4-manifold. This is not the case with the original $\mathcal{N}=2$ supersymmetric Yang–Mills, which contains fermionic fields. Making global sense of those on arbitrary Riemannian 4-manifolds requires the manifold to be Spin.

The dynamics of the twisted theory is governed by an action which can be obtained by twisting the action [22]. On an arbitrary Riemannian 4-manifold endowed with a metric $g_{\mu\nu}$, the twisted action becomes

$$\begin{aligned}
S = \int \mathrm{d}^4x\sqrt{g}\,\mathrm{tr}\Big(&\nabla_\mu\phi\nabla^\mu\phi^\dagger - \mathrm{i}\psi^{\dot\beta}{}_\alpha\overline{\sigma}^{\mu\dot\alpha\alpha}\nabla_\mu\chi_{\dot\alpha\dot\beta}\\
&- \mathrm{i}\psi_{\alpha\dot\alpha}\nabla^{\dot\alpha\alpha}\eta - \frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \frac{1}{4}D_{\dot\alpha\dot\beta}D^{\dot\alpha\dot\beta}\\
&- \frac{1}{2}[\phi,\phi^\dagger]^2 - \frac{\mathrm{i}}{\sqrt{2}}\chi^{\dot\alpha\dot\beta}[\phi,\chi_{\dot\alpha\dot\beta}]\\
&+ \mathrm{i}\sqrt{2}\eta[\phi,\eta] - \frac{\mathrm{i}}{\sqrt{2}}\psi_{\alpha\dot\alpha}[\psi^{\alpha\dot\alpha},\phi^\dagger]\Big)
\end{aligned} \qquad [25]$$

where $\sqrt{g} = (\det(g_{\mu\nu}))^{1/2}$.

To obtain the transformations of the fields under the topological symmetry, we need to compute the $\overline{\mathcal{Q}}$-transformations. These are easily obtained using [18] and [23]. They turn out to be

$$\begin{aligned}
[\overline{\mathcal{Q}},\phi] &= 0\\
[\overline{\mathcal{Q}},A_\mu] &= \psi_\mu\\
\{\overline{\mathcal{Q}},\eta\} &= [\phi,\phi^\dagger]\\
\{\overline{\mathcal{Q}},\psi_\mu\} &= 2\sqrt{2}\nabla_\mu\phi\\
[\overline{\mathcal{Q}},\phi^\dagger] &= 2\sqrt{2}\mathrm{i}\eta\\
\{\overline{\mathcal{Q}},\chi_{\dot\alpha\dot\beta}\} &= \mathrm{i}(F^+_{\dot\alpha\dot\beta} - D_{\dot\alpha\dot\beta})\\
[\overline{\mathcal{Q}},D] &= (2\nabla\psi)^+ + 2\sqrt{2}[\phi,\chi]
\end{aligned} \qquad [26]$$

where $\psi_\mu = \sigma_{\mu\alpha\dot\beta}\psi^{\alpha\dot\beta}$ and $F^+_{\dot\alpha\dot\beta} = \sigma^{\mu\nu}_{\dot\alpha\dot\beta}F_{\mu\nu}$ is the self-dual part of $F_{\mu\nu}$. Using these transformations, one easily finds that $\overline{\mathcal{Q}}^2$ is a gauge transformation. This is not unexpected since the $\mathcal{N}=2$ supersymmetric transformations [23] are in the Wess–Zumino gauge and they close only up to gauge transformations. This property implies that one must consider the equivariant cohomology of $\overline{\mathcal{Q}}$ defined on the set of gauge-invariant operators.

The action [25] is $\overline{\mathcal{Q}}$-exact up to a topological term:

$$S = \{\overline{\mathcal{Q}}, V\} - \frac{1}{2}\int F \wedge F \qquad [27]$$

where

$$V = \int d^4x\sqrt{g}\,\mathrm{tr}\left(\frac{i}{4}\chi_{\dot{\alpha}\dot{\beta}}(F^{\dot{\alpha}\dot{\beta}} + D^{\dot{\alpha}\dot{\beta}}) - \frac{1}{2}\eta[\phi, \phi^\dagger] + \frac{1}{2\sqrt{2}}\psi_{\alpha\dot{\alpha}}\nabla^{\dot{\alpha}\alpha}\phi^\dagger\right) \qquad [28]$$

Actually, it turns out that in all the theories obtained after twisting extended supersymmetry, the resulting actions are $\overline{\mathcal{Q}}$-exact up to topological terms. In the case of $\mathcal{N} = 2$ theories, topological (theta) terms $\int F \wedge F$ are generically not observable (due to a chiral anomaly), so it is customary to pick

$$S_{\mathrm{DW}} = \{\overline{\mathcal{Q}}, V\} \qquad [29]$$

as the action of the theory, which immediately implies [2] and therefore the topological character of the theory. Notice, however, that [29] is stronger than [2].

As we described in the previous section, the observables of the theory can be constructed using the operator $G_\mu$ in [20]. Its action on the twisted fields is easily obtained using [23]:

$$\begin{aligned}
&[G_\mu, \phi] = \frac{1}{2\sqrt{2}}\psi_\mu \\
&[G_\nu, A_\mu] = \frac{i}{2}g_{\mu\nu}\eta - i\chi_{\mu\nu} \\
&[G, \eta] = -\frac{i\sqrt{2}}{4}\nabla\overline{\phi} \\
&\{G_\mu, \psi_\nu\} = -(F^-_{\mu\nu} + D^+_{\mu\nu}) \\
&[G, \overline{\phi}] = 0 \\
&[G, F^+] = i\nabla\chi + \frac{3i}{2} * \nabla\eta \\
&\{G, \chi\} = -\frac{3i\sqrt{2}}{8} * \nabla\overline{\phi} \\
&[G, D] = -\frac{3i}{4} * \nabla\eta + \frac{3i}{2}\nabla\chi
\end{aligned} \qquad [30]$$

We now need to fix the basic operator $\phi^{(0)}$ in [14]. The starting point must be a set of gauge-invariant, $\overline{\mathcal{Q}}$-closed operators which are not $\overline{\mathcal{Q}}$-trivial. Since $[\overline{\mathcal{Q}}, \phi] = 0$, these operators are the gauge-invariant polynomials in the field $\phi$. For a simple gauge group of rank $r$ the algebra of these polynomials is generated by $r$ elements, and we shall denote this basis by $\mathcal{O}_n, n = 1, \ldots, r$. A simple choice for SU($N$) consists of the following Casimirs:

$$\mathcal{O}_n = \mathrm{tr}(\phi^{n+1}), \quad n = 1, \ldots, N \qquad [31]$$

Using $G_\mu$ we can now construct the map between the homology of $X$ and the equivariant cohomology of $\overline{\mathcal{Q}}$. Let us consider the simple case SU(2). There exists only one independent Casimir and, correspondingly, only one basic operator:

$$\mathcal{O} = \mathrm{tr}(\phi^2) \qquad [32]$$

for which one finds the following set of descendants:

$$\begin{aligned}
\mathcal{O}^{(1)} &= \mathrm{tr}\left(\frac{1}{\sqrt{2}}\phi\psi_\mu\right)dx^\mu \\
\mathcal{O}^{(2)} &= -\frac{1}{2}\mathrm{tr}\left(\frac{1}{\sqrt{2}}\phi(F^-_{\mu\nu} + D_{\mu\nu}) - \frac{1}{4}\psi_\mu\psi_\nu\right)dx^\mu \wedge dx^\nu \\
&\ \ \vdots
\end{aligned} \qquad [33]$$

The map from the homology of $X$ to the equivariant cohomology of $\overline{\mathcal{Q}}$ can now be constructed very easily. Let $\gamma_i$ be an element of the homology group $H_i(X)$. We associate to it the following observable:

$$\gamma_i \to I_i(\gamma_i) = \int_{\gamma_i}\mathcal{O}^{(i)} \qquad [34]$$

where $\mathcal{O}^{(i)}$ is given in [33]. The construction assures that $I_i(\gamma_i)$ is invariant under $\overline{\mathcal{Q}}$ and gauge transformations. Furthermore, it is also assured that $I_i(\gamma_i)$ is not $\overline{\mathcal{Q}}$-exact.

Let us consider the computation of correlation functions. The discussion will be presented for a generic gauge group. We will consider the topological theory defined by the Donaldson–Witten action

$$S_{\mathrm{DW}} = \{\overline{\mathcal{Q}}, V\} \qquad [35]$$

where $V$ is defined in [28]. The property [35] has a very important consequence. The action $S_{\mathrm{DW}}$ shows up in the correlation functions as $\exp(-S_{\mathrm{DW}}/e^2)$, where $e$ is a free parameter which corresponds to the coupling constant of the $\mathcal{N} = 2$ theory. Since the term involving the coupling constant is $\overline{\mathcal{Q}}$-exact, the correlation functions of $\overline{\mathcal{Q}}$-invariant operators are independent of $e$. Let us explain this in some detail. The (unnormalized) correlation functions of the theory are defined by

$$\langle\phi_1\cdots\phi_n\rangle = \int \mathcal{D}\phi\,\phi_1\cdots\phi_n\,e^{-(1/e^2)S_{\mathrm{DW}}} \qquad [36]$$

where $\phi_1, \ldots, \phi_n$ are invariant under $\overline{\mathcal{Q}}$ transformations. Using the fact that $S_{\mathrm{DW}}$ is $\overline{\mathcal{Q}}$-exact, one obtains

$$\begin{aligned}
\frac{\partial}{\partial e}\langle\phi_1\cdots\phi_n\rangle &= \frac{2}{e^3}\langle\phi_1\cdots\phi_n S_{\mathrm{DW}}\rangle \\
&= \frac{2}{e^3}\langle\{\overline{\mathcal{Q}}, \phi_1\cdots\phi_n V\}\rangle = 0
\end{aligned} \qquad [37]$$

where we have used the fact that $\overline{\mathcal{Q}}$ is a symmetry of the theory, and therefore as in [3] the last functional integral gives zero. This result implies that one can compute these correlation functions in different limits of $e$. In the weak-coupling limit (semiclassical or saddle point approximation), one establishes the connection with Donaldson theory. In the strong-coupling limit, Seiberg–Witten invariants appear and one finds the connection between these two types of invariants. We will briefly explore the weak-coupling limit $e \to 0$. The functional integral [36] can be evaluated exactly in two steps: first one analyzes the zero modes or classical configurations that minimize the action, then one expands around them considering only quadratic fluctuations. The integration over these quadratic fluctuations involves ratios of determinants of kinetic operators that because of the $\overline{\mathcal{Q}}$-symmetry of the theory (which in fact is a Bose–Fermi symmetry) are $\pm 1$. One is then left with an integral over the bosonic zero modes which leads to a finite-dimensional integral over the space of bosonic collective coordinates, and a finite Grassmannian integral over the zero modes of the fermionic fields. A careful analysis of the zero modes, first carried out by Witten, reveals that the infinite-dimensional functional integral is replaced by a finite-dimensional integral over the moduli space of anti-self-dual (ASD) connections $\mathcal{M}_{\text{ASD}}$, that is, the space of connections satisfying $F^{+}_{\mu\nu} = 0$.

Therefore, the correlation functions [36] have the form

$$\langle \phi_1 \cdots \phi_n \rangle = \int_{\mathcal{M}_{\text{ASD}}} \hat{\phi}_1 \wedge \cdots \wedge \hat{\phi}_n \qquad [38]$$

where the fields in $\phi_1 \cdots \phi_n$ are mapped to differential forms $\hat{\phi}_1 \cdots \hat{\phi}_n$ on $\mathcal{M}_{\text{ASD}}$ – the degree of each form being given by the ghost number of its partner. Notice that the integral on the right-hand side vanishes unless the form has top degree. From the field-theoretical point of view, this is the requirement that the overall ghost number of the correlation function must be equal to $\dim \mathcal{M}_{\text{ASD}}$.

The quantities on the right-hand side of [38] are – for gauge group SU(2) – precisely the Donaldson invariants. Thus, Witten's work provided a new point of view on these invariants by reformulating them in a quantum field theory language. This is a very important contribution since quantum field theory is a very rich framework and a wide variety of methods can be used to analyze the correlation functions. This opened an entirely new strategy to investigate the Donaldson invariants. The emergence of Seiberg–Witten invariants is perhaps the greatest achievement of the implementation of this strategy.

We finish this section by pointing out that many features of the evaluation of the functional integral of the Donaldson–Witten theory developed here are common to most topological field theories of the Witten type. These features can be studied in the context of the Mathai–Quillen formalism which is the object of a separate article in the encyclopedia (*see* Mathai–Quillen Formalism).

## Chern–Simons Gauge Theory for Knots and Links

Chern–Simons gauge theory is the most important example of Schwarz-type TQFTs. Let us begin by introducing its basic elements. Chern–Simons gauge theory is a quantum field theory whose action is based on the Chern–Simons form associated to a nonabelian gauge group. The theory is defined by the following data: a smooth 3-manifold $M$ which will be taken to be compact, a gauge group $G$ which will be taken semisimple and compact, and an integer parameter $k$. The action of the theory is

$$S_{\text{CS}}(A) = \frac{k}{4\pi} \int_M \operatorname{tr}\left( A \wedge \mathrm{d}A + \frac{2}{3} A \wedge A \wedge A \right) \qquad [39]$$

where $A$ is a gauge connection and the trace is taken in the fundamental representation. The exponential of i times this action is invariant under gauge transformations,

$$A \to A + g^{-1}\,\mathrm{d}g \qquad [40]$$

where $g$ is a map $g: M \to G$.

Notice that the action [39] is independent of the metric on the 3-manifold $M$. In this theory, appropriate observables lead to correlation functions which correspond to topological invariants. Candidates to be observables of this type must be metric independent and gauge invariant. Wilson loops satisfy these properties. They correspond to the holonomy of the gauge connection $A$ along a loop. Given a representation $R$ of the gauge group $G$ and a 1-cycle $\gamma$ on $M$, it is defined as

$$W^R_\gamma(A) = \operatorname{tr}_R\big(\operatorname{Hol}_\gamma(A)\big) = \operatorname{tr}_R P \exp \int_\gamma A \qquad [41]$$

Products of these operators are the natural candidates to obtain topological invariants after computing their correlation functions. These correlation functions are formally written as

$$\langle W^{R_1}_{\gamma_1} W^{R_2}_{\gamma_2} \cdots W^{R_n}_{\gamma_n} \rangle = \int [DA]\, W^{R_1}_{\gamma_1}(A)\, W^{R_2}_{\gamma_2}(A) \cdots W^{R_n}_{\gamma_n}(A)\, \mathrm{e}^{\mathrm{i}S_{\text{CS}}(A)} \qquad [42]$$

where $\gamma_1, \gamma_2, \ldots, \gamma_n$ are 1-cycles on $M$ and $R_1, R_2$, and $R_n$ are representations of $G$. In [42], the quantity $[DA]$ denotes the functional integral measure and it is assumed that an integration over connections modulo gauge transformations is carried out. As usual in quantum field theory, this integration is not well defined. Field theorists have developed methods to assign a meaning to the right-hand side of [42]. These methods mainly fall into two categories – perturbative and nonperturbative – and their degree of success mostly depends on the quantum field theory under consideration. For gauge theories, it is also possible to take an alternative approach, the large-$N$ expansion, which in general provides further insights into the theory. In Chern–Simons gauge theory all these three methods have proved of great value.

Witten (1989) showed, using nonperturbative methods, that when one considers nonintersecting cycles $\gamma_1, \gamma_2, \ldots, \gamma_n$ without self-intersections, the correlation functions [42] lead to the polynomial invariants of knot theory discovered a few years earlier starting with the work of Jones (1985).

Knot theory studies embeddings $\gamma: S^1 \to M$. Any two of such embeddings are considered equivalent if the image of one of them can be deformed into the image of the other by a homeomorphism on $M$. The main goal of knot theory is to classify the resulting equivalence classes. Each of these classes is a knot. Most of the work on knot theory has been carried out for the simple case $M = S^3$. Chern–Simons gauge theory, however, being a formulation intrinsically three dimensional, provides a framework to study the case of more general 3-manifolds $M$.

A powerful approach to classify knots is based on the construction of knot invariants. These are quantities which can be computed for a representative of a class and are invariant within the class, that is, under continuous deformations of the chosen representative. At present, it is not known if there exist enough knot invariants to classify knots. Vassiliev invariants (Vassiliev 1990) are the most promising candidates, but it is already known that if they do provide such a classification, infinitely many of them are needed.

The problem of the classification of knots in $S^3$ can be reformulated in a two-dimensional framework using regular knot projections. Given a representative of a knot in $S^3$, deform it continuously in such a way that the projection on a plane has simple crossings. Draw the projection on the plane, and at each crossing use the convention that the line that goes under the crossing is erased in a neighborhood of the crossing. The resulting diagram is a set of segments on the plane, containing the relevant information at the crossings. The problem of classifying knots is equivalent to the problem of classifying knot projections modulo a series of relations among them. These relations are known as Reidemeister moves. Invariance of a quantity under the three Reidemeister moves is called invariance under ambient isotopy. If a quantity is invariant under all but the first move, it is said to possess invariance under regular isotopy.

The formalism described for knots generalizes to the case of links. For a link of $n$ components, one considers $n$ embeddings, $\gamma_i: S^1 \to M$ $(i = 1, \ldots, n)$, with no intersections among them. Again, the main problem that link theory faces is the problem of their classification modulo homeomorphisms on $M$. In this case one can also define regular projections and reformulate the problem in terms of their classification modulo the Reidemeister moves.

The study of knot and link invariants experimented important progress in the 1980s. Jones (1985) discovered a new invariant which carries his name. The Jones polynomial can be defined very simply in terms of skein relations. These are a set of rules that can be applied to the diagram of a regular knot projection to construct the polynomial invariant. They establish a relation between the invariants associated to three links which only differ in a region as shown in Figure 1 where arrows have been introduced to take into account that the Jones polynomial is defined for oriented links.

If one denotes by $V_L(t)$ the Jones polynomial corresponding to a link $L$, $t$ being the argument of the polynomial, it must satisfy the skein relation:

$$\frac{1}{t} V_{L_+} - t V_{L_-} = \left( \sqrt{t} - \frac{1}{\sqrt{t}} \right) V_{L_0} \qquad [43]$$

where $L_+, L_-$, and $L_0$ are the links shown in Figure 1. This relation plus a choice of normalization for the unknot ($U$) are enough to compute the Jones polynomial for any link. The standard choice for the unknot is

$$V_U = 1 \qquad [44]$$

though it is not the most natural one from the point of view of Chern–Simons gauge theory. After Jones

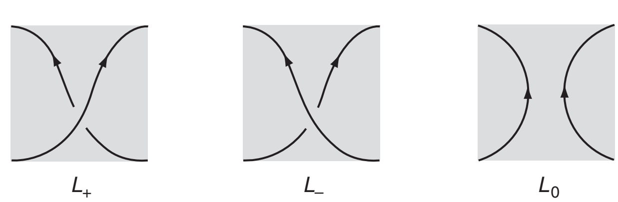

**Figure 1** Skein relations.

work in 1984, many other polynomial invariants were discovered, as the HOMFLY and the Kauffman polynomial invariants.

The pioneering work of Witten in 1988 showed that the correlation functions of products of Wilson loops [42] correspond to the Jones polynomial when one considers SU(2) as gauge group and all the Wilson loops entering in the correlation function are taken in the fundamental representation $F$. For example, if one considers a knot $K$, Witten showed that

$$V_K(t) = \langle W_K^F \rangle \qquad [45]$$

provided that one performs the identification

$$t = \exp\left(\frac{2\pi \mathrm{i}}{k+h}\right) \qquad [46]$$

where $h = 2$ is the dual Coxeter number of the gauge group SU(2). Witten also showed that if instead of SU(2) one considers SU($N$) and the Wilson loop carries the fundamental representation, the resulting invariant is the HOMFLY polynomial. The second variable of this polynomial originates in this context from the $N$ dependence. However, these cases are just a sample of the general framework intrinsic to Chern–Simons gauge theory. Taking other groups and other representations, one possesses an enormous set of knot and link invariants. These invariants can also be obtained in the context of quantum groups.

Many nonperturbative studies of Chern–Simons gauge theory have been carried out. The quantization of the theory has been studied from the point of view of the operator formalism as well as other more geometrical methods. Also, its connection to two-dimensional conformal field theory has been further elucidated, and a powerful method for the general computation of knot and link invariants has been developed by Kaul and collaborators.

Chern–Simons theory is also amenable to perturbative analysis, which has provided important representations of the Vassiliev invariants. These invariants, proposed by Vassiliev in 1990, turned out to be the coefficients of the perturbative series expansion of the correlators of Chern–Simons gauge theory. Perturbative studies can be carried out in different gauges, originating a variety of new representations of Vassiliev invariants. Among the most relevant results related to these topics are the integral expressions for Vassiliev invariants by Kontsevich and by Bott and Taubes, as well as the recent combinatorial ones. These developments are not described here but the interested reader is referred to the recent review (Labastida 1999).

## Advanced Developments

Topological sigma models are another important type of (Witten-type) TQFTs. These theories are obtained after twisting 2D $\mathcal{N} = 2$ supersymmetric sigma models. The twisting can be done in two different ways leading to two types of models, A and B. Their existence is related to mirror symmetry. Only type-A models will be described in what follows. These models can be defined on an arbitrary almost-complex manifold, though typically they are considered on Kähler manifolds. The theory involves maps from two-dimensional Riemann surfaces $\Sigma$ to target spaces $X$, together with fermionic degrees of freedom on $\Sigma$ which are mapped to tangent vectors on $X$. The functional integral of the resulting theory is localized on holomorphic maps, defining the corresponding moduli space. The corresponding $\overline{\mathcal{Q}}$-cohomology provides the set of physical observables, which can be mapped to cohomology classes on the moduli space and integrated to produce topological invariants.

Topological sigma models keep fixed the complex structure of the Riemann surface $\Sigma$. Motivated by string theory, one also considers the situation in which one integrates over complex structures. In this case, one ends up working with holomorphic maps in the entire moduli space of curves. The resulting theories are called topological strings.

We will review now a particular example of topological string theory which, besides being very interesting from the point of view of physics and mathematics, will be very useful in establishing a relation with Chern–Simons gauge theory. Let us consider topological strings with target manifold $X$ a Calabi–Yau 3-fold. In this case, the virtual dimension of the moduli space of holomorphic maps turns out to be zero. Two situations can occur: either the space is given by a number of points (the real dimension is zero) or the moduli space is finite dimensional and possesses a bundle of the same dimension as the tangent bundle. In the first case, topological strings count the number of points weighted by the exponential of the area of the holomorphic map (the pullback of the Kähler form integrated over the surface) times $x^{2g-2}$, where $x$ is the string-coupling constant and $g$ is the genus of $\Sigma$. In the second case, one computes the top Chern class of the appropriate bundles (properly defined), again weighted by the same factor. In both cases one can classify the contributions according to the cohomology class $\beta$ on $X$ in which the image of the holomorphic map is contained. The sum of the numbers obtained for each $\beta$ and fixed $g$ are known as Gromov–Witten

invariants, $N_g^\beta$. The topological string contribution takes the form

$$\sum_{g\geq 0} x^{2g-2}\left(\sum_{\beta\in H_2(X,Z)} N_g^\beta\, e^{\int_\beta \omega}\right) \qquad [47]$$

where $\omega$ is the Kähler class of the Calabi–Yau manifold. In general, the quantities $N_g^\beta$ are rational numbers.

The precedent discussion has shown how Gromov–Witten invariants can be interpreted in terms of string theory. One could think that this is just a fancy observation and that no further insight on these invariants can be gained from this formulation. The situation turns out to be quite the opposite. Once a string formulation has been obtained, the whole machinery of string theory is at our disposal. One should look to new ways to compute the quantity [47], where Gromov–Witten invariants are packed. The hope is that, if this is possible, the new emerging picture will provide new insights on these invariants. This is indeed what occurred recently. It turns out that the quantity [47] can be obtained from an alternative point of view in which the embedded Riemann surfaces are regarded as D-branes. The outcome of this approach is that the Gromov–Witten invariants can be written in terms of other invariants which are integers and that possess a geometrical interpretation. To be more specific, the quantity [47] takes the form

$$\sum_{\substack{g\geq 0\\ \beta\in H_2(X,Z)}} \sum_{d>0} n_g^\beta \frac{1}{d}\left(2\sin\left(\frac{dx}{2}\right)\right)^{2g-2} e^{d\int_\beta \omega} \qquad [48]$$

where $n_g^\beta$ are the new "integer" invariants. This prediction has been verified in all the cases in which it has been tested. A similar structure will be found in the next section in the context of knot theory in the large-$N$ limit.

Let us now consider also Donaldson–Witten theory from a new perspective. To be more specific, let us consider the case in which the gauge group is SU(2), and the 4-manifold $X$ is simply connected and has $b_2^+ > 1$ (the case $b_2^+ = 1$ is anomalous). In this situation there are $1 + b_2$ physical observables [34], $\mathcal{O} = I_1$ and $I(\Sigma_a) = I_2(\Sigma_a)$ $(a = 1, \ldots, b_2)$, where $\Sigma_a$ is a basis of $H_2(X)$. These can be packed in a generating functional:

$$\left\langle \exp\left(\sum_a \alpha_a I(\Sigma_a) + \lambda\mathcal{O}\right)\right\rangle \qquad [49]$$

where $\lambda$ and $\alpha_a\,(a = 1, \ldots, b_2)$ are parameters. In computing this quantity one can argue that the contribution is localized on the moduli space of instantons configurations and one ends up, after taking into account the selection rule dictated by the dimensionality of the moduli space, with integrations over the moduli space of the selected forms. The resulting quantities are Donaldson invariants.

As in the case of topological sigma models one could be tempted to argue that the observation leading to a field-theoretical interpretation of Donaldson invariants does not provide any new insight. Quite on the contrary, once a field theory formulation is available, one has at his disposal a huge machinery which could lead, on the one hand, to further generalizations of the theory and, on the other hand, to new ways to compute quantities such as [49], obtaining new insights on these invariants. This is indeed what happened in the 1990s, leading to an important breakthrough in 1994 when Seiberg and Witten calculated [49] in a different way and pointed out the relation of Donaldson invariants to new integer invariants that nowadays bear their names.

The localization argument that led to the interpretation of [49] as Donaldson invariants is valid because the theory under consideration is exact in the weak-coupling limit. Actually, the topological theory under consideration is independent of the coupling constant and thus calculations in the strong-coupling limit are also exact. These types of calculations were out of reach before 1994. The situation changed dramatically after the work of Seiberg and Witten in which $\mathcal{N} = 2$ super Yang–Mills theory was solved in the strong-coupling limit. Its application to the corresponding twisted version was immediate and it turned out that Donaldson invariants can be written in terms of new integer invariants now known as Seiberg–Witten invariants (Witten 1994). The development has a strong resemblance with the one described above for topological strings: certain noninteger invariants can be expressed in terms of new integer invariants.

The Seiberg–Witten invariants are actually simpler to compute than Donaldson invariants. They correspond to partition functions of topological Yang–Mills theories where the gauge group is abelian. These contributions can be grouped into classes labeled by $x = -2c_1(L)$, where $c_1(L)$ is the first Chern class of the corresponding line bundle. The sum of contributions, each being $\pm 1$, for a given class $x$ is the integer Seiberg–Witten invariant $n_x$. The strong-coupling analysis of topological Yang–Mills theory leads to the following expression for [49]:

$$2^{1+(1/4)(7\chi+11\sigma)}\Big(e^{((v^2/2)+2\lambda)}\sum_x n_x e^{v\cdot x} + i^{\chi+\sigma/4}\, e^{(-(v^2/2)-2\lambda)}\sum_x n_x\, e^{-iv\cdot x}\Big) \qquad [50]$$

where $v = \sum_a \alpha_a \Sigma_a$, and $\chi$ and $\sigma$ are the Euler number and the signature of the manifold $X$. This result matches the known structure of [49] (structure theorem of Kronheimer and Mrowka) and provides

a meaning to its unknown quantities in terms of the new Seiberg–Witten invariants. Equation [50] is a rather remarkable prediction that has been tested in many cases, and for which a general proof has been recently proposed. For a review of the subject, see Labastida and Lozano (1998).

The situation for manifolds with $b_2^+=1$ involves a metric dependence and has been worked out in detail (Moore and Witten 1998). The formulation of Donaldson invariants in field-theoretical terms has also provided a generalization of these invariants. This generalization has been carried out in several directions: (1) the consideration of higher-rank groups, (2) the coupling to matter fields after twisting $\mathcal{N}=2$ hypermultiplets, and (3) the twist of theories involving $\mathcal{N}=4$ supersymmetry.

We will now look at Chern–Simons gauge theory from the perspective that emerges from its treatment in the context of the large-$N$ expansion. We will restrict the discussion to the case of knots on $S^3$ with gauge group SU($N$). Gauge theories with gauge group SU($N$) admit, besides the perturbative expansion, a large-$N$ expansion. In this expansion correlators are expanded in powers of $1/N$ while keeping the 't Hooft coupling $t=Nx$ fixed, $x$ being the coupling constant of the gauge theory. For example, for the free energy of the theory, one has the general form

$$F=\sum_{\substack{g\geq 0\\ h\geq 1}}^{\infty} C_{g,h}N^{2-2g}t^{2g-2+h} \qquad [51]$$

In the case of Chern–Simons gauge theory, the coupling constant is $x=2\pi i/(k+N)$ after taking into account the shift in $k$. The large-$N$ expansion [51] resembles a string-theory expansion and indeed the quantities $C_{g,h}$ can be identified with the partition function of a topological open string with $g$ handles and $h$ boundaries, with $N$ D-branes on $S^3$ in an ambient six-dimensional target space $T^*S^3$. This was pointed out by Witten in 1992. The result makes a connection between a topological three-dimensional field theory and the topological strings described in the previous section.

In 1998 an important breakthrough took place which provided a new approach to compute quantities such as [51]. Using arguments inspired by the AdS/CFT correspondence, Gopakumar and Vafa (1999) provided a closed-string-theory interpretation of the partition function [51]. They conjectured that the free energy $F$ can be expressed as

$$F=\sum_{g\geq 0}^{\infty} N^{2-2g}F_g(t) \qquad [52]$$

where $F_g(t)$ corresponds to the partition function of a topological closed-string theory on the noncompact Calabi–Yau manifold $X$ called the resolved conifold, $\mathcal{O}(-1)\oplus\mathcal{O}(-1)\to \boldsymbol{P}^1$, $t$ being the flux of the $B$-field through $\boldsymbol{P}^1$. The quantities $F_g(t)$ have been computed using both physical and mathematical arguments, thus proving the conjecture.

Once a new picture for the partition function of Chern–Simons gauge theory is available, one should ask about the form that the expectation values of Wilson loops could take in the new context. The question was faced by Ooguri and Vafa and they provided the answer, later refined by Labastida, Mariño, and Vafa. The outcome is an entirely new point of view in the theory of knot and link invariants. The new picture provides a geometrical interpretation of the integer coefficients of the quantum group invariants, an issue that has been investigated during many years. To present an account of these developments, one needs to review first some basic facts of large-$N$ expansions.

To consider the presence of Wilson loops, it is convenient to introduce a particular generating functional. First, one performs a change of basis from representations $R$ to conjugacy classes $C(\boldsymbol{k})$ of the symmetric group, labeled by vectors $\boldsymbol{k}=(k_1,k_2,\ldots)$ with $k_i\geq 0$, and $|\boldsymbol{k}|=\sum_j k_j>0$. The change of basis is $W_{\boldsymbol{k}}=\sum_R \chi_R(C(\boldsymbol{k}))W_R$, where $\chi_R$ are characters of the permutation group $S_\ell$ of $\ell=\sum_j jk_j$ elements ($\ell$ is also the number of boxes of the Young tableau associated to $R$). Second, one introduces the generating functional:

$$F(V)=\log Z(V)=\sum_{\boldsymbol{k}}\frac{|C(\boldsymbol{k})|}{\ell!}W_{\boldsymbol{k}}^{(c)}\Upsilon_{\boldsymbol{k}}(V) \qquad [53]$$

where

$$Z(V)=\sum_{\boldsymbol{k}}\frac{|C(\boldsymbol{k})|}{\ell!}W_{\boldsymbol{k}}\Upsilon_{\boldsymbol{k}}(V)$$

$$\Upsilon_{\boldsymbol{k}}(V)=\prod_j(\mathrm{tr}\,V^j)^{k_j}$$

In these expressions $|C(\boldsymbol{k})|$ denotes the number of elements of the class $C(\boldsymbol{k})$ in $S_\ell$. The reason behind the introduction of this generating functional is that the large-$N$ structure of the connected Wilson loops, $W_{\boldsymbol{k}}^{(c)}$, turns out to be very simple:

$$\frac{|C(\boldsymbol{k})|}{\ell!}W_{\boldsymbol{k}}^{(c)}=\sum_{g=0}^{\infty}x^{2g-2+|\boldsymbol{k}|}F_{g,\boldsymbol{k}}(\lambda) \qquad [54]$$

where $\lambda=e^t$ and $t=Nx$ is the 't Hooft coupling. Writing $x=t/N$, it corresponds to a power series expansion in $1/N$. As before, the expansion looks like a perturbative series in string theory where $g$ is the genus and $|\boldsymbol{k}|$ is the number of holes. Ooguri and Vafa conjectured in 1999 the appropriate string-theory description of [54]. It corresponds to an open topological string theory (notice that the ones

described in the previous section were closed), whose target space is the resolved conifold $X$. The contribution from this theory will lead to open-string analogs of Gromov–Witten invariants.

In order to describe in more detail the fact that one is dealing with open strings, some new data need to be introduced. Here is where the knot description intrinsic to the Wilson loop enters. Given a knot $K$ on $S^3$, let us associate to it a Lagrangian submanifold $C_K$ with $b_1 = 1$ in the resolved conifold $X$ and consider a topological open string on it. The contributions in this open topological string are localized on holomorphic maps $f : \Sigma_{g,h} \to X$ with $h = |\boldsymbol{k}|$ which satisfy $f_*[\Sigma_{g,h}] = \mathcal{Q}$, and $f_*[C] = j[\gamma]$ for $k_j$ oriented circles $C$. In these expressions $\gamma \in H_1(C_K, \boldsymbol{Z})$, and $\mathcal{Q} \in H_2(X, C_K, \boldsymbol{Z})$, that is, the map is such that $k_j$ boundaries of $\Sigma_{g,h}$ wrap the knot $j$ times, and $\Sigma_{g,h}$ itself gets mapped to a relative two-homology class characterized by the Lagrangian submanifold $C_K$. The number of such maps (in the sense described in the previous section) is the open-string analog of Gromov–Witten invariants. They will be denoted by $N^{\mathcal{Q}}_{g,\boldsymbol{k}}$. Comparing to the situation that led to [47] in the closed-string case, one concludes that in this case the quantities $F_{g,\boldsymbol{k}}(\lambda)$ in [54] must take the form

$$F_{g,\boldsymbol{k}}(\lambda) = \sum_{\mathcal{Q}} N^{\mathcal{Q}}_{g,\boldsymbol{k}}\, \mathrm{e}^{\int_{\mathcal{Q}} \omega}, \qquad t = \int_{\boldsymbol{P}^1} \omega \qquad [55]$$

where $\omega$ is the Kähler class of the Calabi–Yau manifold $X$ and $\lambda = \mathrm{e}^t$. For any $\mathcal{Q}$, one can always write $\int_{\mathcal{Q}} \omega = Qt$, where $Q$ is in general a half-integer number. Therefore, $F_{g,\boldsymbol{k}}(\lambda)$ is a polynomial in $\lambda^{\pm 1/2}$ with rational coefficients.

The result [55] is very impressive but still does not provide a representation where one can assign a geometrical interpretation to the integer coefficients of the quantum-group invariants. Notice that to match a polynomial invariant to [55], after obtaining its connected part, one must expand it in $x$ after setting $q = \mathrm{e}^x$ keeping $\lambda$ fixed. One would like to have a refined version of [55], in the spirit of what was described in the previous section leading from the Gromov–Witten invariants $N^{\beta}_g$ of [47] to the new integer invariants $n^{\beta}_g$ of [48]. It turns out that, indeed, $F(V)$ can be expressed in terms of integer invariants in complete analogy with the description presented in the previous section for topological strings. A good review on the subject can be found in Mariño (2005).

## Concluding Remarks

In this overview we have introduced key features of TQFTs and we have described some of the most relevant results emerged from them. We have described how the many faces of TQFT provide a variety of important insights in a selected set of problems in topology. Among these outstand the reformulation of Donaldson theory and the discovery of the Seiberg–Witten invariants, and the string-theory description of the large-$N$ expansion of Chern–Simons gauge theory, which provides an entirely new point of view in the study of knot and link invariants and points to an underlying fascinating interplay between string theory, knot theory, and enumerative geometry which opens new fields of study.

In addition to their intrinsic mathematical interest, TQFTs have been found relevant to important questions in physics as well. This is so because, in a sense, TQFTs are easier to solve than conventional quantum field theories. For example, topological sigma models are relevant to the computation of certain couplings in string theory. Also, Witten-type gauge TQFTs such as Donaldson–Witten theories and its generalizations play a role in string theory as effective world-volume theories of extended string states (branes) wrapping curved spaces, and TQFTs arising from $\mathcal{N} = 4$ gauge theories in four dimensions have shed light on field- (and string-) theory dualities.

Most of these developments, and others that we have not touched upon or only mentioned in passing have their own entries in the encyclopedia, to which we refer the interested reader for further details.

# Topological Sigma Models

**D Birmingham**, University of the Pacific, Stockton, CA, USA

## Introduction

Topological sigma models govern the quantum mechanics of maps from a Riemann surface $\Sigma$ to a target space $M$. In contrast to the standard supersymmetric sigma model, the topological version has a special local shift symmetry. This symmetry takes the form $\delta u^i = \epsilon^i$, where $\epsilon^i$ is an arbitrary local function of the coordinates on the base manifold $\Sigma$. In essence, this topological shift symmetry ensures that all local degrees of freedom of the model can be gauged away. As a result, the dynamics of such a model resides in a finite number of global topological degrees of freedom. This feature is generic to all topological field theories of Witten type, also known as cohomological field theories (*see* Topological Quantum Field Theory: Overview). The topological shift symmetry is responsible for the special topological nature of the model, which is seen most readily by BRST quantizing the local shift symmetry. This gives rise to a nilpotent BRST operator $Q$. The properties of this BRST operator are crucial for establishing the topological nature of the model. The key point in the construction of any cohomological field theory is the fact that the full quantum action $S_{\mathrm{q}}$ can be written as a BRST commutator $S_{\mathrm{q}} = \{Q, V\}$, where $V$ is a function of the fields needed to define the path integral. In particular, one can show that the partition function and all correlation functions are independent of the metric on both the base manifold $\Sigma$ and the target space $M$. For example, let us define the path integral by

$$Z = \int \mathrm{d}\Phi \, \mathrm{e}^{-\{Q,V\}} \qquad [1]$$

where $\Phi$ denotes the full set of fields required at the quantum level. In general, the function $V$ depends on geometric data of both $\Sigma$ and $M$. Nevertheless, one can easily establish that the partition function is independent of this data by noting the following. Variation of $Z$ with respect to the metric of the target space $g$ (for example) gives

$$\delta_g Z = -\int \mathrm{d}\Phi \, \mathrm{e}^{-\{Q,V\}} \, \{Q, \delta_g V\} \qquad [2]$$

The right-hand side of this equation is nothing but the vacuum expectation value of a BRST commutator, and this vanishes by BRST invariance of the vacuum. It is important to note here that the BRST operator $Q$ can be constructed to be independent of $g$. Apart from the necessity of introducing the metric tensor, these models also require additional geometric data for their construction. The complex structure of $\Sigma$, and at least an almost-complex structure on $M$, is required. By a similar argument, one can show that the partition function and correlation functions are independent of this extra

geometric data. As mentioned above, these models possess no local degrees of freedom. One can then show that the path-integral expression for the correlation functions can be localized to a finite-dimensional moduli space of instanton configurations which minimize the classical action.

We will first show how the full quantum action of the theory can be obtained as a BRST quantization of a classical action with a local gauge symmetry. However, we shall then highlight the fact that the gauge algebra for this topological shift symmetry only closes on-shell. In order to proceed with a BRST quantization of the model, and obtain the complete quantum action, one must take recourse to the Batalin–Vilkovisky quantization scheme. This machinery is ideally tailored for such a problem, with the end result that quartic ghost terms are present in the action. However, the presence of such terms does not affect the arguments presented above, since the quantum is still obtained as a BRST commutator. Following this, we construct all observables of the theory and demonstrate their connection to the de Rham cohomology of the target space. The special topological properties of the observables are then discussed, and it is shown how their computation is localized to the moduli space $\mathcal{M}$ of holomorphic maps from $\Sigma$ to $M$. As a particular example, we show how the computation of a certain class of observables determines the intersection numbers of the moduli space $\mathcal{M}$. We present a brief discussion of the connection between topological sigma models with Calabi–Yau target space $M$, and the mirror symmetry of $M$.

## Construction of the Model

We begin with the following classical action:

$$S_{\mathrm{c}} = \int_{\Sigma} \mathrm{d}^2\sigma \sqrt{h}\, h_{\alpha\beta}\, g_{ij} K^{\alpha i} K^{\beta j} \qquad [3]$$

where

$$K^{\alpha i} = G^{\alpha i} - \tfrac{1}{2}\left(\partial^\alpha u^i + \epsilon^\alpha{}_\beta J^i{}_j \partial^\beta u^j\right) \qquad [4]$$

The fields $G^{\alpha i}$ and $K^{\alpha i}$ both satisfy the self-duality constraint

$$\begin{aligned} G^{\alpha i} &= P^{\alpha i}_{+\ \beta j} G^{\beta j} \\ K^{\alpha i} &= P^{\alpha i}_{+\ \beta j} K^{\beta j} \end{aligned} \qquad [5]$$

where the self-dual and anti-self-dual projection operators are defined as

$$P^{\alpha i}_{\pm\ \beta_j} = \tfrac{1}{2}\left(\delta^\alpha{}_\beta \delta^i{}_j \pm \epsilon^\alpha{}_\beta J^i{}_j\right) \qquad [6]$$

The above action describes a theory of maps $u^i(\sigma)$ from a Riemann surface $\Sigma$ to an almost complex manifold $M$. The coordinates on $\Sigma$ are denoted by $\sigma^\alpha (\alpha = 1, 2)$, while those on the target manifold $M$ are denoted by $u^i (i = 1, \ldots, \dim M)$. The metric and complex structure of $\Sigma$ are denoted by $h_{\alpha\beta}$ and $\epsilon^\alpha{}_\beta$, respectively; they obey the relations $\epsilon^\alpha{}_\beta \epsilon^\beta{}_\gamma = -\delta^\alpha{}_\gamma$ and $\epsilon_{\alpha\beta} = h_{\alpha\gamma}\epsilon^\gamma{}_\beta$. The metric tensor $g_{ij}$ and almost-complex structure $J^i{}_j$ of $M$ obey analogous relations to the above. In the general model, the target space need only be an almost-complex manifold. This requires the existence of a globally defined tensor field $J^i{}_j$ such that $J^i{}_j J^j{}_k = -\delta^i{}_k$.

The action [3] is invariant under the topological shift symmetry

$$\delta u^i = \epsilon^i \qquad [7]$$

where $\epsilon^i$ is an arbitrary local function of the coordinates on the base manifold $\Sigma$. Already, at this level, we see the distinction with the standard sigma model. The presence of this shift symmetry means that all local degrees of freedom can be gauged away, leaving only a finite number of global topological degrees of freedom. It requires some work to determine the corresponding transformation for $G^{\alpha i}$, the key point being the preservation of the self-duality constraint. We find

$$\begin{aligned} \delta G^{\alpha i} = {} & P^{\alpha i}_{+\ \beta j}\left(D^\beta \epsilon^j + \tfrac{1}{2}\epsilon^\beta{}_\gamma \epsilon^l \left(D_l J^j{}_k\right)\partial^\gamma u^k\right) \\ & + \tfrac{1}{2}\epsilon^\alpha{}_\beta \epsilon^k \left(D_k J^i{}_j\right) G^{\beta j} - \Gamma^i_{lk}\epsilon^k G^{\alpha l} \end{aligned} \qquad [8]$$

where the covariant derivative is defined by $D_\alpha \epsilon^i = \partial_\alpha \epsilon^i + \Gamma^i_{jk}(\partial_\alpha u^j)\epsilon^k$.

Having determined the classical symmetries of the model, we can now proceed with the BRST quantized form of the quantum action. As a topological field theory of Witten type, one can show that the quantum action can be written as a BRST commutator, that is, $S_{\mathrm{q}} = \{Q, V\}$, where the gauge fermion $V$ is defined by

$$V = \int \mathrm{d}^2\sigma \sqrt{h}\, \bar{C}_{\alpha i}\left(\partial^\alpha u^i - \frac{\alpha}{4} B^{\alpha i}\right) \qquad [9]$$

where $\alpha$ is an arbitrary gauge-fixing parameter. The BRST operator $Q$ is nilpotent $Q^2 = 0$, off-shell. It is defined by $\delta\Phi = \epsilon\{Q, \Phi\}$, and takes the form

$$\begin{aligned} \delta u^i &= -\epsilon C^i \\ \delta C^i &= 0 \\ \delta \bar{C}_{\alpha i} &= \epsilon\left(B_{\alpha i} + \frac{1}{2}\epsilon_\alpha{}^\beta \left(D_k J_i{}^j\right)\bar{C}_{\beta j} C^k + \Gamma^k_{ij}\bar{C}_{\alpha k} C^j\right) \\ \delta B^{\alpha i} &= \frac{\epsilon}{4} C^k C^l \left(R^{i_t}_{kl} + R_{klrs} J^{ri} J^s{}_t\right)\bar{C}^{\alpha t} \\ & \quad - \frac{\epsilon}{2}\epsilon^\alpha{}_\beta \left(D_k J^i{}_j\right) C^k B^{\beta j} \\ & \quad + \frac{\epsilon}{4}\left(C^k D_k J^i{}_s\right)\left(C^l D_l J_t{}^s\right)\bar{C}^{\alpha t} + \epsilon \Gamma^i_{jk} C^j B^{\alpha k} \end{aligned} \qquad [10]$$

In the above, the ghost field is denoted by $C^i$, while the anti-ghost field $\bar{C}_{\alpha i}$ and the multiplier field $B_{\alpha i}$ obey the self-duality constraint [5]. The key point to note in the above transformations is the fact that the ghost field $C^i$ is BRST invariant. Again, this is a feature which is generic to all cohomological field theories. The existence of such a field allows the construction of an entire set of topological correlation functions, as we shall see in the following section.

While the gauge-fixing parameter $\alpha$ is arbitrary, a conventional choice is to take $\alpha = 1$, and then integrate out the multiplier field $B$. This yields the action in the form

$$\begin{aligned} S_q = \int d^2\sigma\sqrt{h}\Big[&\frac{1}{2}h^{\alpha\beta}g_{ij}\partial_\alpha u^i\partial_\beta u^j + \frac{1}{2}\epsilon^{\alpha\beta}J_{ij}\partial_\alpha u^i\partial_\beta u^j \\ &+ \bar{C}_{\alpha i}\left(D^\alpha C^i + \frac{1}{2}\epsilon^\alpha{}_\beta(D_j J^i{}_k)\partial^\beta u^k C^j\right) \\ &+ \frac{1}{8}\bar{C}_\alpha{}^m\bar{C}^{\alpha k}R_{mkjr}C^jC^r \\ &+ \frac{1}{16}\bar{C}_{\alpha i}\bar{C}^{\alpha k}(D_j J^{li})(D_r J_{lk})C^jC^r\Big] \end{aligned} \qquad [11]$$

It should be stressed that the classical gauge algebra [7] and [8] only closes on-shell. Quantization of the model is therefore more subtle, and requires use of the Batalin–Vilkovisky formalism. The on-shell closure problem automatically results in the presence of quartic ghost coupling terms in the action and consequently cubic terms in the BRST transformations. Despite this, we have established that the full quantum action can be written as a BRST commutator.

The form of the action simplifies when the complex structure of the target manifold is covariantly constant, $D_k J^i{}_j = 0$. In this case, the target manifold $M$ is Kähler and we denote the complex coordinates as $u^I$, with their complex conjugates denoted by $u^{\bar{I}}$. The nonzero components of the metric tensor are then $g_{I\bar{J}}$. Similarly, the coordinates of $\Sigma$ are denoted $\sigma^\pm$, with nonzero metric components $h_{+-}$. The nonzero components of the ghost and anti-ghost are then given by $C^I, C^{\bar{I}}, \bar{C}_{+\bar{I}}, \bar{C}_{-I}$. The action can be written in the form

$$\begin{aligned} S_q = \int d^2\sigma\sqrt{h}\Big[&h^{+-}g_{I\bar{J}}\partial_+ u^I\partial_- u^{\bar{J}} + \frac{1}{2}\bar{C}_+{}^I(D_- C^{\bar{J}})h^{+-}g_{I\bar{J}} \\ &+ \frac{1}{2}\bar{C}_-{}^{\bar{I}}(D_+ C^J)h^{+-}g_{I\bar{J}} \\ &+ \frac{1}{4}h^{+-}\bar{C}_+{}^I\bar{C}_-{}^{\bar{I}}R_{I\bar{I}J\bar{J}}C^JC^{\bar{J}}\Big] \end{aligned} \qquad [12]$$

## Construction of Observables

Having defined the quantum action, it is now of interest to consider the correlation functions of the model. In the functional integral, we integrate over all maps $\Sigma \to M$ in a fixed homotopy class. Let us consider a correlation function

$$\langle\mathcal{O}\rangle = \int du^i\, d\bar{C}_{\alpha i}\, dC^i\, e^{-tS_q}\mathcal{O} \qquad [13]$$

where $t > 0$ is a parameter, and the observable $\mathcal{O}$ is BRST invariant $\{Q, \mathcal{O}\} = 0$. From the BRST invariance of the vacuum, it follows immediately that the vacuum expectation value of a BRST commutator is zero, $\langle\{Q, \mathcal{O}\}\rangle = 0$. An operator which is a BRST commutator is said to be $Q$-exact. Hence, our interest is in the $Q$-cohomology classes of operators, that is, BRST invariant operators modulo BRST exact operators. It is for this reason that such a model is called a cohomological field theory.

One can now show that the variation of [13] with respect to $t$ is a BRST commutator, namely

$$\delta_t\langle\mathcal{O}\rangle = -\delta t\int du^i\, d\bar{C}_{\alpha i}\, dC^i\, e^{-tS_q}\{Q, V\mathcal{O}\} = 0 \qquad [14]$$

As a result, one can evaluate the correlation function in the large-$t$ (weak-coupling) limit. In this limit, the path integral is dominated by fluctuations around the classical minima. For the sigma model under study, the classical action is minimized by the instanton configurations

$$\partial_\alpha u^i + \epsilon_\alpha{}^\beta J^i{}_j\partial_\beta u^i = 0 \qquad [15]$$

Indeed, this localization of the path integral to the moduli space of instantons can also be seen by choosing the $\alpha = 0$ gauge in [9]. Integration over the multiplier field then imposes a delta function constraint to the instanton configurations. The key point in the above derivation is the fact that the quantum action is a BRST commutator, $S_q = \{Q, V\}$. By a similar argument, one can show that variations of $\langle\mathcal{O}\rangle$ with respect to the metric and complex structure of $\Sigma$ and $M$ are also zero.

Our aim now is to construct the $Q$-cohomology classes of operators in the theory. Let us first associate an operator $\mathcal{O}_A^{(0)}$ to each $p$-form $A = A_{i_1\cdots i_p}\, du^{i_1}\wedge\cdots\wedge du^{i_p}$ on the target space $M$, given by

$$\mathcal{O}_A^{(0)} = A_{i_1\cdots i_p}C^{i_1}\cdots C^{i_p} \qquad [16]$$

where $C^i$ is the ghost field. Under a BRST transformation, we see that

$$\begin{aligned} \{Q, \mathcal{O}_A^{(0)}\} &= -\partial_{i_0}A_{i_1\cdots i_p}C^{i_0}\cdots C^{i_p} \\ &= -\mathcal{O}_{dA}^{(0)} \end{aligned} \qquad [17]$$

since the ghost fields are BRST invariant by [10]. Hence, $\mathcal{O}_A^{(0)}$ is BRST invariant if and only if $A$ is a closed $p$-form. Similarly, if $A$ is an exact $p$-form, then the corresponding operator is $Q$-exact. Hence, the BRST cohomology classes of these operators are in one to one correspondence with the de Rham cohomology classes on $M$. The reason for assigning the peculiar superscript to the operator $\mathcal{O}^{(0)}$ will become clear at the end of this construction. Notice also that operators of the form $\mathcal{O}_A^{(0)}$ can be used as building blocks for constructing new observables. If we consider a set of closed forms $A_1, \ldots, A_k$, then the product of the associated operators $\mathcal{O}_{A_1}^{(0)} \cdots \mathcal{O}_{A_k}^{(0)}$ is clearly $Q$-invariant as well.

When considering the vacuum expectation values of operators which are polynomials in the fields, there is an implicit dependence on the points where the operators are located. In the case at hand however, the operator $\mathcal{O}_A^{(0)}(\sigma)$ at the point $\sigma$ has a vacuum expectation value which is a topological invariant, and thus cannot depend on the chosen point. To see this explicitly, we consider all fields defined over $\Sigma$, and differentiate the operator with respect to some local coordinates $\sigma^\alpha$:

$$\frac{\partial}{\partial\sigma^\alpha} A_{i_1\cdots i_p} C^{i_1}\cdots C^{i_p} = (\partial_{i_0} A_{i_1\cdots i_p}) \frac{\partial u^{i_0}}{\partial\sigma^\alpha} C^{i_1}\cdots C^{i_p} + p A_{i_1\cdots i_p} (\partial_{i_0} C^{i_1}) \frac{\partial u^{i_0}}{\partial\sigma^\alpha} C^{i_2}\cdots C^{i_p} \qquad [18]$$

In terms of exterior derivatives, this takes the form,

$$\begin{aligned} d\mathcal{O}_A^{(0)} &= \partial_{i_0} A_{i_1\cdots i_p} du^{i_0} C^{i_1}\cdots C^{i_p} + p A_{i_1\cdots i_p} dC^{i_1} C^{i_2}\cdots C^{i_p} \\ &= \{Q, \mathcal{O}_A^{(1)}\} \end{aligned} \qquad [19]$$

where $\mathcal{O}_A^{(1)} = -p A_{i_1\cdots i_p} du^{i_1} C^{i_2}\cdots C^{i_p}$, and we have used the fact that $A$ is a closed $p$-form. If we let $\gamma$ represent any path between two arbitrary points $P$ and $P'$, then this expression has the integral form,

$$\mathcal{O}_A^{(0)}(P) - \mathcal{O}_A^{(0)}(P') = \left\{Q, \int_\gamma \mathcal{O}_A^{(1)}\right\} \qquad [20]$$

and we see that the vacuum expectation value of $\mathcal{O}_A^{(0)}$ is point independent by the BRST invariance of the vacuum. The same remark applies to any product of operators of the form we are considering.

To continue our construction, consider a one-dimensional homology cycle $\gamma(\partial\gamma = 0)$, and define

$$W_A^{(1)}(\gamma) = \int_\gamma \mathcal{O}_A^{(1)} \qquad [21]$$

This new operator $W_A^{(1)}(\gamma)$ is BRST invariant by inspection,

$$\left\{Q, W_A^{(1)}(\gamma)\right\} = \int_\gamma \left\{Q, \mathcal{O}_A^{(1)}\right\} = \int_\gamma d\mathcal{O}_A^{(0)} = 0 \qquad [22]$$

Moreover, if $\gamma$ happens to be the boundary of a two-dimensional surface $(\gamma = \partial\beta)$, so that $\gamma$ is trivial in homology, then this new operator is likewise trivial in $Q$ cohomology:

$$W_A^{(1)}(\gamma) = \int_\gamma \mathcal{O}_A^{(1)} = \int_\beta d\mathcal{O}_A^{(1)} = \left\{Q, \int_\beta \mathcal{O}_A^{(2)}\right\} \qquad [23]$$

where

$$\mathcal{O}_A^{(2)} = -\frac{p(p-1)}{2} A_{i_1\cdots i_p} du^{i_1} \wedge du^{i_2} C^{i_3}\cdots C^{i_p}$$

As before, let us now associate to each homology 2-cycle $\beta(\partial\beta = 0)$, another BRST invariant operator $W_A^{(2)}$ defined by

$$W_A^{(2)}(\beta) = \int_\beta \mathcal{O}_A^{(2)} \qquad [24]$$

The BRST invariance follows trivially as in [23].

In summary, we have produced three operators $\mathcal{O}_A^{(0)}, \mathcal{O}_A^{(1)}$, and $\mathcal{O}_A^{(2)}$ from any given closed form $A$, which satisfy the relations:

$$\begin{aligned} 0 &= \left\{Q, \mathcal{O}_A^{(0)}\right\}, & d\mathcal{O}_A^{(0)} &= \left\{Q, \mathcal{O}_A^{(1)}\right\} \\ d\mathcal{O}_A^{(1)} &= \left\{Q, \mathcal{O}_A^{(2)}\right\}, & d\mathcal{O}_A^{(2)} &= 0 \end{aligned} \qquad [25]$$

The BRST observables are then given by arbitrary products of the integrated operators $W_A^{(i)}(\gamma) = \int_\gamma \mathcal{O}_A^{(i)}$, where $\gamma$ is any $i$-cycle in homology.

## Observables and Intersection Theory

Let us consider the computation of the correlation function $\langle\mathcal{O}\rangle$ in the background field method. We first pick a background instanton configuration [15], and then integrate over the quantum fluctuations around that instanton. The relevant part of the quantum action is quadratic in the quantum fields, and localization of the model then ensures that such a computation is exact. The quantum fields are expanded into eigenfunctions of the operators that appear in the quadratic part of the action, and the functional integral is replaced by an integral over the eigenmodes. However, if there are fermionic zero modes, then those modes do not enter in the action. As a result, the fermionic integrals $(\int d\chi = 0)$ over those modes will cause $\langle\mathcal{O}\rangle$ to vanish unless it has the correct fermion content; the zero modes must be absorbed. In our case, a glance at the quantum action indicates that we should concern ourselves with the zero modes of the ghost $C^i$ and anti-ghost

$\bar{C}_{\alpha i}$. A $C^i$ zero mode is clearly in the kernel of the operator

$$\bar{D}^i_{\alpha j} = D_\alpha \delta^i{}_j + \epsilon_{\alpha\beta} J^i{}_j D^\beta + \epsilon_{\alpha\beta}(D_j J^i{}_k)\partial^\beta u^k \qquad [26]$$

and a $\bar{C}_{\alpha i}$ zero mode is a zero eigenfunction of its adjoint $\bar{D}^*$. In the BRST quantization of the model, the ghost fields $C^i$ are assigned ghost number +1, while the anti-ghost fields $\bar{C}_{\alpha i}$ have ghost number –1. It is therefore apparent that the vacuum expectation value of any observable will vanish unless that observable has a ghost number equal to the number of $\bar{D}$ zero modes, $a$, minus the number of $\bar{D}^*$ zero modes, $b$. This difference, $\omega = a - b$, is called the index of the operator $\bar{D}$.

There is a direct link between this index and the dimension of the moduli space of instantons. Recall that we are considering the space of maps $\Sigma \to M$ in a specified homotopy class, which satisfy equation [15]. It is then of interest to determine the dimension of the space of such solutions. To this aim, we examine the constraint that arises by considering an instanton $u^i$, and another neighboring solution $u^i + \hat{u}^i$, where $\hat{u}^i$ is an infinitesimal deformation. To first order in $\hat{u}^i$, we see that $\hat{u}^i$ must be a zero mode of the operator $\bar{D}$. This is no coincidence, and we can thus interpret the ghost fields $C^i$ as cotangent vectors to instanton moduli space $\mathcal{M}$. In particular, if $\mathcal{M}$ is a smooth manifold, then $\dim \mathcal{M} = a$. The index of the operator $\bar{D}$ is called the virtual dimension of the moduli space. In generic situations, the virtual dimension is equal to the actual dimension $\dim \mathcal{M}$.

It is possible to interpret some of the observables that we have described in terms of intersection theory applied to the moduli space of instantons. In particular, one can show that all correlation functions of the form

$$\left\langle \mathcal{O}^{(0)}_{A_1} \cdots \mathcal{O}^{(0)}_{A_s} \right\rangle \qquad [27]$$

are intersection numbers of certain submanifolds of moduli space. In order to see this in a simple example, we first recall the notion of Poincaré duality and the relationship between cohomology and homology.

Poincaré duality can be formulated as a relationship between de Rham cohomology (defined in terms of closed differential forms) and homology (defined in terms of subspaces of $M$). For our purposes here, it is sufficient to state that we can associate to each boundaryless submanifold $N$ of codimension $k$, a cohomology class $[\phi] \in H^k(M)$, such that

$$\int_M \phi \wedge \psi = \int_N \psi \qquad [28]$$

for all $[\psi] \in H^{n-k}(M)$. By $\psi$ on the right-hand side of this equation, we mean the pullback $i^*\psi$ under the inclusion $i : N \to M$. Conversely, to each closed $k$-form $\phi$ on $M$, we can associate an $(n-k)$-cycle $N$ (it is in general a chain of subspaces), unique up to homology, such that the previous relation is satisfied. Furthermore, one can show that the Poincaré dual to $N$ can be chosen in such a way that its support is localized within any given open neighborhood of $N$ in $M$ (essentially delta function support on $N$).

Let us now define the notion of transversal intersection. For simplicity, we will first consider the intersection of two submanifolds $M_1$ and $M_2$ contained in $M$. We will say that these two submanifolds have transversal intersection if the tangent spaces satisfy

$$T_x(M_1) + T_x(M_2) = T_x(M) \qquad [29]$$

for all $x \in M_1 \cap M_2$. It is a theorem that a submanifold of codimension $k$ can be locally "cut-out" by $k$ smooth functions, that is, the submanifold is locally specified by the zeros of this set of functions. It is a worthwhile exercise to convince oneself that the definition of transversal intersection is equivalent to the statement that the functions which cut-out $M_1$ are independent from those which cut-out $M_2$. Thus, we can write

$$\operatorname{codim}(M_1 \cap M_2) = \operatorname{codim}(M_1) + \operatorname{codim}(M_2) \qquad [30]$$

More generally, we say that the intersection $M_1 \cap \cdots \cap M_s$ of $s$ submanifolds is transversal if the intersection of every pair of them is transversal. It then follows trivially by the previous argument that the codimensions must satisfy

$$\operatorname{codim}(M_1 \cap \cdots \cap M_s) = \sum_{i=1}^{s} \operatorname{codim}(M_i) \qquad [31]$$

The special case which will be important for us occurs when the intersection of submanifolds is a collection of points, that is, when the codimension of the intersection is equal to the dimension of $M$. Since these points are isolated, the compactness of $M$ guarantees that they are finite in number.

We are now in a position to describe in what sense correlation functions of the form $\left\langle \mathcal{O}^{(0)}_{A_1} \cdots \mathcal{O}^{(0)}_{A_s} \right\rangle$ determine intersection numbers in the moduli space $\mathcal{M}$ of instantons. By definition, this moduli space is the set of maps from $\Sigma$ to $M$ which satisfy [15]. Let us consider the generic situation, where the virtual dimension of $\mathcal{M}$ (i.e., the index of $\bar{D}$) is equal to $\dim \mathcal{M}$. For convenience, let us begin by choosing the forms $A_i$ which represent de Rham cohomology classes on $M$, together with their Poincaré duals $M_i$, such that the forms have essentially delta function

support on their respective submanifolds. Since each of the operators in the correlation function depends on some fixed point $\sigma_i$, it is meaningful to define the submanifolds $L_i \equiv \{u \in \mathcal{M} \mid u(\sigma_i) \in M_i\} \subset \mathcal{M}$. Now, the correlation function represents a functional integral over the space of maps $\mathrm{Map}(\Sigma, M)$, and we have argued that this integral only receives contributions from the instanton configurations. Since the operators $A_i(u(\sigma_i))$ vanish unless $u \in L_i$ by our choice of the Poincaré duals, we see that the only contribution to the functional integral can be from those maps which lie in the intersection $L_1 \cap \cdots \cap L_s$. By ghost number considerations, this correlation function must vanish unless the codimension of the intersection equals the virtual dimension of $\mathcal{M}$. In the generic case where the virtual dimension is equal to $\dim \mathcal{M}$, this means that the intersection is simply a finite number of points. Intersection numbers $\pm 1$ can then be assigned to each point in the intersection $L_1 \cap \cdots \cap L_s$, by considering the relative orientation of the submanifolds $L_i$ at the intersection points. From the functional integral point of view, the computation reduces to an evaluation of the ratio of the bosonic determinant (integration over $u^i$) to the fermionic determinant (integration over $C^i$ and $\bar{C}_{\alpha i}$). In the Kähler case, for example, the intersection number assigned to each point in the intersection is always +1. This is due to the fact that the $C^I, \bar{C}_-{}^{\bar{I}}$ determinant is the complex conjugate of the $C^{\bar{I}}, \bar{C}_+{}^{I}$ determinant.

## *A* and *B* Models and Mirror Symmetry

The topological sigma model for a Kähler target space [12] is also known as the topological *A* model. In this case, the action can be recovered by twisting the standard $N=2$ supersymmetric sigma model. This twisting procedure amounts to a reassignment of the spins of the fields in the theory. However, there is an alternative twisting which can be done, and this leads to another model known as the topological *B* model. The usefulness of this observation lies in the fact that the topological *A* model on a Calabi–Yau target space *M* is related to the topological *B* model on the mirror of *M*. This relationship and the computation of correlation functions in the *A* and *B* models thus sheds light on the nature of mirror symmetry.

# Turbulence Theories

**R M S Rosa**, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

## Introduction

Turbulence has initially been defined as an irregular motion in fluids. The cloud formations in the atmosphere and the motion of water in rivers make this point clear. These are but a few readily available examples of a multitude of flows which display turbulent regimes: from the blood that flows in our veins and arteries to the motion of air within our lungs and around us; from the flow of water in creeks to the atmospheric and oceanic currents; from the flows past submarines, ships, automobiles, and aircraft to the combustion processes propelling them; and in the flow of gas, oil, and water, from the prospecting end to the entrails of the cities. The great majority of flows in nature and in engineering applications are somehow turbulent.

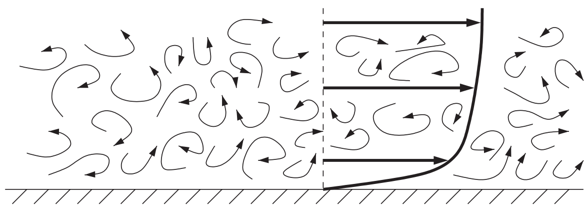

**Figure 1** Illustration of the irregular motion of a turbulent flow over a flat plate (thin lines), and of the well-defined velocity profile of the mean flow (thick lines).

But turbulent flows are much more than simply irregular. More refined definitions were desirable and were later coined. A definitive and precise one, however, may only come when the phenomenon is fully understood. Nevertheless, several characteristic properties of a turbulent flow can be listed:

*Irregularity and unpredictability* A turbulent flow is irregular both in space and time, displaying unpredictable, random patterns.

*Statistical order* From the irregularity of a turbulent motion there emerges a certain statistical order. Mean quantities and correlation are regular and predictable (Figure 1).

*Wide range of active scales* A wide range of scales of motion are active and display an irregular motion, yielding a large number of degrees of freedom.

*Mixing and enhanced diffusivity* The fluid particles undergo complicated and convoluted paths, causing a large mixing of different parts of fluid. This mixing significantly enhances diffusion, increasing the transport of momentum, energy, heat, and other advected quantities.

*Vortex stretching* When a moving portion of fluid also rotates transversally to its motion an increase in speed causes it to rotate faster, a phenomenon called vortex stretching. This causes that portion of fluid to become thinner and elongated, and fold and intertwine with other such portions. This is an intrinsically three-dimensional mechanism which plays a fundamental role in turbulence and is associated with large fluctuations in the vorticity field.

## Turbulent Regimes

Turbulence is studied from many perspectives. The subject of "transition to turbulence" attempts to describe the initial mechanisms responsible for the generation of turbulence starting from a laminar motion in particular geometries. This transition can be followed with respect to position in space (e.g., the flow becomes more complicated as we look further downstream on a flow past an obstacle or over a flat plate) or to parameters (e.g., as we increase the angle of attack of a wing or the pressure gradient in a pipe). This subject is divided into two cases: wall-bounded and free-shear flows. In the former, the viscosity, which causes the fluid to adhere to the surface of the wall, is the primary cause of the instability in the transition process. In the latter, inviscid mechanisms such as mixing layers and jets are the main factors. The tools for studying the transition to turbulence include linearization of the equations of motion around the laminar solution, nonlinear amplitude equations, and bifurcation theory.

"Fully developed turbulence," on the other hand, concerns turbulence which evolves without imposed constraints, such as boundaries and external forces. This can be thought of turbulence in its "pure" form, and it is somewhat a theoretical framework for research due to its idealized nature. Hypotheses of homogeneity (when the mean quantities associated with the statistical order characterizing a turbulent flow are independent in space), stationarity (*idem* in time), and isotropy (*idem* with respect to rotations in space) concern fully developed turbulent flows. The Kolmogorov theory was developed in this context and it is the most fundamental theory of turbulence. Current research is dedicated in great part to unveil the mechanisms behind a phenomenon called intermittency and how it affects the laws obtained from the conventional theory. Research is also dedicated to derive such laws as much from first principles as possible, minimizing the use of phenomenological and dimensional analysis.

Real turbulent flows involve various regimes at once. A typical flow past a blunt object, for instance, displays laminar motion at its upstream edge, a turbulent boundary layer further downstream, and the formation of a turbulent wake (Figure 2). The subject of turbulent boundary layer is a world in itself with current research aiming to determine mean properties of flows over rough surfaces and varied topography. Convective turbulence involves coupling with active scalars such as

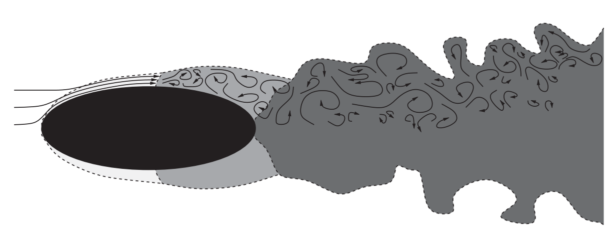

**Figure 2** Illustration of a flow past an object, with a laminar boundary layer (light gray), a turbulent boundary layer (medium gray), and a turbulent wake (dark gray).

large heat gradients, occurring in the atmosphere, and large salinity gradients, in the ocean. Geophysical turbulence involves also stratification and the anisotropy generated by Earth's rotation. Anisotropic turbulence is also crucial in astrophysics and plasma theory. Multiphase and multicomponent turbulence appear in flows with suspended particles or bubbles and in mixtures such as gas, water, and oil. Transonic and supersonic flows are also of great importance and fall into the category of compressible turbulence, much less explored than the incompressible case.

In all those real situations one would like, from the engineering point of view, to compute mean properties of the flow, such as drag and lift for more efficient designs of aircraft, ships, and other vehicles. Knowledge of the drag coefficient is also of fundamental importance in the design of pipes and pumps, from pipelines to artificial human organs. Mean turbulent diffusion coefficients of heat and other passive scalars – quantities advected by the flow without interfering on it, such as chemical products, nutrients, moisture, and pollutants – are also of major importance in industry, ecology, meteorology, and climatology, for instance. And in most of those cases a large amount of research is dedicated to the "control of turbulence," either to increase mixing or reduce drag, for instance. From a theoretical point of view, one would like to fully understand and characterize the mechanisms involved in turbulent flows, clarifying this fascinating phenomenon. This could also improve practical applications and lead to a better control of turbulence.

The concept of "two-dimensional turbulence" is controversial. A two-dimensional flow may be irregular and display mixing, statistical order, and a wide range of active scales but definitely it does not involve vortex stretching since the velocity field is always perpendicular to the vorticity field. For this reason many researchers discard two-dimensional turbulence altogether. It is also argued that real two-dimensional flows are unstable at complicated regimes and soon develop into a three-dimensional flow. Nevertheless, many believe that two-dimensional turbulence, even lacking vortex stretching, is of fundamental theoretical importance. It may shed some light into the three-dimensional theory and modeling, and it can serve as an approximation to some situations such as the motion of the atmosphere and oceans in the large and meso scales and some magnetohydrodynamic flows. The relative shallowness of the atmosphere and oceans or the imposition of a strong uniform magnetic field may force the flow into two-dimensionality, at least for a certain range of scales.

"Chaos" serves as a paradigm for turbulence, in the sense that it is now accepted that turbulence is a dynamic processes in a sensitive deterministic system. But not all chaotic motions in fluids are termed turbulent for they may not display mixing and vortex stretching or involve a wide range of scales. An important such example appears in the dispersive, nonlinear interactions of waves.

## The Equations of Motion

It is usually stressed that turbulence is a continuum phenomenon, in the sense that the active scales are much larger than the collision mean free path between molecules. For this reason, turbulence is believed to be fully accounted for by the Navier–Stokes equations.

In the case of incompressible homogeneous flows, the Navier–Stokes equations in the Eulerian form and in vector notation read

$$\frac{\partial \boldsymbol{u}}{\partial t} - \nu\Delta\boldsymbol{u} + (\boldsymbol{u}\cdot\nabla)\boldsymbol{u} + \nabla p = \boldsymbol{f} \qquad [1a]$$

$$\nabla\cdot\boldsymbol{u} = 0. \qquad [1b]$$

Here, $\boldsymbol{u} = \boldsymbol{u}(\boldsymbol{x}, t) = (u_1, u_2, u_3)$ denotes the velocity vector of an idealized fluid particle located at position $\boldsymbol{x} = (x_1, x_2, x_3)$, at time $t$. The mass density in a homogeneous flow is constant, denoted $\rho$. The constant $\nu$ denotes the kinematic viscosity of the fluid, which is the molecular viscosity $\mu$ divided by $\rho$. The variable $p = p(\boldsymbol{x}, t)$ is the kinematic pressure, and $\boldsymbol{f} = \boldsymbol{f}(\boldsymbol{x}, t) = (f_1, f_2, f_3)$ denotes the mass density of volume forces.

Equation [1a] expresses the conservation of linear momentum. The term $\nu\Delta\boldsymbol{u}$ accounts for the dissipation of energy due to molecular viscosity, and the nonlinear term $(\boldsymbol{u}\cdot\nabla)\boldsymbol{u}$, also called the inertial term, accounts for the redistribution of energy among different structures and scales of motion. Equation [1b] represents the incompressibility condition. In Einstein's summation convention, these equations can be written as

$$\frac{\partial u_i}{\partial t} + \nu\frac{\partial^2 u_i}{\partial x_j^2} + u_j\frac{\partial u_i}{\partial x_j} + \frac{\partial p}{\partial x_i} = f_i, \quad \frac{\partial u_j}{\partial x_j} = 0$$

## The Reynolds Number

The transition to turbulence was carefully studied by Reynolds in the late nineteenth century in a series of experiments in which water at rest in a tank was allowed to flow through a glass pipe. Starting with dimensional analysis, Reynolds argued that a critical

value of a certain nondimensional quantity was likely to exist beyond which a laminar flow gives rise to a "sinuous" motion. This was followed by observations of the flow for tubes with different diameter $L$, different mean velocities $U$ across the tube section, and with the kinematic viscosity $\nu = \rho/\mu$ being altered through changes in temperature. The experiments confirmed the existence of such a critical value for what is now called the Reynolds number:

$$Re = \frac{LU}{\nu}$$

The dimensional analysis argument can be reproduced in the following form: the physical dimension for the inertial term in [1a] is $U^2/L$, while that for the viscous term is $\nu U/L^2$. The ratio between them is precisely $Re = LU/\nu$. For small values of $Re$ viscosity dominates and the flow is laminar, whereas for large values of $Re$ the inertial term dominates, and the flow becomes more complicated and eventually turbulent. In applications, different types of Reynolds number can be used depending on the choice of the characteristic velocity and length, but in any case, the larger the Reynolds number, the more complicated the flow.

## The Reynolds Equations

Another advance put forward by Reynolds in a subsequent article was to decompose the flow into a mean component and the remaining fluctuations. In terms of the velocity and pressure fields this can be written as

$$\boldsymbol{u} = \bar{\boldsymbol{u}} + \boldsymbol{u}', \qquad p = \bar{p} + p' \qquad [2]$$

with $\bar{\boldsymbol{u}}$ and $\bar{p}$ representing the mean components and $\boldsymbol{u}'$ and $p'$, the fluctuations. By substituting [2] into [1], one finds the Reynolds-averaged Navier–Stokes (RANS) equations for the mean flow:

$$\frac{\partial \bar{\boldsymbol{u}}}{\partial t} - \nu \Delta \bar{\boldsymbol{u}} + (\bar{\boldsymbol{u}} \cdot \nabla)\bar{\boldsymbol{u}} + \nabla \bar{p} = \boldsymbol{f} + \nabla \cdot \tau$$

$$\nabla \cdot \bar{\boldsymbol{u}} = 0$$

It differs from [1] only by the addition of the Reynolds stress tensor:

$$\tau = -\overline{\boldsymbol{u}' \otimes \boldsymbol{u}'} = -\left(\overline{u_i' u_j'}\right)_{i,j=1}^{3}$$

In a laminar flow, the fluctuations are negligible, otherwise this decomposition shows how they influence the mean flow through this additional turbulent stresses.

## The Closure Problem and Turbulence Models

The RANS equations cannot be solved directly for the mean flow since the Reynolds stresses are unknown. Equations for these stress terms can be derived but they involve further unknown moments. This continues with equations for moments of a given order depending on new moments up to a higher order, leading to an infinite system of equations known as the Friedman–Keller system. For practical applications, approximations closing the system at some finite order are needed, in what is called the closure problem. Several *ad hoc* approximations exist, the most famous being the Boussinesq eddy-viscosity approximation, in which the turbulent fluctuations are regarded as increasing the viscosity of the flow. Prandtl's mixing-length hypothesis yields a prescription for the computation of this eddy viscosity, and together they form the basis of the algebraic models of turbulence. Other models involve additional equations, such as the $k$-$\epsilon$ and $k$-$\omega$ models. Most of the practical computations of industrial flows are based on such lower-order models, and a large amount of research is done to determine appropriate values for the various *ad hoc* parameters which appear in these models and which are highly dependent on the geometry of the flow. This dependency can be explained by the fact that the RANS is supposed to model the mean flow even at the large scales of motion, which are highly affected by the geometry.

Computational fluid dynamics (CFD) is indeed a fundamental tool in turbulence, both for research and engineering applications. From the theoretical side, direct numerical simulations (DNS), which attempt to resolve all the active scales of the flow, reveal some fundamental mechanisms involved in the transition to turbulence and in vortex stretching. As for applications, DNS applies to flows up to low-Reynolds turbulence, with the current computational power not allowing for a full resolution of all the scales involved in high-Reynolds flows. And the current rate of evolution of computational power predicts that this will continue so for several decades.

An intermediate CFD method between RANS and DNS is the large-eddy simulation (LES), which attempts to fully resolve the large scales while modeling the turbulent motion at the smaller scales. Several models have been proposed which have their own advantages and limitations as compared to RANS and DNS. It is currently a subject of intense research, particularly for the development of suitable models for the structure functions near the boundary. Theoretical results on fully developed turbulence play a fundamental role in the modeling process.

LESs are a promising tool and they have been successfully applied to a number of situations. The choice of the best method for a given application, however, depends very much on the Reynolds number of the flow and the prior knowledge of similar situations for adjusting the parameters.

## Elements of the Statistical Theory

Several types of averages can be used. The ensemble average is taken with respect to a number of experiments at nearly identical conditions. Despite the irregular motion of, say, the velocity vector $\boldsymbol{u}^{(n)}(\boldsymbol{x}, t)$ of each experiment $n = 1, \ldots, N$, the average value

$$\bar{u}(\boldsymbol{x}, t) = \frac{1}{N}\sum_{n=1}^{N} \boldsymbol{u}^{(n)}(\boldsymbol{x}, t)$$

is expected to behave in a more regular way. This type of averaging is usually denoted with the symbol $\langle \cdot \rangle$. This notion can be cast into the context of a probability space $(\mathcal{M}, \Sigma, \mathcal{P})$, where $\mathcal{M}$ is a set, $\Sigma$ is a $\sigma$-algebra of subsets of $\mathcal{M}$, and $\mathcal{P}$ is a probability measure on $\Sigma$. The velocity field is a random variable in the sense that it is a density function $\omega \mapsto \boldsymbol{u}(\boldsymbol{x}, t, \omega)$ from $\mathcal{M}$ into the space of time-dependent divergence-free velocity fields. The mean velocity field in this context is regarded as

$$\langle \boldsymbol{u}(\boldsymbol{x}, t)\rangle = \int_{\mathcal{M}} \boldsymbol{u}(\boldsymbol{x}, t, \omega)\mathrm{d}\mathcal{P}(\omega)$$

Other flow quantities such as energy and correlations in space and time can be expressed by means of a function $\varphi = \varphi(\boldsymbol{u}(\cdot, \cdot))$ of the velocity field, with their mean value given by

$$\langle \varphi(\boldsymbol{u}(\cdot, \cdot))\rangle = \int_{\mathcal{M}} \varphi(\boldsymbol{u}(\cdot, \cdot, \omega)\mathrm{d}\mathcal{P}(\omega)$$

In general, the statistics of the flow are allowed to change with time. A particular situation is when statistical equilibrium is reached, so that $\langle \boldsymbol{u}(\boldsymbol{x}, t)\rangle$ and, more generally, $\langle \varphi(\boldsymbol{u}(\cdot, \cdot + t))\rangle$ are independent of $t$. In this case, an ergodic assumption is usually invoked, which means that for "most" individual flows $\boldsymbol{u}(\cdot, \cdot, \omega_0)$ (i.e, for almost all $\omega_0$ with respect to the probability measure $\mathcal{P}$), the time averages along this flow converge to the mean ensemble value as the period of the average increases to the mean value obtained by the ensemble average:

$$\lim_{T\to\infty} \frac{1}{T}\int_0^T \varphi(\boldsymbol{u}(\cdot, \cdot + s, \omega_0))\mathrm{d}s = \int_{\mathcal{M}} \varphi(\boldsymbol{u}(\cdot, \cdot, \omega))\mathrm{d}\mathcal{P}(\omega)$$

Based on this assumption, the averages may in practice be calculated as time averages over a sufficiently large period $T$. There is a related argument for substituting space averages by time averages and based on the mechanics of turbulence which is called the "Taylor hypothesis."

Another fundamental concept in the statistical theory is that of homogeneity, which is the spatial analog of the statistical equilibrium in time. In homogeneous turbulence, the statistical quantities of a flow are independent of translations in space, that is,

$$\langle \varphi(\boldsymbol{u}(\cdot + \ell, \cdot))\rangle = \langle \varphi(\boldsymbol{u}(\cdot, \cdot))\rangle$$

for all $\ell \in \mathbb{R}^3$. The concept of isotropic turbulence assumes further independence with respect to rotations and reflections in the frame of reference, that is,

$$\langle \varphi(Q^{\mathrm{t}}\boldsymbol{u}(Q\cdot, \cdot))\rangle = \langle \varphi(\boldsymbol{u}(\cdot, \cdot))\rangle$$

for all orthogonal transformations $Q$ in $\mathbb{R}^3$, with adjoint $Q^{\mathrm{t}}$.

Under the homogeneity assumption, mean quantities can be defined independently of position in space, such as the mean kinetic energy per unit mass

$$e = \frac{1}{2}\langle |\boldsymbol{u}(\boldsymbol{x})|^2\rangle = \frac{1}{2}\sum_{j=1}^{3}\langle |u_i(\boldsymbol{x})|^2\rangle$$

and the mean rate of viscous energy dissipation per unit mass and unit time

$$\epsilon = \nu \sum_{i=1}^{3}\langle |\nabla u_i(\boldsymbol{x})|^2\rangle = \nu \sum_{i,j=1}^{3}\left\langle \left|\frac{\partial u_i(\boldsymbol{x})}{\partial x_j}\right|^2\right\rangle$$

The mean kinetic energy can be written as $e = \mathrm{tr}R(0)/2$, where

$$\mathrm{tr}R(\ell) = R_{11}(\ell) + R_{22}(\ell) + R_{33}(\ell), \quad \ell \in \mathbb{R}^3,$$

is the trace of the correlation tensor

$$R(\ell) = \langle \boldsymbol{u}(\boldsymbol{x}) \otimes \boldsymbol{u}(\boldsymbol{x} + \ell)\rangle = (R_{ij}(\ell))_{i,j=1}^3 = (\langle u_i(\boldsymbol{x})u_j(\boldsymbol{x} + \ell)\rangle)_{i,j=1}^3$$

which measures the correlation between the velocity components at different positions in space. From the homogeneity assumption, this tensor is a function only of the relative position $\ell$. Then, assuming that the Fourier transform of $\mathrm{tr}R(\ell)$ exists, and denoting it by $Q(\kappa)$, for $\kappa \in \mathbb{R}^3$, we have

$$\mathrm{tr}R(\ell) = \frac{1}{(2\pi)^{3/2}}\int_{\mathbb{R}^3} Q(\kappa)\mathrm{e}^{\mathrm{i}\ell\cdot\kappa}\mathrm{d}\kappa = 2\int_0^\infty S(\kappa)\mathrm{e}^{\mathrm{i}\ell\cdot\kappa}\mathrm{d}\kappa$$

where $\mathcal{S}(\kappa)$ is the energy spectrum defined by

$$\mathcal{S}(\kappa) = \frac{1}{2(2\pi)^{3/2}} \int_{|\kappa|=\kappa} Q(\kappa) \mathrm{d}\Sigma(\kappa)$$
$$\forall \kappa > 0$$

with $\mathrm{d}\Sigma(\kappa)$ denoting the area element of the 2-sphere of radius $|\kappa|$. Then we can write

$$e = \frac{1}{2}\langle |\boldsymbol{u}(\boldsymbol{x})|^2 \rangle = \frac{1}{2}\mathrm{tr}R(0) = \int_0^\infty \mathcal{S}(\kappa)\mathrm{d}\kappa$$

By expanding the velocity coordinates into Fourier modes $\exp(\ell \cdot \kappa)$, with $\kappa \le |\kappa| \le \kappa + \mathrm{d}\kappa$ and interpreting them as "eddies" with characteristic wave number $|\kappa|$, the quantity $\mathcal{S}(\kappa)\mathrm{d}\kappa$ can be interpreted as the energy of the component of the flow formed by the "eddies" with characteristic wave number between $\kappa$ and $\kappa + \mathrm{d}\kappa$.
Similarly,

$$\epsilon = 2\nu \int_0^\infty \kappa^2 \mathcal{S}(\kappa)\mathrm{d}\kappa$$

and we obtain the dissipation spectrum $2\nu\kappa^2\mathcal{S}(\kappa)$, which can be interpreted as the density of energy dissipation occurring at wave number $\kappa$.

In the previous arguments it is assumed that the flow extends to all the space $\mathbb{R}^3$. This avoids the presence of boundaries, addressing the idealized case of fully developed turbulence. It is sometimes customary to assume as well that the flow is periodic in space to avoid problems with unbounded domains such as infinite kinetic energy.

The random nature of turbulent flows was greatly explored by Taylor in the early twentieth century, who introduced most of the concepts described above. Another important concept he introduced was the Taylor microlength $\ell_\mathrm{T}$, which is a characteristic length for the small scales based on the correlation tensor. A microscale Reynolds number based on the Taylor microlength is very often used in applications.

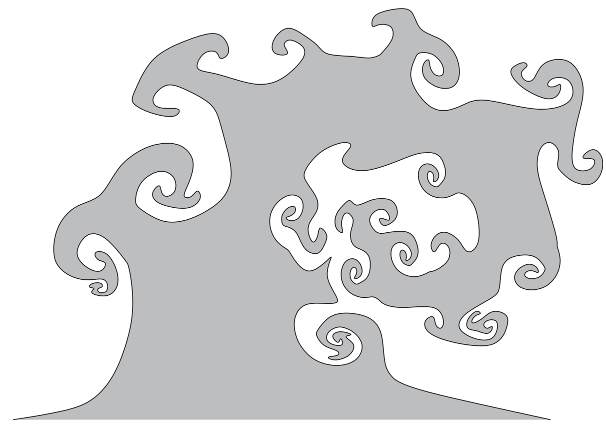

**Figure 3** Illustration of the eddy breakdown process in which energy is transferred to smaller eddies and so on until the smallest scales are reached and the energy is dissipated by viscosity.

## Kolmogorov Theory

An inspiring concept in the theory of turbulence is Richardson's "energy cascade" process. For large Reynolds numbers the nonlinear term dominates the viscosity according to the dimensional analysis, but this is valid only for the large-scale structures. The small scales have their own characteristic length and velocity. In the cascade process, the inertial term is responsible for the transfer of energy to smaller and smaller scales until small enough scales are reached for which viscosity becomes important (Figure 3). At those smallest scales kinetic energy is finally dissipated into heat. It should be emphasized that turbulence is a dissipative process; no matter how large the Reynolds number is, viscosity plays a role in the smallest scales.

The Kolmogorov theory of locally isotropic turbulence allows for inhomogeneity and anisotropy in the large scales, which contain most of the energy, assuming that with the cascade transfer of energy to smaller scales, the orienting effects generated in the large scales become weaker and weaker so that for sufficiently small eddies the motion becomes statistically homogeneous, isotropic, and independent of the particular energy-productive mechanisms. He proposed that the statistical regime of the small-scale eddies is then universal and depends only on $\nu$ and $\epsilon$. The equilibrium range is defined as the range of scales in which this universality holds.

Simple dimensional analysis shows that the only algebraic combination of $\nu$ and $\epsilon$ with dimension of length is $\ell_\epsilon = (\nu^3/\epsilon)^{1/4}$, which is then interpreted as that near which the viscous effect becomes important and hence most of the energy dissipation takes place. The scale $\ell_\epsilon$ is known as Kolmogorov dissipation length.

Kolmogorov theory gives particular attention to moments involving differences of velocities, such as the $p$th-order structure function

$$S_p(\ell) \stackrel{\mathrm{def}}{=} \langle (\boldsymbol{u}(\boldsymbol{x} + \ell\boldsymbol{e}) \cdot \boldsymbol{e} - \boldsymbol{u}(\boldsymbol{x})\boldsymbol{e})^p \rangle$$

where $\boldsymbol{e}$ may be taken as an arbitrary unit vector, thanks to the isotropy assumption. By restricting the search for universal laws for the structure functions only for small values of $\ell$ anisotropy and inhomogeneity are allowed in the large scales.

The theory assumes a wide separation between the energy-containing scales, of order say $\ell_0$, and the energy-dissipative scales, of order $\ell_\epsilon$, so that the cascade process occurs within a wide range of scales $\ell$ such that $\ell_0 \gg \ell \gg \ell_\epsilon$. In this range, termed the inertial range, the viscous effects are still negligible and the statistical regime should depend only on $\epsilon$. Then, the Kolmogorov "two-thirds law" asserts that within the inertial range the second-order correlations must be proportional to $(\epsilon\ell)^{2/3}$, that is,

$$S_2(\ell) = C_K(\epsilon\ell)^{2/3}$$

for some constant $C_K$ known as the Kolmogorov constant in physical space (there is a related constant in spectral space). The argument extends to higher-order structure functions, yielding

$$S_p(\ell) = C_p(\epsilon\ell)^{p/3}$$

Kolmogorov's derivation of these results was not by dimensional analysis, it was in fact a more convincing self-similarity argument based on the universality assumed for the equilibrium range. A different argument without resorting to universality assumptions, however, was applied to the third-order structure function, yielding the more precise "four-fifths law":

$$S_3(\ell) = -\tfrac{4}{5}\epsilon\ell$$

The "Kolmogorov five-thirds law" concerns the energy spectrum $\mathcal{S}(\kappa)$ and is the spectral version of the two-thirds law, given by Obukhoff:

$$\mathcal{S}(\kappa) = C'_K\epsilon^{2/3}\kappa^{-5/3}$$

The constant $C'_K$ is the Kolmogorov constant in spectral space. The spectral version of the dissipation length is the Kolmogorov wave number $\kappa_\epsilon = (\epsilon/\nu^3)^{1/4}$.

A typical distribution of energy in a turbulent flow is depicted in Figure 4. The energy is concentrated on the large scales, while the dissipation is concentrated near the Kolmogorov scale $\ell_\epsilon$. The four-fifths law becomes visible as a straight line in the logarithmic scale.

A more precise mechanism for the energy cascade assumes that in the inertial range, eddies with length scale $\ell$ transfer kinetic energy to smaller eddies during their characteristic timescale, also known as circulation time. If $u_\ell$ is their characteristic velocity, then $\tau_\ell = \ell/u_\ell$ is their circulation time, so that the kinetic energy transferred from these eddies during this time is

$$\epsilon_\ell \sim \frac{u_\ell^2}{\tau_\ell} = \frac{u_\ell^3}{\ell}$$

In statistical equilibrium, the energy lost to the smaller scales equals the energy gained from the larger scales, and that should also equal the total kinetic energy dissipated by viscous effects. Hence, $\epsilon_\ell \equiv \epsilon$, and we find

$$\epsilon \sim \frac{u_\ell^3}{\ell}$$

It also follows that $\tau_\ell = \ell/u_\ell = \ell(\epsilon\ell)^{-1/3} = \epsilon^{-1/3}\ell^{2/3}$ so that the circulation time decreases with the length scale and becomes of the order of the viscous dissipation time $(\nu/\epsilon)^{1/2}$ precisely when $\ell \sim \ell_\epsilon$.

A similar relation between $\epsilon$ and the large scales can also be obtained with heuristic arguments: let $e$ be the mean kinetic energy and $\ell_0$, a characteristic length for the large scales. Then $u_0$ given by $e = u_0^2/2$ is a characteristic velocity for the large scales, and $\tau_0 = \ell_0/u_0$ is the large-scale circulation time. In statistical equilibrium, the rate $\epsilon$ of kinetic energy dissipated per unit time and unit mass is expected to be of the order of $e/\tau_0$, hence

$$\epsilon \sim \frac{u_0^3}{\ell_0}$$

which is called the "energy dissipation law."

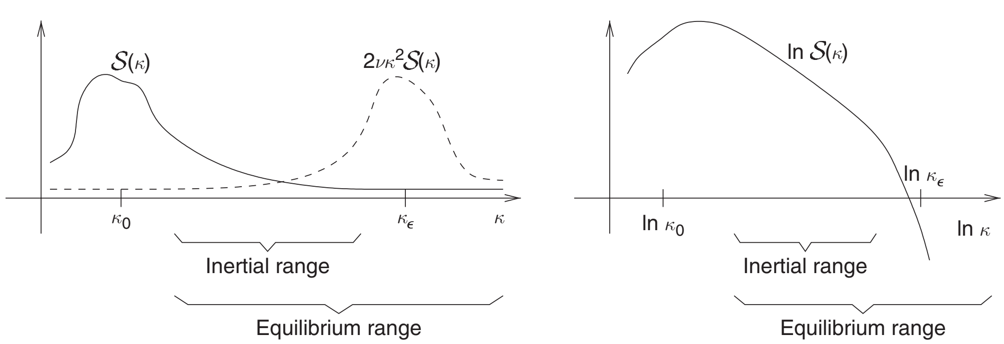

**Figure 4** A typical distribution for the energy spectrum $\mathcal{S}(\kappa)$ and the dissipation spectrum $2\nu\kappa^2\mathcal{S}(\kappa)$ in spectral space in nonlogarithmic and logarithmic scales. The energy is mostly concentrated on the large scales while the dissipation is concentrated near the dissipation scale. In the logarithmic scale, the four-fifths law for the energy spectrum stands out as a straight line with slope $-4/5$ over the inertial range.

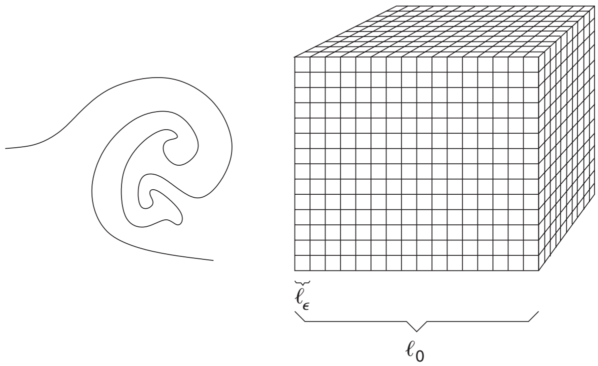

**Figure 5** A schematic representation of a flow structure displaying a range of active scales and a three-dimensional grid with linear dimension $\ell_0$ and mesh length $\ell_\epsilon$, sufficient to represent all the active scales in a turbulent flow. The number of degrees of freedom is the number of blocks: $(\ell_0/\ell_\epsilon)^3$.

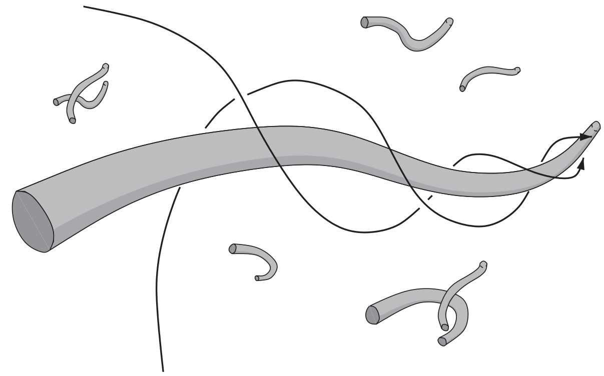

**Figure 6** A portion of rotating fluid gets stretched and thinned as the flow speeds up, generating one of many coherent structures of high vorticity and low dissipation.

From the energy dissipation law, several relations between characteristic quantities of turbulent flows can be obtained, such as $\ell_0/\ell_\epsilon \sim Re^{3/4}$, for $Re = \ell_0 u_0/\nu$.

Now, assuming the active scales in a turbulent flow exist down to the Kolmogorov scale $\ell_\epsilon$, one needs a three-dimensional grid with mesh spacing $\ell_\epsilon$ to resolve all the scales, which means that the number $N$ of degrees of freedom of the system is of the order of $N \sim (\ell_0/\ell_\epsilon)^3$ (see Figure 5). This number can be estimated in terms of the Reynolds number by $N \sim Re^{9/4}$. This relation is important in predicting the computational power needed to simulate all the active scales in turbulent flows.

Several such universal laws can be deduced and extended to other situations such as turbulent boundary layers, with the famous logarithmic law of the wall. They play a fundamental role in turbulence modeling and closure, for the calculation of the mean flow and other quantities.

## Intermittency

The universality hypothesis based on a constant mean energy dissipation rate throughout the flow received some criticisms and was later modified by Kolmogorov in an attempt to account for observed large deviations on the mean rate of energy dissipation. Such phenomenon of intermittency is related to the vortex stretching and thinning mechanism, which leads to the formation of coherent structures of vortex filaments of high vorticity and low dissipation (Figure 6). These filaments have diameter as small as the Kolmogorov scale and longitudinal length extending from the Taylor scale up to the large scales and with a lifetime of the order of the large-scale circulation time.

It has been argued based on experimental evidence that intermittency leads to modified power laws $S_p(\ell) \propto \ell^{\zeta(p)}, \zeta(p) < p/3$, for high-order ($p > 3$) structure functions. The issues of intermittency and coherent structures and whether and how they could affect the deductions of the universality theory such as the power laws for the structure functions are far from settled and are currently one of the major and most fascinating issues being addressed in turbulence theory. Several phenomenological theories attempt to adjust the universality theory to the existence of such coherent structures. Multifractal models, for instance, suppose that the eddies generated in the cascade process do not fill up the space and form multifractal structures. Field-theoretic renormalization group develops techniques based on quantum field renormalization theory. Intermediate asymptotics also exploits self-similar analysis and renormalization theory but with a somewhat different flavor. Detailed mathematical analysis of the vorticity equations is also playing a major role in the understanding of the dynamics of the vorticity field.

## Mathematical Aspects of Turbulence Theory

From a mathematical perspective, it is fundamental to develop a rigorous background upon which to study the physical quantities of a turbulent flow. The first problem in the mathematical theory is related to the deterministic nature of chaotic systems assumed in dynamical system theory and believed to hold in turbulence. This has actually not been proved for the Navier–Stokes equations. It is in fact one of the most outstanding open problems in mathematics to determine whether given an initial condition for the velocity field there exists, in some sense, a unique solution of the Navier–Stokes equations starting with this initial condition and valid for all later times. It has been proved that a global solution (i.e., valid for all later

times) exists but which may not be unique, and it has been proved that unique solutions exist which may not be global (i.e., they are guaranteed to exist as unique solutions only for a finite time).

The difficulty here is the possible existence of singularities in the vorticity field (vorticity becoming infinite at some points in space and time). Depending on how large the singularity set is, uniqueness may fail in strictly mathematical terms. The existence of singularities may not be a purely mathematical curiosity, it may in fact be related with the intermittency phenomenon. Rigorous studies of the vorticity equation may continue to reveal more fundamental aspects on vortex dynamics and coherent structures.

The statistical theory has also been put into a firm foundation with the notion of statistical solution of the Navier–Stokes equations. It addresses the existence and regularity of the probability distribution assumed for turbulent flows and of the fundamental elements of the statistical theory such as correlation functions and spectra. Based on that, a number of relations between physical quantities of turbulent flows may be derived in a mathematically sound and definitive way. This does not replace other theories, it is mostly a mathematical framework upon which other techniques can be applied to yield rigorous results.

Despite the difficulties in the mathematical theory of the NSE some successes have been collected such as estimates for the number of degrees of freedom in terms of fractal dimensions of suitable sets associated with the solutions of the Navier–Stokes equations, and partial estimates of a number of relations derived in the statistical theory of fully developed turbulence.

# Twistor Theory: Some Applications

**L Mason**, University of Oxford, Oxford, UK

## Introduction

Roger Penrose introduced twistor theory as a geometrical framework for basic physics in order to unify quantum theory and gravity. This program has had many successes along the way, but the long-term goals of reformulating and superceding the established theories of basic physics are still a long way from being fulfilled. Nevertheless, the successes have had many important applications across mathematics and mathematical physics. This article will concentrate on three areas of application: integrable systems, geometry, and perturbative gauge theory (via twistor-string theory). It is intended to be self-contained as far as possible, but the reader may well find it easier to first read the article Twistors.

## Twistor Theory

A basic motivation of twistor theory is to bring out the complex (holomorphic) geometry that underlies real spacetime. In general relativity, a spacetime is a 4-manifold with metric $g$ of signature $(1,3)$, and when it is flat, that is, $g = \mathrm{d}t^2 - \mathrm{d}x^2 - \mathrm{d}y^2 - \mathrm{d}z^2$, where $(t,x,y,z)$ are coordinates on $\mathbb{R}^4$, it is called Minkowski space. The first appearance of a complex structure arises from the fact that, at a given event, the celestial sphere of light rays (directions of zero length with respect to $g$) naturally has the structure of the Riemann sphere, $\mathbb{CP}^1$, in such a way that Lorentz transformations (linear transformations of the tangent space preserving the metric) act on this sphere by Möbius transformations. These are the maximal group of complex analytic transformations of $\mathbb{CP}^1$.

Twistor space extends this idea to the whole of Minkowski space. Denoted $\mathbb{PT}$, the twistor space for Minkowski space is complex projective 3-space, $\mathbb{CP}^3$, the space of one-dimensional subspaces of $\mathbb{C}^4$; it is a three-dimensional complex manifold obtained by adding a "plane at infinity" to $\mathbb{C}^3$. Explicitly, we can introduce homogeneous coordinates $Z^\alpha \in \mathbb{C}^4 - \{0\}$ with $\alpha = 0,1,2,3$ but where $Z^\alpha \sim \lambda Z^\alpha$ for $\lambda \in \mathbb{C} - \{0\}$. Affine coordinates on a $\mathbb{C}^3$ chart $Z^3 \neq 0$ can be obtained by setting $(z_1, z_2, \lambda) = (Z^0/Z^3, Z^1/Z^3, Z^2/Z^3)$. Physically, points of twistor space correspond to spinning massless particles in Minkowski space. Mathematically, the correspondence can be understood as the Klein correspondence.

## The Klein Correspondence

The correspondence between $\mathbb{PT}$ and Minkowski space can be extended first to complexified Minkowski space so that the coordinates are allowed to take on values in $\mathbb{C}$, and then to its conformal compactification by including the "light cone at infinity." It then coincides with the classical complex Klein correspondence. The Klein correspondence is the one-to-one correspondence between lines in $\mathbb{CP}^3$ and points of a four complex-dimensional quadric, $\mathbb{CM}$, in $\mathbb{CP}^5$. The 4-quadric $\mathbb{CM}$ can be understood as conformally compactified complexified Minkowski space. Introducing affine coordinates $(z_1, z_2, \lambda)$ on $\mathbb{PT}$ and $(t,x,y,z)$ on $\mathbb{CM}$, we find that a point $(t,x,y,z)$ in $\mathbb{CM}$ corresponds to a line in $\mathbb{PT}$ according to

$$\begin{pmatrix} z_1 \\ z_2 \end{pmatrix} = \begin{pmatrix} t - z & x + \mathrm{i}y \\ x - \mathrm{i}y & t + z \end{pmatrix} \begin{pmatrix} 1 \\ \lambda \end{pmatrix}$$

Alternatively, fixing $(\lambda, z_1, z_2)$ in these equations gives a 2-plane in complex Minkowski space corresponding to all the lines in $\mathbb{PT}$ through $(\lambda, z_1, z_2)$. Such 2-planes are called "$\alpha$-planes." They are totally null (i.e., the tangent vectors not only have zero length but are also mutually orthogonal) and also self-dual (under the differential geometer's notion of Hodge duality).

This complex correspondence can also be restricted to give correspondences for $\mathbb{R}^4$ with metrics of positive-definite, Euclidean, signature or ultrahyperbolic, $(2,2)$, signature. A particular simplification in Euclidean signature is that the complex $\alpha$-planes intersect the real slice in a point. The conformal compactification of Euclidean $\mathbb{R}^4$ is the 4-sphere $S^4$ given by adding a single point at infinity, and so we have a projection $p : \mathbb{PT} \to S^4$ whose fibers are holomorphically embedded $\mathbb{CP}^1$s. These fibers can be characterized as the lines in $\mathbb{PT}$ that are invariant under a quaternionic complex conjugation which is an antiholomorpic map $\hat{}: \mathbb{PT} \to \mathbb{PT}$ with no fixed points. (Here quaternionic means that on the nonprojective twistor space, $\mathbb{T} = \mathbb{C}^4$, the conjugation has the property $\hat{\hat{Z}} = -Z$ so that it defines a second complex structure anticommuting with the standard one; this is sufficient to express $\mathbb{T} = \mathbb{Q}^2$, where $\mathbb{Q}$ denotes the quaternions. The complex structures $i$, $j$, and $k$ of the quaternions are given by identifying $i$ with $\sqrt{-1}$ on $\mathbb{C}^4$ and $j$ with $\hat{}$ and $k = ij$.)

## The Penrose Transform

A basic task of twistor theory is to transform solutions to the field equations of mathematical physics into objects on twistor space. This works well for linear massless fields such as the Weyl neutrino equation, Maxwell's equations for electromagnetism and linearized gravity. In its general form, this transform has become known as the Penrose transform. Such fields correspond to freely prescribable holomorphic functions $f(\lambda, z_1, z_2)$ (or, more precisely, analytic cohomology classes) on regions of twistor space. The field can be obtained from this function by means of a contour integral. The simplest of these integral formulas is

$$\phi(x^a) = \oint f(\lambda, t - z + \lambda(x + \mathrm{i}y), x - \mathrm{i}y + \lambda(t + z))\mathrm{d}\lambda$$

and differentiation under the integral sign leads easily to the fact that $\phi$ satisfies the wave equation

$$\frac{\partial^2\phi}{\partial t^2} - \frac{\partial^2\phi}{\partial x^2} - \frac{\partial^2\phi}{\partial y^2} - \frac{\partial^2\phi}{\partial z^2} = 0$$

This formula was originally discovered by Bateman. Note that $f$ must have singularities on twistor space to yield a nontrivial $\phi$ and even then, there are many choices of $f$ that yield zero. For a solution $\phi$ defined

over a region $U$ in spacetime, the function $f$ is correctly understood as a representative of a Cech cohomology class defined on the region $U'$ in twistor space swept out by the lines corresponding to points of $U$. Furthermore, the function $f$ should be taken globally to be a function of homogeneity –2, $f(\lambda Z^\alpha) = \lambda^{-2} f(Z^\alpha)$. This formula has generalizations to massless fields of all helicities in which a field of helicity $s$ corresponds to a function (Cech cocycle) of homogeneity degree $2s - 2$.

The Penrose transform has found important applications in representation theory and integral geometry. For a review, the reader is referred to Baston and Eastwood (1989), the relevant survey articles in Bailey and Baston (1990), or Mason and Hughston (1990, chapter 1).

## Twistor Theory and Nonlinear Equations

The Penrose transform for the Maxwell equations and linearized gravity turns out to be linearizations of correspondences for the nonlinear analogs of these equations: the Einstein vacuum equations and the Yang–Mills equations. However, the constructions only work when these fields are anti-self-dual. This is the condition that the curvature 2-forms satisfy $F^* = -\mathrm{i}F$, where $*$ denotes the Hodge dual (which, up to certain factors of $\pm\mathrm{i}$, has the effect of interchanging electric and magnetic fields); it is a nonlinear generalization of the right-handed circular polarization condition. Explicitly, in terms of spacetime indices $a, b, \ldots = 0, 1, 2, 3$, $F^*_{ab} = (1/2)\varepsilon_{abcd}F^{cd}$, where $\varepsilon_{0123} = 1$ and $\varepsilon_{abcd} = \varepsilon_{[abcd]}$. In Minkowski signature, the i factor in the anti-self-duality condition implies that real fields cannot be anti-self-dual. Thus, these extensions are not sufficient to fulfill the ambitions of twistor theory to incorporate real classical nonlinear physics in Minkowski space. However, the factor of i is not present in Euclidean and ultrahyperbolic signature, so the anti-self-duality condition is consistent with real fields in these signatures and this is where the main applications of these constructions have been.

### The Nonlinear Graviton Construction and Its Generalizations

The first nonlinear twistor construction was due to Penrose (1976), and was inspired by Newman's (1976) construction of "heavens" from the infinities of asymptotically flat spacetimes in general relativity.

The nonlinear graviton construction proceeds from the definition of twistors in flat spacetime as $\alpha$-planes in complexified Minkowski space. It is natural to ask which complexified metrics admit a full family of $\alpha$-surfaces, that is, 2-surfaces that are totally null and self-dual. The answer is that a full family of $\alpha$-surfaces exists iff the conformally invariant part of the curvature tensor, the Weyl tensor, is anti-self-dual. If this is the case, twistor space can be defined to be the (necessarily three-dimensional) space of such $\alpha$-surfaces.

The remarkable fact is that the twistor space, together with its complex structure, is sufficient to determine the original spacetime. Twistor space is again a three-dimensional complex manifold, and contains holomorphically embedded rational curves, $\mathbb{CP}^1$s, at least one for each point of the spacetime. However, holomorphic rigidity implies that the family of rational curves is precisely four-dimensional over the complex numbers. Furthermore, incidence of a pair of curves can be taken to imply that the corresponding points in spacetime lie on a null geodesic and this yields a conformal structure on spacetime. Further structures on twistor space can be imposed to give the complex spacetime a metric that is vacuum, perhaps with a cosmological constant. The correspondence is stable under small deformations and so the data defining the twistor space is effectively freely prescribable, see Penrose (1976).

In Euclidean signature, again the complex $\alpha$-planes intersect the real spacetime in a point, so the twistor space again fibers over spacetime. The twistor fibration can be constructed as the projectivized bundle of self-dual spinors or more commonly as the unit sphere bundle in the space of self-dual 2-forms (Atiyah *et al.* 1978). In the latter formulation, the complex structure on the twistor space arises from the direct sum of the naturally defined complex structures on the horizontal and vertical tangent spaces to the bundle; that on the vertical subspace is the standard one on the sphere, and that on the horizontal subspace is a multiple of the self-dual 2-form at the given point of the fiber.

There are now large families of extensions, generalizations, and reductions of this construction. They are all based on the idea of realizing a space with a given complexified geometric structure as the parameter space of a family of holomorphically embedded submanifolds inside a twistor space. In general, the most useful of these constructions are those in which the "spacetime" is obtained as the space of rational curves in a twistor space. This is because the equations that are solved on the corresponding spacetime can be thought of as a completely integrable system in which the integrability condition for the generalized $\alpha$-surfaces is interpreted as the consistency condition of a Lax

pair or more general linear system. For a more detailed discussion from this point of view, see Mason and Woodhouse (1996, chapter 13).

### The Anti-Self-Dual Yang–Mills Equation and Its Twistor Correspondence

The anti-self-dual Yang–Mills equations extend Maxwell's equations for electromagnetism in the right-circularly polarized case. They are a family of equations that depend on a choice of Lie group $G$, usually taken to be a group of complex matrices; Maxwell's equations arise when $G = \mathrm{U}(1)$.

Introduce coordinates $x^a, a = 0, 1, 2, 3$, on $\mathbb{R}^4$ with metric $\mathrm{d}s^2 = \mathrm{d}x^0 \cdot \mathrm{d}x^3 - \mathrm{d}x^1 \cdot \mathrm{d}x^2$ (this is a metric of ultrahyperbolic signature – Euclidean signature can be obtained by choosing the coordinates to be complex, but with $(x^3, -x^2)$ the complex conjugates of $(x^0, x^1)$). The dependent variables are the components $A_a$ of a connection $D_a = \partial_a - A_a$, where $\partial_a = \partial/\partial x^a$ and $A_a = A_a(x^b) \in \mathrm{Lie}\, G$, the Lie algebra of $G$. This connection defines a method of differentiating vector-valued functions $s$ in some representation of $G$. The freedom in changing bases for the vector bundle induce the gauge transformations $A_a \to g^{-1}A_a g - g^{-1}\partial_a g, g(x) \in G$ on $A_a$; two connections that are related by a gauge transformation are deemed to be the same. The self-dual Yang–Mills equations are the condition

$$[D_0, D_2] = [D_1, D_3] = [D_0, D_3] - [D_1, D_2] = 0$$

They are the compatibility conditions

$$[D_0 + \lambda D_1,\, D_2 + \lambda D_3] = 0$$

for the linear system of equations

$$(D_0 - \lambda D_1)s = (D_2 - \lambda D_3)s = 0 \qquad [1]$$

where $\lambda \in C$ and $s$ is an $n$-component column vector. These latter equations form a "Lax pair" for the system.

The Ward (1977) construction provides a one–one correspondence between gauge equivalence classes of solutions of the self-dual Yang–Mills equations and holomorphic vector bundles on regions in twistor space. The key point here is that eqn [1] defines parallel propagation along $\alpha$-planes. To each point $Z$ in twistor space, we can associate the vector space $E_Z$ of solutions to eqn [1] along the corresponding $\alpha$-plane. These vector spaces vary holomorphically with $Z$ and that is what one means by a holomorphic vector bundle $E \to \mathbb{PT}$. The remarkable fact is that the anti-self-dual Yang–Mills field can be reconstructed up to gauge from $E$, and, in effect, for local analytic solutions, $E$ can be represented by freely prescribable "patching" data consisting of local holomorphic matrix-valued functions on twistor space. To construct the solution on spacetime, one must first find a Birkhoff factorization of the patching data on each Riemann sphere in twistor space corresponding to points of the appropriate region in spacetime. On each Riemann sphere, the Birkhoff factorization starts with the given patching function with values in $\mathrm{GL}(n, \mathbb{C})$ on the real axis in the complex plane, and expresses it as a product of functions with values in $\mathrm{GL}(n, \mathbb{C})$ one of which extends over the upper-half plane, and the other over the lower-half complex plane. The anti-self-dual connection can be obtained by differentiating the resulting matrices. See Penrose (1984, 1986), Ward and Wells (1990), or Mason and Woodhouse (1996) for a full discussion, and Atiyah (1979) for the formulation appropriate to Euclidean signature.

## Completely Integrable Systems

In effect, the twistor constructions amount to providing a geometric general local solution to the anti-self-duality equations; the twistor data is, for a local solution, freely prescribable. In this sense, they demonstrate complete integrability of the anti-self-duality equations. The reconstruction of a solution on spacetime from twistor data is not a quadrature – it involves, in the anti-self-dual Yang–Mills case, a Birkhoff factorization (also sometimes referred to as the solution to a Riemann–Hilbert problem), and in the case of the anti-self-dual Einstein equations, the construction of a family of rational curves inside a complex manifold. Nevertheless, such constructions are a familiar part of the apparatus of the theory of integrable systems.

In Ward (1985), this connection with integrable systems was developed further, and the anti-self-dual Yang–Mills equations were shown to yield many important integrable systems under symmetry reduction. Ward's list has been extended and now includes many of the most famous examples of integrable systems such as the Painlevé equations, the Korteweg–de Vries (KdV) equation, the nonlinear Schrödinger equation, the $n$-wave equations, and so on, see Mason and Woodhouse (1996) for a review. There are some notable omissions from the list such as the Kadomtsev–Petviashvili (KP) and Davey–Stewartson equations (at least if one restricts oneself to finite-dimensional gauge groups; reductions using infinite dimensional gauge groups have been obtained).

The list of integrable systems obtainable by symmetry reduction nevertheless remains impressive and provides a route to the classification of at least those integrable systems that can be obtained in this

way. Such systems can be classified by the choice of ingredients required in the symmetry reduction: the gauge group, the group of spacetime symmetries to be reduced by, the choice of Euclidean or ultra-hyperbolic signature, and the choice of certain constants of integration that arise in the reduction.

Another implication is that if an integrable system can be obtained from one of the self-duality equations by symmetry reduction, then it inherits a reduced twistor correspondence because the twistor correspondences share the symmetry groups of the spacetime field equations. These twistor correspondences can be seen to underlie much of the theory of these equations; for example, Backlund transformations of solutions correspond to elementary algebraic operations on the twistor data, similarly the Kac–Moody Lie algebras of hidden symmetries act locally on the twistor data by matrix multiplication of the appropriate loop algebras. Similarly, the inverse-scattering transform for the KdV and non-linear Schrodinger equations can be seen to arise as particular presentations of the twistor construction.

By and large, although twistor methods have yielded new insight into the geometry and structure of systems in dimensions 1 and 2, they have not necessarily superceded pre-existing techniques for constructing solutions and analyzing the solution space. The systems for which twistor methods have been particularly effective for constructing solutions and characterizing their properties are in $2+1$ or higher dimension. Key examples here are of course the anti-self-dual Yang–Mills and Einstein equations themselves, and their single translation reductions. In the anti-self-dual Yang–Mills case, these reductions lead either to Ward's or Manakov and Zakharov's chiral model in Lorentzian signature, $2+1$, or the Bogomolny equations for monopoles, the reduction from Euclidean signature. In both cases, the twistor construction has played a major role in constructing and studying the solitonic solutions.

See Ward and Wells (1990), Mason and Woodhouse (1996), Ward's article in Huggett *et al.* (1998) and the first few chapters of Mason *et al.* (1995), and Mason *et al.* (2001) for more examples of aspects of the theory of integrable systems arising from twistor correspondences.

## Applications to Geometry

These applications are, to a large extent, higher-dimensional analogs of those discussed above; most of the problems in geometry to which twistor theory has been applied are those for which the underlying differential equations are integrable. These start with the Euclidean signature versions of the original Ward construction for anti-self-dual Yang–Mills fields and Penrose's nonlinear graviton construction for Ricci-flat anti-self-dual metrics but, as we will discuss, these constructions have a number of extensions and generalizations.

The first dramatic application of these constructions was the ADHM construction of Yang–Mills instantons. These are absolute minima of the Yang–Mills action, $S[A] = \int \mathrm{tr}(F \wedge F^*)$ on the 4-sphere, $S^4$, with its round metric. A simple argument shows that the action is bounded below by the second Chern class of the bundle and that this bound is achieved only for anti-self-dual fields. Thus, the problem was to characterize all the anti-self-dual Yang–Mills fields on $S^4$. In this Euclidean context, twistor space, $\mathbb{CP}^3$, fibers over $S^4$ and the corresponding Ward vector bundle is a bundle over all of $\mathbb{CP}^3$. It turns out that all such bundles satisfying a certain stability condition had been constructed reasonably explicitly by algebraic geometers. Since the stability condition was implied by the context, this could be turned into an algebraic construction of the general instanton explicit enough to give some insight into both the local and global structure of the solution space. See Atiyah (1979) for a review.

Hitchin used the Euclidean version of the non-linear graviton to develop the theory of gravitational instantons that are asymptotically locally Euclidean (i.e., asymptotically $\mathbb{R}^4/\Gamma$, where $\Gamma$ is a finite subgroup of the rotation group). These were finally constructed by Kronheimer who again used twistor theory to identify the appropriate parameter space, see his article in Mason *et al.* (2001) and Dancer's review of hyper-Kähler manifolds in LeBrun and Wang (1999).

Even in four dimensions, there are a number of variants of the nonlinear graviton construction. The basic twistor correspondence produces a twistor space that is a complex 3-manifold $\mathcal{PT}$ for 4-manifolds with conformal structures whose Weyl tensor is anti-self-dual. There are four natural specializations that have attracted study: (1) the Ricci-flat case, (2) the Einstein case (with nonzero cosmological constant), (3) the scalar-flat Kähler case, and (4) the hypercomplex case.

The twistor space in the Ricci-flat case admits the additional structure of a fibration over $\mathbb{CP}^1$ together with a holomorphic Poisson structure on the fibers with values in the pullback of the 1-forms on $\mathbb{CP}^1$ (alternatively, the bundle of holomorphic 3-forms should be the pullback of the square of the bundle of holomorphic 1-forms on $\mathbb{CP}^1$). The Einstein case with nonzero cosmological constant is a variant of this in which the twistor space admits a

nondegenerate holomorphic contact structure, that is, a distribution of 2-plane elements, which are only integrable when the cosmological constant vanishes. It also admits a Kähler form when the scalar curvature is positive (in the negative case the corresponding Kähler form is indefinite). For the case of Kähler metrics with vanishing scalar curvature, the twistor space admits a holomorphic volume form with a double pole. The Ricci-flat case is equivalent to the case of hyper-Kähler metrics, those that are Kähler with respect to three different complex structures $I, J$, and $K$ satisfying the standard quaternionic relations $IJ = K$, etc. A hypercomplex structure is obtained when one only has the three integrable complex structures satisfying the quaternion relations. Such manifolds admit an underlying conformal structure that is anti-self-dual, and the corresponding twistor space admits a fibration to $\mathbb{CP}^1$.

These constructions have all played a significant role in the general analysis of these geometric structures, and the construction of examples. A striking example of an application of the nonlinear graviton construction to general properties is due to Donaldson and Friedman who show that if two 4-manifolds admit anti-self-dual conformal structures, then their direct sum does also.

In higher dimensions, most generalizations rely on quaternionic geometry and its reductions. The Euclidean signature formulation of the nonlinear graviton construction has natural extensions to quaternionic manifolds in $4k$ dimensions. These are manifolds with metric whose holonomies are contained in $\mathrm{Sp}(k) \times \mathrm{Sp}(1)$. The latter $\mathrm{SP}(1) = \mathrm{SU}(2)$ factor leads to an associated $S^2$ bundle whose total space is the twistor space $\mathcal{PT}$ and it naturally has the structure of a $(2k+1)$-dimensional complex manifold.

For a series of review articles, the reader is referred to Bailey and Baston (1990, chapters 3 and 4) and also LeBrun and Wang (1999, chapters 2, 5, 6, 10, and 14) which, despite being a book on the distinct subject of Einstein manifolds, is strongly influenced by twistor theory. Other applications along these lines are summarized in Mason *et al.* (2001, chapter 1).

There are a number of applications that go beyond complete integrability. A striking application is the twistor framework of Merkulov for studying arbitrary geometric structures. This has led to a classification of all possible irreducible holonomies of torsion-free affine connections, see Merkulov's article in Huggett *et al.* (1998). Another important area is in the field of conformal invariants in which the local twistor connection plays a prominent role. This is a connection that is naturally defined on any conformal manifold being the spinor representation of the Cartan conformal connection. An impressive application here is the construction of conformally invariant differential operators and other conformal invariants. See the article by Baston and Eastwood in Bailey and Baston (1990).

## Beyond Classical Integrability: Twistor-String Theory

Until Witten (2004), there was little indication that twistor theory would have much useful to say about Yang–Mills or gravitational fields that are not anti-self-dual. Furthermore, it was problematic to incorporate quantum field theory into twistor ideas. However, twistor-string theory has transformed the situation and has furthermore had impressive applications to the field of perturbative gauge theory.

The story starts with a formulation by Nair of the remarkable Park–Taylor formulas for the so-called maximal helicity violating (MHV) amplitudes in gauge theory. These are scattering amplitudes at tree level in which helicity conservation is maximally violated; using crossing symmetry to take all the particles to be outgoing, these are amplitudes in which $n-2$ of the particles have helicity –1 and two have helicity +1. These amplitudes can be expressed simply as follows. Let the $n$ particles have color $t_i$ in the Lie algebra of the gauge group and null momenta $p_i$ with spinor decompositions $p_i^a = \tilde{\pi}_i^A \pi_i^{A'}$, $i = 1, \ldots, n$ where the $\pi_i^{A'}$ are self-dual spinors and $\tilde{\pi}^A$ are anti-self-dual spinors using the index notation of Spinors and Spin Coefficients, and Twistors. Let $i = r$ and $i = s$ be the two gluons of helicity +1. Then the coefficient of the colour term $\mathrm{tr}(t_1 t_2 \cdots t_n)$ is

$$\delta^4\left(\sum_{i=1}^n p_i^a\right) \frac{\pi_r \cdot \pi_s}{\Pi_{i=1}^n \pi_i \cdot \pi_{i+1}}$$

where $\pi_i \cdot \pi_j = \pi_i^{A'} \pi_{jA'}$ denotes the standard skew-symmetric inner product on chiral spinors and $\pi_{n+1} = \pi_1$. A striking feature is that, except for the delta function, it is holomorphic in the $\pi_i$s except at the simple poles $\pi_i \cdot \pi_{i+1} = 0$. Nair interprets these poles as those associated to fermion correlators in a current algebra on a $\mathbb{CP}^1$ parametrized by $\pi$. Using a supersymmetric formulation adapted to $N = 4$ super Yang–Mills, he formulated the amplitude as arising from an integral over lines in supertwistor space $\mathbb{CP}^{3|4}$.

Witten extends these ideas to give, at least conjecturally, a complete theory. He proposes that full perturbative $N = 4$ super Yang–Mills theory on spacetime is equivalent to a string theory, a topological

$B$ model, on a supersymmetric version of twistor space, $\mathbb{PT}_s = \mathbb{CP}^{3|4}$. This is the space obtained by taking $\mathbb{C}^{4|4}$ with bosonic coordinates $Z^\alpha, \alpha = 0, \ldots, 3$ and fermionic coordinates $\eta^i, i = 1, \ldots, 4$ moduli the equivalence relation $(Z^\alpha, \eta^i) \sim \lambda(Z^\alpha, \eta^i)$ where $\lambda \in \mathbb{C}, \lambda \neq 0$.

The number 4 here plays two crucial but different roles. It is the maximum number of supersymmetries that Yang–Mills can have; it has the effect of incorporating both the positive and negative helicity parts of the gauge field in the same supermultiplet. It is also the only value of $N$ for which $\mathbb{CP}^{3|N}$ is a Calabi–Yau manifold and this is a necessary condition for the topological twisted $B$ model to be anomaly-free. The Calabi–Yau condition is the condition that the manifold admit a global holomorphic volume form which here is

$$\Omega_s = \varepsilon_{\alpha\beta\gamma\delta} Z^\alpha \mathrm{d}Z^\beta \wedge \mathrm{d}Z^\gamma \wedge \mathrm{d}Z^\delta \wedge \mathrm{d}\eta^1 \wedge \mathrm{d}\eta^2 \wedge \mathrm{d}\eta^3 \wedge \mathrm{d}\eta^4$$

This is invariant under $(Z^\alpha, \eta^i) \to (\lambda Z^\alpha, \lambda\eta^i)$ because $\mathrm{d}(\lambda\eta^i) = \lambda^{-1}\mathrm{d}\eta^i, \lambda \in \mathbb{C}$ follows from the Berezinian rule of integration $\int \theta \mathrm{d}\theta = 1$ for anticommuting variables.

Open-string topological twisted $B$ models are known to correspond to holomorphic Chern–Simons theories on their target space. A holomorphic Chern–Simons theory is a theory whose basic variable is a d-bar operator $\bar\partial_{\mathcal{A}} = \bar\partial + \mathcal{A}$ on a complex vector bundle $E \to \mathbb{PT}^{3|4}$, where $\mathcal{A}$ is a Lie algebra valued $(0,1)$-form on the target space and whose action is

$$S[\mathcal{A}] = \int \frac{1}{2}\left(\mathcal{A}\bar\partial\mathcal{A} + \frac{1}{3}\mathcal{A}^3\right) \wedge \Omega_s$$

The field equations are $\bar\partial_{\mathcal{A}}^2 = 0$. The classical solutions therefore consist of holomorphic vector bundles on the target space, here $\mathbb{CP}^{3|4}$. The twistor-space representation of the fields are obtained by expanding $\mathcal{A}$ in the anticommuting variables $\eta^i$ to obtain

$$\mathcal{A} = a + \eta^i b_i + \eta^i\eta^j c_{ij} + \eta^i\eta^j\eta^k d_{ijk} + \eta^1\eta^2\eta^3\eta^4 g$$

and $a$ has homogeneity zero, but because the homogeneity of $\eta^i$ is of degree 1, $b_i$ has homogeneity degree –1, and so on down to homogeneity degree $-4$ for $g$. Via the Ward construction, the $a$ component corresponds to an anti-self-dual Yang–Mills field on spacetime. The other components of $\mathcal{A}$ can be seen to correspond to spacetime fields with helicities –1/2 to +1 that are background coupled to the anti-self-dual Yang–Mills field.

As it stands, although this holomorphic Chern–Simons theory gives the correct field content of $N = 4$ super Yang–Mills, the couplings are only those of an anti-self-dual sector and more couplings are needed to obtain full $N = 4$ super Yang–Mills. The remarkable fact is that these can be naturally introduced by coupling in certain D1 instantons. The D1 instantons are algebraic curves $C$ in twistor space and the coupling is via a pair of spinor fields $\alpha$ and $\beta$ on $C$ with values in $E$ and $E^*$, respectively with action

$$S[\alpha, \beta, \mathcal{A}] = \int_C \beta\bar\partial_{\mathcal{A}}\alpha$$

This leads to explicit expressions for Yang–Mills scattering amplitudes in terms of integrals of fermion correlators over the moduli spaces of such algebraic curves in supertwistor space. In principle, the integral is over all algebraic curves. However, algebraic curves have two topological invariants, their degree denoted $d$ and genus $g$. An argument based on a classical scaling symmetry gives that integration over just those of curves of degree $d$ gives the subset of processes for which

$$d = q - 1 + l$$

where $q$ is the number of outgoing particles of helicity +1 in the process and $l$ is the number of loops. It is also the case that $g \leq l$.

An elegant formula for the amplitudes is that for the on-shell generating functional for tree-level scattering amplitudes $\mathscr{A}[\mathcal{A}]$, where $\mathcal{A}$ is the on-shell twistor field, being the above-mentioned $(0,1)$-form. The generating functional for processes with $q = d + 1$ external fields of helicity +1 is then

$$\mathscr{A}^d[\mathcal{A}] = \int_{C \in \mathscr{M}^d} \det(\bar\partial + \mathcal{A})|_C \mathrm{d}\mu$$

where $\mathrm{d}\mu$ is a natural measure on the moduli space $\mathscr{M}^d$ of connected rational (genus 0) curves in $\mathbb{CP}^{3|4}$ of degree $d$. This approach has been successfully exploited to obtain implicit algebraic formulas for all tree-level scattering amplitudes.

In an alternative version, the curves of degree $d$ can be taken to be maximally disconnected, being the union of $d$ lines. However, in this approach, we need to also incorporate Chern–Simons propagators which, for tree diagrams, join the lines into a tree. This gives a very flexible calculus for perturbative gauge theory in which scattering processes are obtained by gluing together MHV diagrams. It has been argued that the two formulations are equivalent. On the one hand, the Chern–Simons propagator has a simple pole when the lines meet and the

contour integral over the moduli space can be performed using residues in such a way as to eliminate the Chern–Simons propagators leaving an integral over *d* intersecting lines. On the other hand, the measure on the space of connected curves has a simple pole where the curve acquires double points and again the contour integral can be performed in such a way as to yield the same integral over *d* intersecting lines.

It should be mentioned that Berkovits has given an alternative version of twistor-string theory which is a heterotic open-string theory with target supertwistor space in which the strings are taken to have boundary on the real slice $\mathbb{RP}^3$ in $\mathbb{CP}^3$ (this is appropriate to a spacetime with split signature) and the D1-instanton expansions are replaced by expansions in the fundamental modes of the string (this is not a topological theory). This gives rise to the same formulas for scattering amplitudes as Witten's original model.

There have been many applications now of these ideas, perhaps the most striking being the recursion relations of Britto, Cachazo, Feng, and Witten which give, at tree level, on-shell recurrence relations for Yang–Mills scattering amplitudes that suggests a hitherto unsuspected underlying structure for Yang-Mills theory.

Despite all these successes, twistor-string theory is not thought by string theorists to be a good vehicle for basic physics. The most serious problem is that the closed-string sector gives rise to conformal supergravity which is an unphysical theory. This is particularly pernicious from the point of view of analyzing loop diagrams as from the point of view of string theory, loop diagrams will carry supergravity modes. From this point of view, twistor-string theory is another duality, like AdS-CFT etc., that gives insight into some standard physics but is fundamentally limited.

From the point of view of a twistor theorist, however, twistor-string theory has overcome major obstacles to the twistor programme. Hodges has used the BCFW recursion relations to provide all twistor diagrams for gauge theory. In Mason (2005) it is shown how to derive the main generating function formulas from Yang–Mills and conformal gravity spacetime action principles via a twistor space actions for these theories. These twistor actions can in the first instance be expressed purely bosonically and distinctly and the twistor-string generating function formulas are obtained by expanding and re-summing the classical limit of the path integral in a parameter that expands about the anti-self-dual sector. This allows one to decouple the Yang–Mills and conformal gravity modes, and indeed to work purely bosonically – one is not tied to super Yang–Mills. Although there is much work to be done to extend these ideas to provide a consistent approach to the main equations of basic physics, obstacles that seemed insurmountable a few years ago have been overcome.

# Twistors

**K P Tod**, University of Oxford, Oxford, UK

## Introduction

Twistor theory initially arose from two principal motivations: a desire for a conformally invariant calculus for spacetime geometry and fields on spacetime, and a desire to unify and account for the various occurrences of complex numbers and holomorphic functions in mathematical physics, especially in general relativity (Penrose and MacCallum 1973). The theory leads to a nonlocal relation between spacetime and twistor space, whereby a point in one is an extended object in the other. Part of the present-day motivation of the subject is that this nonlocal relation will be a fruitful way to approach the quantization of spacetime. A comparison is often invoked with Hamiltonian mechanics, which is a formal rephrasing of classical mechanics that nonetheless provides a bridge from that theory to quantum mechanics. The hope is that the twistor theory has the right character to provide a bridge from general relativity to quantum theory, specifically to quantum gravity.

The principal successes of twistor theory in mathematical physics can be characterized as the linear Penrose transform, which provides a solution of the zero-rest-mass free-field equations in Minkowski space in terms of sheaf cohomology in twistor space, and the nonlinear Penrose transform, which provides solutions of certain nonlinear field equations in terms of holomorphic geometry. These are treated below, together with other applications of twistor theory, following a brief introduction to twistor geometry.

Very recently, there has been a resurgence of interest in twistor theory following Witten's introduction of twistor string theory (Witten 2003) as a string theory in twistor space. This is not treated here, but this article does provide the necessary background.

## Twistor Geometry

General references for this section are the books by Penrose and Rindler (1986) and Hugget and Tod (1994). It will be convenient to use Penrose's abstract index convention (Penrose and Rindler 1984, 1986), which is also used in Spinors and Spin Coefficients. This can be used wherever vector or tensor indices occur. Suppose that $V$ is a (real or complex) finite-dimensional vector space with dual $V'$. Elements of $V$ are written $v^a, u^b, w^c, \ldots$, where an index $a, b, c, \ldots$ is regarded not as an integer in the range 1 to $\dim V$ but simply as an abstract label indicating that the object to which it is attached is a vector. Elements of $V'$ are similarly written $u_a, v_b, w_c, \ldots$ and elements of the tensor algebra as $t^{a\cdots b}{}_{c\cdots d}$ according to valence, and so on. The usual operations of tensor algebra are written in the way that component calculations would suggest, but without necessitating a choice of basis. The jump to tensor fields on a manifold $M$ is immediate. A metric is a particular field $g_{ab}$ and determines a Levi-Civita connection $\nabla_a$ which defines maps $\nabla_a : v^b \to \nabla_a v^b$ and similar for other valences. The virtue of the formalism is that, while remaining invariant, it can harness the strength and flexibility of calculations in components.

With this understanding, twistors may first be defined as the fundamental representation of SU(2, 2), so that they are elements $Z^\alpha$ of a four-dimensional complex vector space $\mathbb{T}$. $\mathbb{T}$ carries a Hermitian form $\Sigma$ of signature $(++--)$ which is made explicit below and which provides an isomorphism from the complex conjugate of $\mathbb{T}$ to its dual. This isomorphism is used to eliminate all appearances of complex-conjugate twistors from the formalism and is therefore regarded as an antilinear map to the dual.

SU(2, 2) is the double cover of $O(2, 4)$, the rotation group of $E_{2,4}$, the six-dimensional space with flat metric $\eta_{2,4}$ of signature $(+---+-)$, which in turn is the double cover of $C(1, 3)$, the conformal group of Minkowski space $M$. This last group homomorphism may be made explicit as follows (suspending the abstract-index convention for the duration of this

aside): introduce pseudo-Cartesian coordinates $x^a = (x^0, x^1, x^2, x^3)$ on $M$ and $y^\alpha = (y^0, y^1, y^2, y^3, y^4, y^5)$ on $E_{2,4}$. The corresponding metrics are

$$\eta_{1,3} = \eta_{ab}\mathrm{d}x^a\mathrm{d}x^b = (\mathrm{d}x^0)^2 - (\mathrm{d}x^1)^2 - (\mathrm{d}x^2)^2 - (\mathrm{d}x^3)^2 \quad [1]$$

$$\eta_{2,4} = \eta_{\alpha\beta}\mathrm{d}y^\alpha\mathrm{d}y^\beta = (\mathrm{d}y^0)^2 - (\mathrm{d}y^1)^2 - (\mathrm{d}y^2)^2 - (\mathrm{d}y^3)^2 + (\mathrm{d}y^4)^2 - (\mathrm{d}y^5)^2 \quad [2]$$

We map $M$ into $E_{2,4}$ by

$$\phi(x^a) = (x^0, x^1, x^2, x^3, (1-\eta)/2, (1+\eta)/2) \quad [3]$$

where $\eta = \eta_{ab}x^a x^b$ with $\eta_{ab}$ as in [1], and it can be checked that $\phi(M)$ is the intersection of the null cone $N$ of the origin in $E_{2,4}$ with the plane $P$ defined by $y^4 + y^5 = 1$. $P$ is in fact a null hyperplane in $E_{2,4}$ and any point of $N$ not on the null hyperplane defined by

$$y^4 + y^5 = 0 \quad [4]$$

can be mapped along the generators of $N$ to a unique point of $P$ (recall that any point on a cone lies on a line through the vertex: these lines are the generators). Thus, the image of $M$ under $\phi$ gives a point on every generator of $N$ except those satisfying [4]. It can also be seen from [2] that the intrinsic metric in $E_{2,4}$ on the intersection of $N$ and $P$ is just $\eta_{1,3}$.

Now let $\mathbb{P}N$ be the projective null cone, or, equivalently, the space of generators of $N$. This is a compact manifold with topology $S^1 \times S^3$, as one can see by intersecting $N$ with the sphere

$$(y^0)^2 + (y^1)^2 + (y^2)^2 + (y^3)^2 + (y^4)^2 + (y^5)^2 = 2$$

Each generator meets this sphere twice at, say, $y^\alpha$ and $-y^\alpha$, and $\mathbb{P}N$ is the quotient by this identification of the two surfaces

$$(y^0)^2 + (y^4)^2 = 1 = (y^1)^2 + (y^2)^2 + (y^3)^2 + (y^5)^2$$

which define the intersection. The metric $\eta_{2,4}$ defines a degenerate metric on $N$, which, however, is nondegenerate on any smooth cross section of $N$ which meets each generator once. Furthermore, the map along the generators between any two such cross sections is conformal. Thus, there is a conformal metric on $\mathbb{P}N$ and it is conformal to $\eta_{1,3}$. We call $\mathbb{P}N$ compactified Minkowski space $M_c$ as it is compact and has the same conformal metric as Minkowski space. It can be thought of as $M$ compactified by the addition of some points, namely the points of $\mathbb{P}N$ corresponding to the generators satisfying [4]. To interpret these, we consider the points satisfying the similar equation $y^4 - y^5 = 0$. By inspection of $\phi$, [3], we see that these points correspond to the light cone of the origin in $M$. Thus, $M_c$ is obtained from $M$ by adding a single light cone, the light cone at infinity known as $\mathcal{I}$ and read as "scri," short for "script-I."

Now the rotation group $O(2,4)$ of $E_{2,4}$ maps $N$ to itself preserving the metric and consequently maps $\mathbb{P}N$ to itself, preserving the conformal metric. Thus, $O(2,4)$ defines conformal transformations of $M_c$ and a count of dimension shows that it is locally isomorphic to the conformal group $C(1,3)$. The map is two-to-one with $\pm I$ in $O(2,4)$ maping to $I$ in $C(1,3)$. The fact that $\mathrm{SU}(2,2)$ is four-to-one homomorphic to $C(1,3)$ follows from calculations below. It is because of this homomorphism of $\mathrm{SU}(2,2)$ and $C(1,3)$ that the geometry and analysis of twistors (i.e., twistor theory) provides a formalism adapted to conformally invariant or conformally covariant notions in $M$ or $M_c$.

A twistor may be expressed in terms of two-component spinors of $\mathrm{SL}(2,\mathbb{C})$, the double cover of the Lorentz group, as follows:

$$Z^\alpha = \left(\omega^A, \pi_{A'}\right) \quad [5]$$

where again indices are abstract, so that

$$\mathbb{T} = \mathbb{S} \oplus \bar{\mathbb{S}}'$$

in terms of the spin space $\mathbb{S}$ and complex-conjugate dual spin space $\bar{\mathbb{S}}'$ of $M$. Now we can write the action of infinitesimal elements of $C(1,3)$ explicitly as

$$\begin{aligned}\widehat{\omega}^A &= \phi^A{}_B\omega^B - \mathrm{i}T^{AA'}\pi_{A'} + \Lambda\omega^A \\ \widehat{\pi}_{A'} &= \bar{\phi}^{B'}_{A'}\pi_{B'} + \mathrm{i}B_{AA'}\omega^A + \Lambda\pi_{A'}\end{aligned} \quad [6]$$

where $T^{AA'}$ (a real vector) defines an infinitesimal translation, $B_{AA'}$ (another real vector) defines an infinitesimal special conformal transformation, $\Lambda$ (a real constant) defines a dilatation and the (real) bivector $M_{ab} = \phi_{AB}\epsilon_{A'B'} + \bar{\phi}_{A'B'}\epsilon_{AB}$ defines an infinitesimal rotation. This gives a total of 15 parameters for the transformation, which is the correct dimension for $C(1,3)$.

The Hermitian form $\Sigma(\,,\,)$ can be written as

$$\Sigma(Z, Z) = Z^\alpha\bar{Z}_\alpha = \omega^A\bar{\pi}_A + \bar{\omega}^{A'}\pi_{A'} \quad [7]$$

when it can be checked that the transformations [6] leave it invariant (and that its signature is $(++--)$; this establishes that $\mathrm{SU}(2,2)$ is locally isomorphic to $C(1,3)$). Equation [7] will be referred to as the norm of a twistor.

From [6], a twistor $Z^\alpha = (\omega^A, \pi_{A'})$ gives rise, under translation by a variable $x^{AA'}$, to a spinor field $\Omega^A$ given by

$$\Omega^A = \omega^A - \mathrm{i}x^{AA'}\pi_{A'} \qquad [8]$$

Differentiating [8] and symmetrizing, we see that $\Omega^A$ satisfies the differential equation

$$\nabla_{A'(A}\Omega_{B)} = 0 \qquad [9]$$

which is known as the twistor equation. In fact, the general solution of [9] takes the form of [8] for constant spinors $\omega^A$ and $\pi_{A'}$. Furthermore, the conformal group can be shown directly to act on solutions of [9], so that twistor theory can begin with the study of [9] and its solutions. In this approach, a twistor is precisely a solution of [9].

Given a spinor field $\Omega^A$ of the form of [8], we may seek the points of $M$ where it vanishes. In general, there are none, but if we consider complexified Minkowski space $\mathbb{C}M$, then $\Omega^A$ vanishes on a two-dimensional complex plane with the property that every tangent vector is of the form $\lambda^A\pi^{A'}$ for varying $\lambda^A$ and fixed $\pi^{A'}$. The 2-plane is flat and totally null, in that the (analytically extended) Minkowski metric vanishes identically on it, and it has a self-dual (SD) tangent bivector determined by $\pi^{A'}$. Such a 2-plane is known as an $\alpha$-plane (reserving the term $\beta$-plane for a totally null 2-plane with anti-self-dual (ASD) tangent bivector). At a given point $p$ in $\mathbb{C}M$, there is an $\alpha$-plane for each choice of $\pi_{A'}$ up to scale (in other words, for each element of the projective (primed) spin space at $p$) which is a copy of the complex projective line, $\mathbb{CP}^1$.

The $\alpha$-plane is determined by the twistor up to scale (in that a constant complex multiple of the field $\Omega^A$ determines the same $\alpha$-plane). Thus, we consider the projective twistor space $\mathbb{PT}$ which, since $\mathbb{T}$ is $\mathbb{C}^4$, is a copy of complex projective 3-space, $\mathbb{CP}^3$. This is now the space of $\alpha$-planes, but is also compact. We define complexified, compactified Minkowski space $\mathbb{C}M_c$ as the space of all (complex projective) lines in $\mathbb{PT}$; then it is easy to see that this includes $\mathbb{C}M$ as an open dense subset. $\mathbb{PT}$ is the space of $\alpha$-planes in $\mathbb{C}M_c$ and two lines meet in $\mathbb{PT}$ iff the corresponding points in $\mathbb{C}M_c$ lie on an $\alpha$-plane, or, equivalently, iff they are null separated. Thus, the conformal structure in $\mathbb{C}M_c$ is determined by incidence of lines in $\mathbb{PT}$.

To find $M$ and $M_c$ in this picture, we seek $\alpha$-planes containing real points. If $\Omega^A$ from [8] vanishes at a real $x^{AA'}$, then the contraction $\omega^A\bar{\pi}_A$ must be purely imaginary, so that, by [7], the norm of the twistor is zero. Conversely, one calculates that $\Omega^A$ can indeed vanish at real points if the norm is zero, and that it will then in fact vanish along a null geodesic with tangent vector (proportional to) $\bar{\pi}^A\pi^{A'}$. Twistors with norm zero are called null and the (five-dimensional, real) submanifold of them in $\mathbb{PT}$ is $\mathbb{PN}$. This is a compactification of the space of (unscaled) null geodesics in $M$ by the inclusion of the 2-sphere of null geodesics in $M_c$ which lie on the light cone at $\mathcal{I}$. For use in the next section, we note the definition of $\mathbb{PT}^+$ and $\mathbb{PT}^-$ as the projective twistors with positive and negative norm, respectively.

To summarize, we have found $M$ and $M_c$: (complex projective) lines in $\mathbb{PT}$ define points of $\mathbb{C}M_c$; lines in $\mathbb{PN}$ define points of $M_c$ with one such, call it $I$, picked out as the vertex of the null cone $\mathcal{I}$; lines in $\mathbb{PN}$ which meet $I$ correspond to points of $\mathcal{I}$; lines in $\mathbb{PN}$ which do not meet $I$ correspond to points in $M$. As for $\mathbb{C}M_c$, the conformal structure of $M$ and $M_c$ is determined by incidence in $\mathbb{PN}$. We may now note the nonlocal correspondence mentioned in the introduction: points in $\mathbb{C}M_c$ are lines in $\mathbb{PT}$ and points in $\mathbb{PT}$ are $\alpha$-planes in $\mathbb{C}M_c$.

It will be convenient to refer to the line in $\mathbb{PT}$ associated with a point $x$ in $\mathbb{C}M_c$ as $L_x$. With this notation, it is possible to characterize the forward or future tube in terms of twistor space: a point $x$ of $\mathbb{C}M$ is in the forward tube iff its imaginary part is timelike and past-pointing, and this is equivalent to $L_x$ lying in $\mathbb{PT}^-$.

The starting point for Riemannian twistor theory is the fact that $\mathbb{CP}^3$ is a fibration with fiber $\mathbb{CP}^1$ over $S^4$, where the fiber above a point $p$ can be interpreted as the almost-complex structures at $p$ (since this is the same as the projective primed spin space at $p$). In the picture developed above, this means that there is an $S^4$'s worth of lines filling out $\mathbb{CP}^3$, no two of which intersect (so that there are no null vectors and the metric is definite). The complexification of $S^4$ with its conformal structure is again $\mathbb{C}M_c$.

If a twistor has nonzero norm, say $Z^\alpha\bar{Z}_\alpha = s \neq 0$, then it can be interpreted as a massless particle with spin $s$: the momentum is $p_a = \bar{\pi}_A\pi_{A'}$ and the angular momentum bivector is $M^{ab} = \mathrm{i}\omega^{(A}\bar{\pi}^{B)}\epsilon^{A'B'} - \mathrm{i}\bar{\omega}^{(A'}\pi^{B')}\epsilon^{AB}$. The angular momentum transforms appropriately under translation by virtue of [6] and the (Pauli–Lubanski) spin vector is $sp_a$, as it should be for a massless spinning particle.

## The Linear Penrose Transform: Zero-Rest-Mass Free Fields

A zero-rest-mass free field of spin $s$ is a symmetric spinor field $\phi_{AB\ldots C}$ with $2s$ indices which satisfies the field equation

$$\nabla^{A'A}\phi_{AB\ldots C} = 0 \qquad [10]$$

The Weyl neutrino equation, source-free Maxwell equation, and linearized Einstein vacuum equation are examples of zero-rest-mass free-field equations, with spins 1/2, 1, and 2, respectively, so that these are equations of physical interest. Conventionally, one takes the $s=0$ case to be the wave equation, and the complex-conjugate fields $\psi_{A'B'\dots C'}$ to have the same spin but opposite helicity.

The conformal group acts on solutions of [10], so that the equations are conformally invariant. The equations can be solved by contour integral expressions involving homogeneous functions of a twistor variable. To be explicit, we define an operation $\rho_x$ of restriction to the line $L_x$ for a function of a twistor variable by the following:

$$\rho_x f(Z^\alpha) = f(\mathrm{i}x^{AA'}\pi_{A'}, \pi_{A'}) \qquad [11]$$

Now suppose that $f(Z^\alpha)$ is holomorphic and homogeneous of degree $-2s-2$ in the twistor variable for positive integer $2s$, but otherwise arbitrary, and consider the integral

$$\psi_{A'B'\dots C'}(x) = \int \pi_{A'}\pi_{B'}\dots\pi_{C'}\rho_x f(Z^\alpha)\epsilon^{E'F'}\pi_{E'}\,\mathrm{d}\pi_{F'} \qquad [12]$$

where there are $2s$ indices on $\psi$ and the integration is around a contour in the line $L_x$ in $\mathbb{PT}$. The choice of homogeneity ensures that the integral is well defined but, to obtain a nonzero answer, $\rho_x f$ must have some singularities as a function of $\pi_{A'}$ on $L_x$. The answer then automatically gives a helicity-$(-s)$ solution of [10], as may be checked by differentiation under the integral sign.

For a helicity-$s$ solution, we take an arbitrary function $f(Z^\alpha)$, holomorphic and of homogeneity $(2s-2)$, and consider the integral

$$\phi_{AB\dots C}(x) = \int \rho_x\left(\frac{\partial}{\partial\omega^A}\frac{\partial}{\partial\omega^B}\cdots\frac{\partial}{\partial\omega^C}f(Z^\alpha)\right)\epsilon^{E'F'}\pi_{E'}\mathrm{d}\pi_{F'} \qquad [13]$$

where there are $2s$ indices on $\phi$ and the integration is again around a contour in the line $L_x$. As before, one needs singularities to make the contour integral nonzero, but again the result satisfies [10].

The correct framework in which to understand these integrals is sheaf cohomology theory. For [12], the functions with singularities are actually elements of $H^1(\hat{\mathcal{U}}, \mathcal{O}(-2s-2))$, the first cohomology group of a region $\hat{\mathcal{U}}$ in $\mathbb{PT}$ with coefficients in the sheaf of germs of holomorphic functions of homogeneity $-2s-2$, while the fields are elements of $H^0(\mathcal{U}, \mathcal{Z}_s)$, the zeroth cohomology group of the corresponding region $\mathcal{U}$ of $M$ with coefficients in helicity-$s$ zero-rest-mass fields (thus, $\hat{\mathcal{U}}$ must contain the neighborhood of lines $L_x$ for points $x$ in $\mathcal{U}$). Similarly, [13] is interpreted cohomologically in terms of potentials modulo a gauge. With appropriate conditions on $\hat{\mathcal{U}}$ and $\mathcal{U}$ (for brevity, $\mathcal{U}$ is said to be elementary), these groups can be shown to be isomorphic and this isomorphism is known as the Penrose transform (Ward and Wells (1991)). A particular instance of an elementary $\mathcal{U}$ is the forward tube, when $\hat{\mathcal{U}}$ is $\mathbb{PT}^-$. Since the definition of positive frequency is holomorphicity on the forward tube, this observation geometrizes the notion of positive frequency in terms of twistor space.

For free fields with mass, there are generalizations of [12] and [13] to solve the Dirac equation for different spins. However, the integrands now involve functions of more than one twistor variable, subject to an equation. This equation is a counterpart of the Klein–Gordon equation and breaks the conformal invariance (as it must, since mass does). It can be imposed by a projection which can in turn be written as a contour integral over arbitrary holomorphic functions. It has been argued that the appropriate description of leptons and hadrons in twistor theory is with functions of two and three twistor variables, respectively. Such a function has two or three integer quantum numbers determined by the homogeneities in different variables, and this leads to a twistor particle classification scheme (see, e.g., Hughston and Sheppard (1980) and Sparling (1981)), similar in many respects to, but not identical with, the standard classifications.

Given that free fields, massive or massless, are determined from arbitrary twistor functions through contour integrals, one may translate the Feynman diagrams of a quantum field theory into contour integrals over twistor functions. In the massless case, the contours are compact, so that the integrals are finite without need for renormalization. The massive case is more complicated but essentially parallel. This is twistor diagam theory and there is a substantial literature on it (see, e.g., the article by Hodges in the volume edited by Huggett *et al.* (1998)). There is currently no new physical theory, distinct from a known quantum field theory, to generate the relevant diagrams.

## The Nonlinear Penrose Transform: Curved Twistor Spaces

The electromagnetic field, in Minkowski space say, can be regarded as a spinor field subject to field equations, in which case these equations can be

solved via the Penrose transform by contour integrals. Alternatively, it can be seen as the curvature of a connection on a U(1) bundle over $M$, which is a more active role for the field in curving a bundle. For SD or ASD electromagnetic fields, there are analogous active twistor constructions. From an ASD electromagnetic field, one may define a connection on the primed spin space of $\mathbb{C}M$ which is flat on $\alpha$-planes: if the tangents to the $\alpha$-plane are of the form $\lambda^A \pi^{A'}$ for varying $\lambda^A$ and with $\pi^{A'}$ fixed up to scale, then consider the propagation of $\pi_{A'}$ around the $\alpha$-plane given by

$$\pi^{A'}(\nabla_{A'A} - \mathrm{i}A_{A'A})\pi_{B'} = 0 \qquad [14]$$

where $A_{A'A}$ is a potential for the electromagnetic field. This connection is flat provided

$$\pi^{A'}\pi^{B'}\nabla_{AA'}A^A_{B'} = 0 \qquad [15]$$

and if this is to hold for all $\pi_{A'}$ then $\nabla_{A(A'}A^A_{B')}$ vanishes and the electromagnetic field, defined as usual as the exterior derivative of the potential, is necessarily ASD. Now the space of $\alpha$-planes in $\mathbb{C}M$ is projective twistor space $\mathbb{PT}$, so we define a holomorphic $\mathbb{C}^*$ bundle $\mathcal{T}$ over $\mathbb{PT}$ by taking the fiber above an $\alpha$-plane to be choices of $\pi_{A'}$ scaled as in [14]. If we restrict attention to the $\alpha$-planes through a given point $p$ of $\mathbb{C}M$, then by comparing the scalings at $p$ we can trivialize the bundle; thus, $\mathcal{T}$ is trivial on lines in $\mathbb{PT}$. There is a converse to this construction and we have: *there is a one-to-one correspondence between holomorphic $\mathbb{C}^*$ bundles on a region $\hat{\mathcal{U}}$ in $\mathbb{PT}$ which are trivial on lines and ASD electromagnetic fields on the corresponding region $\mathcal{U}$ of $\mathbb{C}M$ (for elementary $\mathcal{U}$).*

This construction can be extended to solve the ASD Yang–Mills equations with holomorphic vector bundles replacing holomorphic line bundles: *with $\hat{\mathcal{U}}$ and elementary $\mathcal{U}$ as above, there is a natural one-to-one correspondence between ASD $GL(n,\mathbb{C})$ gauge fields on $\mathcal{U}$ and holomorphic rank-n vector bundles $\mathcal{E}$ over $\hat{\mathcal{U}}$ which are trivial on $L_x$ for every $x$ in $\mathcal{U}$.*

ASD Yang–Mills fields cannot be real on $M$, but using Riemannian twistor theory, one can impose appropriate reality and globality conditions to ensure that these ASD Yang–Mills fields are both real and globally defined on $S^4$. These are then instantons. The Atiyah–Drinfeld–Hitchin–Manin (ADHM) construction of instantons (Atiyah *et al.* 1978) proceeds via construction of the corresponding holomorphic vector bundles over twistor space.

The construction of ASD Yang–Mills fields is also the starting point for the twistor theory of integrable systems (Mason and Woodhouse 1996), following the observation that many of the known completely integrable partial differential equations (PDEs) (including the sine-Gordon, Korteweg–de Vries (KdV) and nonlinear Schrödinger equations) are reductions of the ASD Yang–Mills equations. Solutions of these other integrable systems can be given in terms of a geometrical construction, usually of some structure in holomorphic geometry.

The other major active twistor construction, which historically preceded the Yang–Mills one, is Penrose's nonlinear graviton (Penrose 1976), which solves the ASD Einstein vacuum equations. For this, one starts from a complex, four-dimensional manifold $\mathcal{M}$ with holomorphic metric, vanishing Ricci curvature and ASD Weyl tensor. These conditions on the curvature are necessary and sufficient to allow the existence of $\alpha$-surfaces, which generalize $\alpha$-planes. They are two-dimensional totally null (complex) surfaces with SD tangent bivector, one for each choice of (null) SD bivector, or, equivalently, for each choice of primed spinor, at each point.

The space of $\alpha$-surfaces is a three-dimensional complex manifold, the curved twistor space $\mathbb{P}\mathcal{T}$. This is curved inasmuch as it is not now (part of) $\mathbb{CP}^3$, but it still contains complex projective lines: given a point $p$ in $\mathcal{M}$ there is an $\alpha$-surface through $p$ for every primed spinor at $p$ up to scale; these $\alpha$-surfaces make up a projective line $L_p$ in $\mathbb{P}\mathcal{T}$. The conditions on the curvature are equivalent to the statement that the Levi-Civita connection is flat on primed spinors, so that there exist constant primed spinors in $\mathcal{M}$, and the tangent bivector to an $\alpha$-surface can be taken to be constant, without loss of generality. The map associating a constant primed spinor with each $\alpha$-surface defines a projection $\pi$ from $\mathbb{P}\mathcal{T}$ to $\mathbb{CP}^1$, so that $\mathbb{P}\mathcal{T}$ is a fibration over $\mathbb{CP}^1$. The lines $L_p$ define a four-parameter family of sections of this fibration.

To define the metric of $\mathcal{M}$ from $\mathbb{P}\mathcal{T}$, one needs the notion of normal bundle: the normal bundle of a submanifold $Y$ in a manifold $X$ is $N = TX|_Y/TY$ in terms of the tangent bundles $TX$ and $TY$. The normal bundle $\mathcal{N}_p$ of a particular section $L_p$ is the same in $\mathbb{P}\mathcal{T}$ as it was in $\mathbb{PT}$, namely $H \oplus H$, where $H$ is the hyperplane-section line bundle over $\mathbb{CP}^1$ (Ward and Wells 1991). A section $S_V$ of $\mathcal{N}_p$ corresponds to a vector $V$ in $T_p\mathcal{M}$ (think of it as an infinitesimally neighboring point in $\mathcal{M}$) and $V$ is defined to be null iff $S_V$ has a zero. Because of the nature of $\mathcal{N}$, this defines a quadratic conformal metric, which, furthermore, agrees with the conformal metric on $\mathcal{M}$ and generalizes the definition of conformal metric for $\mathbb{C}M_c$ in terms of incidence in $\mathbb{PT}$. To define the actual metric, as opposed to just the conformal metric, one has a covariant-constant

choice of $\epsilon^{A'B'}$ in $\mathcal{M}$ which defines an $\epsilon$ on the base of the fibration, and a Poisson structure on the fibers $\mu$ of the projection. The definition of $\mu$ is more intricate, but the two structures enable the metric of $\mathcal{M}$ to be recovered from $\mathbb{P}\mathcal{T}$. Penrose (1976) and Huggett and Tod (1994) provide more details.

Now the metric and curvature properties of $\mathcal{M}$ are coded into holomorphic properties of $\mathbb{P}\mathcal{T}$ together with $\epsilon$ and $\mu$. These properties characterize $\mathcal{M}$: *subject to topological conditions on* $\mathcal{M}$, *there is a one-to-one correspondence between holomorphic solutions* $\mathcal{M}$ *of the Einstein vacuum equations with ASD Weyl tensor and three-dimensional complex manifolds* $\mathbb{P}\mathcal{T}$ *fibered over* $\mathbb{CP}^1$, *with a four-parameter of sections, each with normal bundle* $H \oplus H$, *and the forms* $\epsilon$ *and* $\mu$ *as above*.

In fact, one only needs to assume the existence of one section with the correct normal bundle and the full four-parameter family will automatically exist, at least near to the initial one. Penrose (1976) showed how curved twistor spaces with the necessary structures could be obtained by deforming the neighborhood of a line in the "flat" twistor space $\mathbb{PT}$. The Kodaira–Spencer theory of complex deformations ensures that the necessary lines continue to exist under this deformation.

The original nonlinear graviton construction has been extended in various ways including the following: to allow the possibility of a cosmological constant (Ward and Wells 1991); to produce real, Riemannian solutions (Hitchin 1995); to solve other but related field equations (e.g., those for hypercomplex metrics, scalar-flat Kahler metrics or Einstein–Weyl structures).

The search for a twistor construction of the SD Einstein equations (distinct from a construction in terms of dual twistors, which is, of course, provided by deforming dual twistor space) is an active area of research. This and other applications of twistor theory, including a quasilocal definition of mass in general relativity, the classification of affine holonomies and the construction of four-dimensional conformal field theories, may be found in the literature cited in the "Further reading" section.

# Two-Dimensional Conformal Field Theory and Vertex Operator Algebras

**M R Gaberdiel**, ETH Zürich, Zürich, Switzerland

## Introduction

For the last twenty years or so, two-dimensional (2D) conformal field theories have played an important role in different areas of modern theoretical physics. One of the main applications of conformal field theory has been in string theory (*see* Compactification of Superstring Theory), where the excitations of the string are described, from the point of view of the world sheet, by a 2D conformal field theory. Conformal field theories have also been studied in the context of statistical physics, since the critical points of second-order phase transition are typically described by a conformal field theory. Finally, conformal field theories are interesting solvable toy models of genuinely interacting quantum field theories.

From an abstract point of view, conformal field theories are (Euclidean) quantum field theories that are characterized by the property that their symmetry group contains, in addition to the Euclidean symmetries, local conformal transformations, that is, transformations that preserve angles but not necessarily lengths. The local conformal symmetry is of special importance in two dimensions since the corresponding symmetry algebra is infinite dimensional in this case. As a consequence, 2D conformal field theories have an infinite number of conserved quantities, and are essentially solvable by symmetry considerations alone. The mathematical formulation of these symmetries has led to the concept of a vertex operator algebra, which has become a new branch of mathematics in its own right. In particular, it has played a major role in the explanation of "monstrous moonshine" for which Richard Borcherds received the Fields medal in 1998.

In the following, we want to explain the main features of conformal field theory using an algebraic approach that will naturally lead to the concept of a vertex operator algebra. There are other approaches to the subject, most notably the formulation, pioneered by Segal, of conformal field theory as a functor from the category of Riemann surfaces to the category of vector spaces. Due to limitations of space, however, we will not be able to discuss any of these other approaches here.

## The Conformal Symmetry Group

The conformal symmetry group of the $n$-dimensional Euclidean space $\mathbb{R}^n$ consists of the (locally defined) transformations that preserve angles but not necessarily lengths. The transformations that preserve angles as well as lengths are the well-known translations and rotations. The conformal group contains (in any dimension) in addition the dilatations or scale transformations

$$x^\mu \mapsto \tilde{x}^\mu = \lambda x^\mu \qquad [1]$$

where $\lambda \in \mathbb{R}$ and $x^\mu \in \mathbb{R}^n$, as well as the so-called special conformal transformations,

$$x^\mu \mapsto \tilde{x}^\mu = \frac{x^\mu + \boldsymbol{x}^2 a^\mu}{1 + 2(\boldsymbol{x}\cdot\boldsymbol{a}) + \boldsymbol{x}^2\boldsymbol{a}^2} \qquad [2]$$

where $a^\mu \in \mathbb{R}^n$ and $\boldsymbol{x}^2 = x^\mu x_\mu$. (Note that this last transformation is only defined for $x^\mu \neq -a^\mu/\boldsymbol{a}^2$.)

If the dimension $n$ of the space $\mathbb{R}^n$ is larger than 2, one can show that the full conformal group is generated by these transformations. For $n=2$, however, the group of (locally defined) conformal transformations is much larger. To see this, it is convenient to introduce complex coordinates for $(x,y)\in\mathbb{R}^2$ by defining $z = x + iy$ and $\bar{z} = x - iy$. Then any (locally) analytic function $f(z)$ defines a conformal transformation by $z \mapsto f(z)$, since analytic maps preserve angles. (Incidentally, the same also applies to $z \mapsto \overline{f(z)}$, but this would reverse the orientation.) Clearly, the group of such transformations is infinite dimensional; this is a special feature of two dimensions.

In this complex notation, the transformations that are generated by translations, rotations, dilatations, and special conformal transformations simply generate the Möbius group of automorphisms of the Riemann sphere

$$z \mapsto f(z) = \frac{az+b}{cz+d} \qquad [3]$$

where $a,b,c,d$ are complex constants with $ad - bc \neq 0$; since rescaling $a,b,c,d$ by a common complex number does not modify [3], the Möbius group is isomorphic to $\mathrm{SL}(2,\mathbb{C})/\mathbb{Z}_2$. In addition to these transformations (that are globally defined on the Riemann sphere), we have an infinite set of infinitesimal transformations generated by $L_n : z \mapsto z + \epsilon z^{n+1}$ for all $n\in\mathbb{Z}$. The generators $L_{\pm1}$ and $L_0$ generate the

subgroup of Möbius transformations, and their commutation relations are simply

$$[L_m, L_n] = (m - n)L_{m+n} \quad [4]$$

In fact, [4] describes also the commutation relations of all generators $L_n$ with $n \in \mathbb{Z}$: this is the Lie algebra of (locally defined) 2D conformal transformations – it is called the Witt algebra.

## The General Structure of Conformal Field Theory

A 2D conformal field theory is determined (like any other field theory) by its space of states and the collection of its correlation functions (vacuum expectation values). The space of states is a vector space $\mathcal{H}$ (which, in many interesting examples, is a Hilbert space), and the correlation functions are defined for collections of vectors in some dense subspace of $\mathcal{H}$. These correlation functions are defined on a 2D (Euclidean) space. We shall mainly be interested in the case where the underlying 2D space is a closed compact surface; the other important case concerning surfaces with boundaries (whose analysis was pioneered by Cardy) will be reviewed elsewhere (*see* the article Boundary Conformal Field Theory). The closed surfaces are classified (topologically) by their genus $g$, which counts the number of handles; the simplest such surface which we shall mainly consider is the sphere with $g = 0$, the surface with $g = 1$ is the torus, etc.

One of the special features of conformal field theory is the fact that the theory is naturally defined on a Riemann surface (or complex curve), that is, on a surface that possesses suitable complex coordinates. In the case of the sphere, the complex coordinates can be taken to be those of the complex plane that cover the sphere except for the point at infinity; complex coordinates around infinity are defined by means of the coordinate function $\gamma(z) = 1/z$ that maps a neighborhood of infinity to a neighborhood of zero. With this choice of complex coordinates, the sphere is usually referred to as the Riemann sphere, and this choice of complex coordinates is, up to Möbius transformations, unique. The correlation functions of a conformal field theory that is defined on the sphere are thus of the form

$$\langle 0|V(\psi_1; z_1, \bar{z}_1) \cdots V(\psi_n; z_n, \bar{z}_n)|0\rangle \quad [5]$$

where $V(\psi, z, \bar{z})$ is the field that is associated to the state $\psi$, and $z_i$ and $\bar{z}_i$ are complex conjugates of one another. Here $|0\rangle$ denotes the $\mathrm{SL}(2, \mathbb{C})/\mathbb{Z}_2$-invariant vacuum. The usual locality assumption of a 2D (bosonic) Euclidean quantum field theory implies that these correlation functions are independent of the order in which the fields appear in [5].

It is conventional to think of $z = 0$ as describing "past infinity," and $z = \infty$ as "future infinity"; this defines a time direction in the Euclidean field theory and thus a quantization scheme (radial quantization). Furthermore, we identify the space of states with the space of "incoming" states; thus, the state $\psi$ is simply

$$\psi = V(\psi; 0, 0)|0\rangle \quad [6]$$

We can think of $z_i$ and $\bar{z}_i$ in [5] as independent variables, that is, we may relax the constraint that $\bar{z}_i$ is the complex conjugate of $z_i$. Then we have two commuting actions of the conformal group on these correlations functions: the infinitesimal action on the $z_i$ variables is described (as before) by the $L_n$ generators, while the generators for the action on the $\bar{z}_i$ variables are $\bar{L}_n$. In a conformal field theory, the space of states $\mathcal{H}$ thus carries two commuting actions of the Witt algebra. The generator $L_0 + \bar{L}_0$ can be identified with the time-translation operator, and thus describes the energy operator. The space of states of the physical theory should have a bounded energy spectrum, and it is thus natural to assume that the spectrum of both $L_0$ and $\bar{L}_0$ is bounded from below; representations with this property are usually called positive-energy representations. It is relatively easy to see that the Witt algebra does not have any unitary positive-energy representations except for the trivial representation. However, as is common in many instances in quantum theory, it possesses many interesting projective representations. These projective representations are conventional representations of the central extension of the Witt algebra

$$[L_m, L_n] = (m - n)L_{m+n} + \frac{c}{12} m(m^2 - 1)\delta_{m,-n} \quad [7]$$

which is the famous Virasoro algebra. Here $c$ is a central element that commutes with all $L_m$; it is called the central charge (or conformal anomaly).

Given the actions of the two Virasoro algebras (that are generated by $L_n$ and $\bar{L}_n$), one can decompose the space of states $\mathcal{H}$ into irreducible representations as

$$\mathcal{H} = \bigoplus_{ij} M_{ij} \mathcal{H}_i \otimes \bar{\mathcal{H}}_j \quad [8]$$

where $\mathcal{H}_i(\bar{\mathcal{H}}_j)$ denotes the irreducible representations of the algebra of $L_n(\bar{L}_n)$, and $M_{ij} \in \mathbb{N}_0$ describe the multiplicities with which these combinations of representations occur. (We are assuming here that the space of states is completely reducible with

respect to the action of the two Virasoro algebras; examples where this is not the case are the so-called logarithmic conformal field theories.) The positive-energy representations of the Virasoro algebra are characterized by the value of the central charge, as well as the lowest eigenvalue of $L_0$; the state $\psi$ whose $L_0$ eigenvalue is smallest is called the highest-weight state, and its eigenvalue $L_0\psi = h\psi$ is the conformal weight. The conformal weight determines the conformal transformation properties of $\psi$: under the conformal transformation $z \mapsto f(z), \bar{z} \mapsto \bar{f}(\bar{z})$, we have

$$V(\psi; z, \bar{z}) \mapsto (f'(z))^h \left(\bar{f}'(\bar{z})\right)^{\bar{h}} V(\psi; f(z), \bar{f}(\bar{z})) \qquad [9]$$

where $L_0\psi = h\psi$ and $\bar{L}_0\psi = \bar{h}\psi$. The corresponding field $V(\psi; z, \bar{z})$ is then called a primary field; if [9] only holds for the Möbius transformations [3], the field is called quasiprimary.

Since $L_m$ with $m > 0$ lowers the conformal weight of a state (see [7]), the highest-weight state $\psi$ is necessarily annihilated by all $L_m$ (and $\bar{L}_m$) with $m > 0$. However, in general the $L_m$ (and $\bar{L}_m$) with $m < 0$ do not annihilate $\psi$; they generate the descendants of $\psi$ that lie in the same representation. Their conformal transformation property is more complicated, but can be deduced from that of the primary state [9], as well as the commutation relations of the Virasoro algebra.

The Möbius symmetry (whose generators annihilate the vacuum) determines the 1-, 2- and 3-point functions of quasiprimary fields up to numerical constants: the 1-point function vanishes, unless $h = \bar{h} = 0$, in which case $\langle 0|V(\psi; z, \bar{z})|0\rangle = C$, independent of $z$ and $\bar{z}$. The 2-point function of $\psi_1$ and $\psi_2$ vanishes unless $h_1 = h_2$ and $\bar{h}_1 = \bar{h}_2$; if the conformal weights agree, it takes the form

$$\langle 0|V(\psi_1; z_1, \bar{z}_1)V(\psi_2; z_2, \bar{z}_2)|0\rangle = C(z_1 - z_2)^{-2h}(\bar{z}_1 - \bar{z}_2)^{-2\bar{h}} \qquad [10]$$

Finally, the structure of the 3-point function of three quasiprimary fields $\psi_1, \psi_2$, and $\psi_3$ is

$$\langle 0|V(\psi_1; z_1, \bar{z}_1)V(\psi_2; z_2, \bar{z}_2)V(\psi_3; z_3, \bar{z}_3)|0\rangle = C\prod_{i<j}(z_i - z_j)^{(h_k - h_i - h_j)}(\bar{z}_i - \bar{z}_j)^{(\bar{h}_k - \bar{h}_i - \bar{h}_j)} \qquad [11]$$

where for each pair $i < j, k$ labels the third field, that is, $k \neq i$ and $k \neq j$. The Möbius symmetry also restricts the higher correlation function of quasiprimary fields: the 4-point function is determined up to an (undetermined) function of the Möbius invariant cross-ratio, and similar statements also hold for $n$-point functions with $n \geq 5$. The full Virasoro symmetry must then be used to restrict these functions further; however, since the generators $L_n$ with $n \leq -2$ do not annihilate the vacuum $|0\rangle$, the Virasoro symmetry leads to Ward identities that cannot be easily evaluated in general. (In typical examples, the Ward identities give rise to differential equations that must be obeyed by the correlation functions.)

## Chiral Fields and Vertex Operator Algebras

The decomposition [8] usually contains a special class of states that transform as the vacuum state with respect to $\bar{L}_m$; these states are the so-called chiral states. (Similarly, the states that transform as the vacuum state with respect to $L_m$ are the antichiral states.) Given the transformation properties described above, it is not difficult to see that the corresponding chiral fields $V(\psi; z, \bar{z})$ only depend on $z$ in any correlation function, that is $V(\psi; z, \bar{z}) \equiv V(\psi, z)$. (Similarly, the antichiral fields only depend on $\bar{z}$.) The chiral fields always contain the field corresponding to the state $L_{-2}|0\rangle$, that describes a specific component of the stress–energy tensor.

In conformal field theory, the product of two fields can be expressed again in terms of the fields of the theory. The conformal symmetry restricts the structure of this operator product expansion:

$$V(\psi_1; z_1, \bar{z}_1)V(\psi_2; z_2, \bar{z}_2) = \sum_i (z_1 - z_2)^{\Delta_i}(\bar{z}_1 - \bar{z}_2)^{\bar{\Delta}_i} \sum_{r,s\geq 0} V(\phi^i_{r,s}; z_2, \bar{z}_2)(z_1 - z_2)^r(\bar{z}_1 - \bar{z}_2)^s \qquad [12]$$

where $\Delta_i$ and $\Delta_{\bar{i}}$ are real numbers, and $r, s \in \mathbb{N}_0$. (Here $i$ labels the conformal representations that appear in the operator-product expansion, while $r$ and $s$ label the different descendants.) The actual form of this expansion (in particular, representations that appear) can be read off from the correlation functions of the theory since the identity [12] has to hold in all correlation functions.

Given that the chiral fields only depend on $z$ in all correlation functions, it is then clear that the operator-product expansion of two chiral fields again only contains chiral fields. Thus, the subspace of chiral fields closes under the operator-product expansion, and therefore defines a consistent (sub)-theory by itself. This subtheory is sometimes referred to as a meromorphic conformal field theory (Goddard 1989). (Obviously, the same also applies to the subtheory of antichiral fields.) The operator-product

expansion defines a product on the space of meromorphic fields. This product involves the complex parameters $z_i$ in a nontrivial way, and therefore does not directly define an algebra structure; it is, however, very similar to an algebra, and is therefore usually called a vertex operator algebra in the mathematical literature. The formal definition involves formal power series calculus and is quite complicated; details can be found in (Frenkel–Lepowski–Meurman 1988).

By virtue of its definition as an identity that holds in arbitrary correlation functions, the operator-product expansion is associative, that is,

$$\begin{aligned}(V(\psi_1;z_1,\bar{z}_1)V(\psi_2;z_2,\bar{z}_2))V(\psi_3;z_3,\bar{z}_3)\\ = V(\psi_1;z_1,\bar{z}_1)(V(\psi_2;z_2,\bar{z}_2)V(\psi_3;z_3,\bar{z}_3))\end{aligned} \quad [13]$$

where the brackets indicate which operator-product expansion is evaluated first. If we consider the case where both $\psi_1$ and $\psi_2$ are meromorphic fields, then the associativity of the operator-product expansion implies that the states in $\mathcal{H}$ form a representation of the vertex operator algebra. The same also holds for the vertex operator algebra associated to the antichiral fields. Thus the meromorphic fields encode in a sense the symmetries of the underlying theory: this symmetry always contains the conformal symmetry (since $L_{-2}\,|\,0\rangle$ is always a chiral field, and $\bar{L}_{-2}\,|\,0\rangle$ always an antichiral field). In general, however, the symmetry may be larger. In order to take full advantage of this symmetry, it is then useful to decompose the full space of states $\mathcal{H}$ not just with respect to the two Virasoro algebras, but rather with respect to the two vertex operator algebras; the structure is again the same as in [8], where, however, each $\mathcal{H}_i$ and $\bar{\mathcal{H}}_j$ is now an irreducible representation of the chiral and antichiral vertex operator algebra, respectively.

## Rational Theories and Zhu's Algebra

Of particular interest are the rational conformal field theories that are characterized by the property that the corresponding vertex operator algebras only possess finitely many irreducible representations. (The name "rational" stems from the fact that the conformal weights and the central charge of these theories are rational numbers.) The simplest example of such rational theories are the so-called minimal models, for which the vertex operator algebra describes just the conformal symmetry: these models exist for a certain discrete set of central charges $c<1$ and were first studied by Belavin, Polyakov, and Zamolodchikov in 1984. (Their paper is contained in the reprint volume of Goddard and Olive (1988).) It was this seminal paper that started many of the modern developments in conformal field theory. Another important class of examples are the Wess–Zumino–Witten (WZW) models that describe the world-sheet theory of strings moving on a compact Lie group. The relevant vertex operator algebra is then generated by the loop group symmetries. There is some evidence that all rational conformal field theories can be obtained from the WZW models by means of two standard constructions, namely by considering cosets and taking orbifolds; thus rational conformal field theory seems to have something of the flavor of (reductive) Lie theory.

Rational theories may be characterized in terms of Zhu's algebra that can be defined as follows. The chiral fields $V(\psi,z)$ that only depend on $z$ must by themselves define local operators; they can therefore be expanded in a Laurent expansion as

$$V(\psi,z)=\sum_{n\in\mathbb{Z}}V_n(\psi)\,z^{-n-h} \quad [14]$$

where $h$ is the conformal weight of the state $\psi$. For example, for the case of the holomorphic component of the stress–energy tensor one finds

$$T(z)=\sum_{n\in\mathbb{Z}}L_n z^{-n-2} \quad [15]$$

where the $L_n$ are the Virasoro generators. By the state/field correspondence [6], it then follows that

$$V_n(\psi)|0\rangle=0 \quad \text{for } n>-h \quad [16]$$

and that

$$V_{-h}(\psi)|0\rangle=\psi \quad [17]$$

(For an example of the above component of the stress–energy tensor, [16] implies that $L_{-1}|0\rangle = L_0\,|0\rangle = L_n|0\rangle = 0$ for $n\geq 0$ – thus the vacuum is in particular $\mathrm{SL}(2,\mathbb{C})/\mathbb{Z}_2$ invariant. Furthermore, [17] shows that $L_{-2}\,|\,0\rangle$ is the state corresponding to this component of the stress–energy tensor.) We denote by $\mathcal{H}_0$ the space of states that can be generated by the action of the modes $V_n(\psi)$ from the vacuum $|0\rangle$. On $\mathcal{H}_0$ we consider the subspace $\mathcal{O}(\mathcal{H}_0)$ that is spanned by the states of the form

$$V^{(N)}(\psi)\chi, \quad N>0 \quad [18]$$

where $V^{(N)}(\psi)$ is defined by

$$V^{(N)}(\psi)=\sum_{n=0}^{h}\binom{h}{n}V_{-n-N}(\psi) \quad [19]$$

and $h$ is the conformal weight of $\psi$. Zhu's algebra is then the quotient space

$$A=\mathcal{H}_0/\mathcal{O}(\mathcal{H}_0) \quad [20]$$

It actually forms an associative algebra, where the algebra structure is defined by

$$\psi \star \chi = V^{(0)}(\psi)\chi \qquad [21]$$

This algebra structure can be identified with the action of the "zero-mode algebra" on an arbitrary highest-weight state.

Zhu's algebra captures much of the structure of the (chiral) conformal field theory: in particular, it was shown by Zhu in 1996 that the irreducible representations of $A$ are in one-to-one correspondence with the representations of the full vertex operator algebra. A conformal field theory is thus rational (in the above, physicists', sense) if Zhu's algebra is finite dimensional. (In the mathematics literature, a vertex operator algebra is usually called rational if in addition every positive-energy representation is completely reducible. It has been conjectured that this is equivalent to the condition that Zhu's algebra is semisimple.)

In practice, the determination of Zhu's algebra is quite complicated, and it is therefore useful to obtain more easily testable conditions for rationality. One of these is the so-called $C_2$ condition of Zhu: a vertex operator algebra is $C_2$-cofinite if the quotient space $\mathcal{H}_0/\mathcal{O}_2(\mathcal{H}_0)$ is finite dimensional, where $\mathcal{O}_2(\mathcal{H}_0)$ is spanned by the vectors of the form

$$V_{-n-h}(\psi)\chi, \quad n \geq 1 \qquad [22]$$

It is easy to show that the $C_2$-cofiniteness condition implies that Zhu's algebra is finite dimensional. Gaberdiel and Neitzke have shown that every $C_2$-cofinite vertex operator algebra has a simple spanning set; this observation can, for example, be used to prove that all the fusion rules (see below) of such a theory are finite.

## Fusion Rules and Verlinde's Formula

As explained above, the correlation function of three primary fields is determined up to an overall constant. One important question is whether or not this constant actually vanishes since this determines the possible "couplings" of the theory. This information is encoded in the so-called fusion rules of the theory. More precisely, the fusion rules $N_{ij}{}^k \in \mathbb{N}_0$ determine the multiplicity with which the representation of the vertex operator algebra labeled by $k$ appears in the operator-product expansion of the two representations labeled by $i$ and $j$.

In 1988, Verlinde found a remarkable relation between the fusion rules of a vertex operator algebra and the modular transformation properties of its characters. To each irreducible representation $\mathcal{H}_i$ of a vertex operator algebra, one can define the character

$$\chi_i(\tau) = \mathrm{tr}_{\mathcal{H}_i}\left(q^{L_0-(c/24)}\right), \quad q = \mathrm{e}^{2\pi \mathrm{i}\tau} \qquad [23]$$

For rational vertex operator algebras (in the mathematical sense) these characters transform under the modular transformation $\tau \mapsto -1/\tau$ as

$$\chi(-1/\tau) = \sum_j S_{ij}\chi_j(\tau) \qquad [24]$$

where $S_{ij}$ are constant matrices. Verlinde's formula then states that, at least for unitary theories,

$$N_{ij}{}^k = \sum_l \frac{S_{il}\, S_{jl}\, S^*_{kl}}{S_{0l}} \qquad [25]$$

where the "0" label denotes the vacuum representation. A general argument for this formula has been given by Moore and Seiberg in 1989; very recently, this has been made more precise by Huang.

## Modular Invariance and the Conformal Bootstrap

Up to now, we have only considered conformal field theories on the sphere. In order for the theory to be well defined also on higher-genus surfaces, it is believed that the only additional requirement comes from the consistency of the torus amplitudes. In particular, the vacuum torus amplitude must only depend on the equivalence class of tori that is described by the modular parameter $\tau \in \mathbb{H}$, up to the discrete identifications that are generated by the usual action of the modular group $\mathrm{SL}(2,\mathbb{Z})$ on the upper half-plane $\mathbb{H}$. For the theory with decomposition [8] this requires that the function

$$Z(\tau,\bar{\tau}) = \sum_{ij} M_{ij}\chi_i(\tau)\chi_j(\bar{\tau}) \qquad [26]$$

is invariant under the action of $\mathrm{SL}(2,\mathbb{Z})$. This is a very powerful constraint on the multiplicity matrices $M_{ij}$ that has been analyzed for various vertex operator algebras. For example, Cappelli, Itzykson, and Zuber have shown that the modular invariant WZW models corresponding to the group SU(2) have an A–D–E classification. The case of SU(3) was solved by Gannon, using the Galois symmetries of these rational conformal field theories.

The condition of modular invariance is relatively easily testable, but it does not, by itself, guarantee that a given space of states $\mathcal{H}$ comes from a consistent conformal field theory. In order to construct a consistent conformal field theory, one needs to solve the conformal bootstrap, that is, one has to determine

all the normalization constants of the correlators so that the resulting set of correlators is local and factorizes appropriately into 3-point correlators (crossing symmetry). This is typically a difficult problem which has only been solved explicitly for rather few theories, for example, the minimal models. Recently, it has been noticed that the conformal bootstrap can be more easily solved for the corresponding boundary conformal field theory. Furthermore, Fuchs, Runkel, and Schweigert have shown that any solution of the boundary problem induces an associated solution for conformal field theory on surfaces without boundary. This construction relies heavily on the relation between 2D conformal field theory and 3D topological field theory (Turaev 1994).

# Two-Dimensional Ising Model

**B M McCoy**, State University of New York at Stony Brook, Stony Brook, NY, USA

## Introduction

The Ising model is a model of a classical ferromagnet on a lattice first introduced in 1925 in the one-dimensional case by E Ising. At each lattice site there is a "spin" variable $\sigma$, which takes on the values +1 (spin up) and –1 (spin down). The mutual interaction energy of the pair of spins $\sigma_\alpha$ and $\sigma_{\alpha'}$, where $\alpha$ and $\alpha'$ are nearest neighbors, is $-E(\alpha, \alpha')$ if $\sigma_\alpha = \sigma_{\alpha'}$ and is $E(\alpha, \alpha')$ if $\sigma_\alpha = -\sigma_{\alpha'}$. In addition, the spins can interact with an external magnetic field as $-H\sigma_\alpha$. On a square lattice, where $j$ specifies the row and $k$ specifies the column, the interaction energy for the homogeneous case where $E_{\rm v}(\alpha, \alpha')$ and $E_{\rm h}(\alpha, \alpha')$ are independent of the position $\alpha, \alpha'$ may be explicitly written as

$$E(H) = -\sum_{j,k}[E_{\rm h}\sigma_{j,k}\sigma_{j,k+1} + E_{\rm v}\sigma_{j,k}\sigma_{j+1,k} + H\sigma_{j,k}] \quad [1]$$

This very simple model [1] has the remarkable property that in two dimensions at $H = 0$ many properties of physical interest can be computed exactly. Furthermore, the model has a ferromagnetic phase transition at a critical temperature $T_{\rm c}$, at which the specific heat diverges and the magnetic susceptibility diverges to infinity and below which there is a nonzero spontaneous magnetization. In addition, the microscopic correlations between spins can also be exactly computed. These exact calculations are the basis of the modern theory of second-order phase transitions used to analyze real ferromagnets and real fluids near their critical points in both two and three dimensions. The model may also be interpreted as a lattice gauge theory.

## Solvability

The solvability of the Ising model at $H = 0$ was discovered by Onsager in 1944 in one of the most profound and inventive papers ever written in mathematical physics. Onsager discovered that the model possesses an infinite-dimensional symmetry, which allowed him to exactly compute the free

energy per site. This symmetry is generated by the relations

$$
\begin{aligned}
[A_l, A_m] &= 4G_{l-m} \\
[G_l, A_m] &= 2A_{m+l} - 2A_{m-l} \\
[G_l, G_m] &= 0
\end{aligned}
\qquad [2]
$$

This algebra of Onsager is a subalgebra of what is now called the loop algebra of the Lie algebra $Sl_2$ and it is the first infinite-dimensional algebra to be used in physics.

In the 60 years since Onsager first computed the free energy, several other methods of exact solution have been found. In 1949, Kaufman reduced the computation of the free energy to a problem of free fermions. A closely related combinatorial method was invented by Kac and Ward, Hurst and Green, and by Kastelyn. Baxter (1982) has computed the free energy by means of star triangle equations and functional equations in his book.

The fermionic and the combinatorial methods are powerful enough to compute the correlation functions but are not generalizable to other models. The functional equation methods of Baxter generalize to many other important models but they do not give correlation functions. There are still aspects of Onsager's method that remain unexplored.

The free energy per site in the thermodynamic limit is defined as

$$F = -k_{\mathrm{B}}T \lim_{\mathcal{N}\to\infty} \mathcal{N}^{-1} \ln Z_I(H) \qquad [3]$$

where $\mathcal{N}$ is the total number of sites of the lattice and the partition function $Z_I(H)$ is defined as

$$Z_I(H) = \sum_{\text{all } \sigma=\pm 1} \mathrm{e}^{E(H)/k_{\mathrm{B}}T} \qquad [4]$$

with the sum being over all values $\sigma_{j,k} = \pm 1$ and $k_{\mathrm{B}}$ is Boltzmann's constant. The result of Onsager is that, at $H=0$,

$$
\begin{aligned}
F/k_{\mathrm{B}}T = \ln 2 + \frac{1}{8\pi^2}\int_0^{2\pi} \mathrm{d}\theta_1 \int_0^{2\pi} \mathrm{d}\theta_2 \ln \Big[ &\cosh 2E_{\mathrm{h}}/k_{\mathrm{B}}T \\
&\times \cosh 2E_{\mathrm{v}}/k_{\mathrm{B}}T - \sinh 2E_{\mathrm{h}}/k_{\mathrm{B}}T \cos\theta_1 \\
&- \sinh 2E_{\mathrm{v}}/k_{\mathrm{B}}T \cos\theta_2 \Big]
\end{aligned}
\qquad [5]
$$

This free energy has a singularity at a temperature $T_{\mathrm{c}}$ defined from

$$\sinh(2E_{\mathrm{v}}/k_{\mathrm{B}}T_{\mathrm{c}}) \sinh(2E_{\mathrm{h}}/k_{\mathrm{B}}T_{\mathrm{c}}) = 1 \qquad [6]$$

and near $T_{\mathrm{c}}$ the specific heat diverges as

$$
\begin{aligned}
c \sim -\frac{2}{k_{\mathrm{B}}T^2\pi} \Big( &E_{\mathrm{h}}^2 \sinh^2 2E_{\mathrm{v}}/k_{\mathrm{B}}T_{\mathrm{c}} + 2E_{\mathrm{v}}E_{\mathrm{h}} \\
&+ E_{\mathrm{v}}^2 \sinh^2 2E_{\mathrm{h}}/k_{\mathrm{B}}T_{\mathrm{c}} \Big) \ln|1 - T/T_{\mathrm{c}}|
\end{aligned}
\qquad [7]
$$

The next property to be computed was the spontaneous magnetization, which is usually defined as

$$M_- = \lim_{H\to 0^+} M(H) \qquad [8]$$

However, because solution is only available at $H=0$, this definition cannot be used and instead $M_-$ is computed from an alternative definition in terms of the spin–spin correlation function

$$\langle\sigma_{0,0}\sigma_{M,N}\rangle = \frac{1}{Z_I(0)} \sum_{\sigma=\pm 1} \sigma_{0,0}\sigma_{M,N} \mathrm{e}^{-E(0)/k_{\mathrm{B}}T} \qquad [9]$$

as

$$M_-^2 = \lim_{M^2+N^2\to\infty} \langle\sigma_{0,0}\sigma_{M.N}\rangle \qquad [10]$$

The result for $M_-$, first announced by Onsager in 1949, is

$$M_- = \begin{cases} (1-k^2)^{1/8} & \text{for } T \le T_{\mathrm{c}} \\ 0 & \text{for } T > T_{\mathrm{c}} \end{cases} \qquad [11]$$

where

$$k = (\sinh 2E_{\mathrm{v}}/k_{\mathrm{B}}T \sinh 2E_{\mathrm{h}}/k_{\mathrm{B}}T)^{-1} \qquad [12]$$

A key point in the computation of the magnetization [11] from [9] is that the spin–spin correlation function can be written as a determinant. In fact, there are many such different, but equal, determinental representations and the size of the smallest one in general is $2(|M| + |N|)$. The simplest case is the diagonal correlation

$$\langle\sigma_{0,0}\sigma_{N,N}\rangle = \begin{vmatrix} a_0 & a_{-1} & a_{-2} & \cdots & a_{1-N} \\ a_1 & a_0 & a_{-1} & \cdots & a_{2-N} \\ a_2 & a_1 & a_0 & \cdots & a_{3-N} \\ \vdots & \vdots & \vdots & \cdots & \vdots \\ a_{N-1} & a_{N-2} & a_{N-3} & \cdots & a_0 \end{vmatrix} \qquad [13]$$

where

$$a_n = \frac{1}{2\pi}\int_{-\pi}^{\pi} \mathrm{d}\theta \mathrm{e}^{-\mathrm{i}n\theta} \left[\frac{1-k\mathrm{e}^{-\mathrm{i}\theta}}{1-k\mathrm{e}^{\mathrm{i}\theta}}\right]^{1/2} \qquad [14]$$

Determinants of the form [13], where the elements on each diagonal are equal, are called Toeplitz.

The study of the spin–spin correlations of the Ising model provides a microscopic picture of the behavior of the ferromagnet near the phase transition temperature $T_{\mathrm{c}}$, and an entire branch of mathematics has developed from the study of the behavior of Toeplitz determinants when the size is large. The first such mathematical advance was the discovery by Szegö of a general formula for the limit as $N \to \infty$, from which the magnetization [11] is computed.

The simplest result for the approach to this $N \to \infty$ limit is the behavior of the diagonal correlation at $T = T_c(k = 1)$, where [13] exactly reduces to

$$<\sigma_{0,0}\sigma_{N,N}> = \left(\frac{2}{\pi}\right)^N \prod_{l=1}^{N-1}\left[1 - \frac{1}{4l^2}\right]^{l-N} \qquad [15]$$

which behaves as $N \to \infty$ as

$$<\sigma_{0,0}\sigma_{N,N}> \sim AN^{-1/4} \qquad [16]$$

where $A \sim 0.6450\cdots$ is a transcendental constant. Further results for large $N$ and $T$ fixed are for $T < T_c(k < 1)$,

$$<\sigma_{0,0}\sigma_{N,N}> \sim M_-{}^2\left\{1 + \frac{2k^{2(N+1)}}{\pi N^2 (k^{-2} - 1)^2} + \cdots\right\} \qquad [17]$$

and for $T > T_c(k > 1)$,

$$<\sigma_{0,0}\sigma_{N,N}> \sim \frac{k^{-N}}{(\pi N)^{1/2}(1 - k^{-2})^{1/4}} + \cdots \qquad [18]$$

By comparing [16] with [17] and [18], we see that at $T = T_c$ the correlations decay algebraically but for $T \neq T_c$ the decay is exponential. It is useful to write the exponential in [17] for $T < T_c$ as

$$k^{-N} = \mathrm{e}^{-N/\xi_-} \quad \text{with } \xi^{-1} = -\ln k \qquad [19]$$

and in [18] for $T > T_c$ as

$$k^N = \mathrm{e}^{-N/\xi_+} \quad \text{with } \xi^{-1} = \ln k \qquad [20]$$

The quantity $\xi$ is called the correlation length and as $T \to T_c$ the correlation length diverges as

$$\xi_\pm \sim |1 - k|^{-1} = \text{const.}\ |T - T_c|^{-1} \qquad [21]$$

A more profound property of the correlations is that they satisfy differential and difference equations. It was found by Jimbo and Miwa (1980) that the diagonal correlation function satisfies the nonlinear differential equation related to the sixth Painlevé function

$$\left(t(t-1)\frac{\mathrm{d}^2\sigma}{\mathrm{d}t^2}\right)^2 = N^2\left((t-1)\frac{\mathrm{d}\sigma}{\mathrm{d}t} - \sigma\right)^2 - 4\frac{\mathrm{d}\sigma}{\mathrm{d}t}\left((t-1)\frac{\mathrm{d}\sigma}{\mathrm{d}t} - \sigma - \frac{1}{4}\right)\left(t\frac{\mathrm{d}\sigma}{\mathrm{d}t} - \sigma\right) \qquad [22]$$

where for $T < T_c$ we set $t = k^{-2}$ and

$$\sigma_N(t) = t(t-1)\frac{\mathrm{d}}{\mathrm{d}t}\ln <\sigma_{0,0}\sigma_{N,N}> - \frac{1}{4} \qquad [23]$$

and for $T > T_c$ we set $t = k^2$ and

$$\sigma_N(t) = t(t-1)\frac{\mathrm{d}}{\mathrm{d}t}\ln <\sigma_{0,0}\sigma_{N,N}> - \frac{t}{4} \qquad [24]$$

Furthermore it was found by McCoy *et al.* (1981) that for a given temperature the general two spin correlation function and all multipoint correlations satisfy quadratic nonlinear partial difference equations in the locations of the spins.

## Scaling Theory

It is evident that the results [17] and [18] do not reduce to [16] when $k \to 1$. Therefore, in order to uniformly characterize the behavior of the correlation function in the critical region near $T_c$, it is necessary to introduce what is called the scaling function. This uniform expansion is obtained by introducing a scaled length defined as

$$r = N/\xi \qquad [25]$$

and considering the joint (scaling limit) where

$$N \to \infty \quad \text{and} \quad T \to \infty \quad \text{with } r \text{ fixed} \qquad [26]$$

We define the scaled correlation function as

$$G_\pm(r) = \lim_{\text{scaling}} M_\pm^{-2} <\sigma_{0,0}\sigma_{N,N}> \qquad [27]$$

where the subscript $\pm$ means that the limit is taken from $T > T_c$ or $T < T_c$, respectively, $M_-$ is the spontaneous magnetization [11] and

$$M_+ = (k^{-2} - 1)^{1/8} \qquad [28]$$

This concept of the scaling limit and scaling function is very general and can be defined for any system with a critical point that has an order parameter like $M_-$ that vanishes at $T_c$ and a correlation length that diverges at $T_c$. However, the Ising model has the further remarkable property discovered by Wu *et al.* (1976) that the scaled correlation function may be explicitly expressed in terms of a function which satisfies an ordinary nonlinear differential equation. Specifically,

$$G_\pm(r) = \frac{1}{2}[1 \mp \eta(r/2)]\eta(r/2)^{-1/2} \times \exp\int_{r/2}^{\infty} r'\frac{r'}{4}\eta^{-2}[(1-\eta^2)^2 - (\eta')^2] \qquad [29]$$

where the function $\eta(r)$ satisfies the Painlevé III equation

$$\eta'' = \frac{1}{\eta}(\eta')^2 - \frac{\eta'}{r} + \eta^3 - \eta^{-1} \qquad [30]$$

with the boundary condition that

$$\eta(r) \sim 1 - 2\lambda K_0(2r) \quad \text{as } r \to \infty \qquad [31]$$

where $K_0(r)$ is the modified Bessel function of the third kind and

$$\lambda = 1/\pi \qquad [32]$$

The leading behavior of $G_{\pm}(r)$ for $r \to \infty$ is

$$G_{+}(r) \sim \lambda K_0(r) \qquad [33]$$

$$G_{-}(r) \sim 1 + \lambda^2 \left\{ r^2[K_1^2(r) - K_0^2(r)] - rK_0(r)K_1(r) + \tfrac{1}{2}K_0^2(r) \right\} \qquad [34]$$

where $K_n(z)$ is the modified Bessel function of the third kind. When $\lambda$ is given by [32] these $r \to \infty$ limits of $G_{\pm}(r)$ agree with the behavior of $<\sigma_{0,0}\sigma_{N,N}>$ for $N \gg 1$ and $|T - T_c|$ small with $N|T - T_c| \gg 1$ which is obtained from [18] and [17]. The behavior of $G_{\pm}(r)$ for $r \to 0$ with the value of $\lambda$ given by [32] is

$$G_{\pm}(r) = \text{const.}\, r^{-1/4} \qquad [35]$$

where the constant agrees with that computed from the result [16] for $<\sigma_{0,0}\sigma_{N,N}>$ at $T = T_c$ for $N \gg 1$. For other values of the boundary condition constant $\lambda$, the scaling function $G_{\pm}(r)$ diverges with a power which differs from 1/4. The computation of the constant in [35] requires the evaluation of a nontrivial integral involving the Painlevé III function.

The agreement of the limits $r \to \infty$ and $r \to 0$ of the function $G_{\pm}(r)$ with the lattice results near $T_c$ means that this scaling function uniformly interpolates between $T \neq T_c$ and $T = T_c$ and that the lattice size (defined here as unity) and the self-generated correlation length $\xi$ are the only two length scales in the theory. This feature that the system generates only one new length scale near $T_c$ is referred to as one length scale scaling.

## Susceptibility

The final quantity of macroscopic thermodynamic interest is the magnetic susceptibility

$$\chi(T) = \left.\frac{\partial M(H)}{\partial H}\right|_{H=0} \qquad [36]$$

which is expressed in terms of the spin–spin correlation function as

$$\chi(T) = \frac{1}{k_B T}\sum_{M,N}\{<\sigma_{0,0}\sigma_{M,N}> - M_{-}^2\} \qquad [37]$$

The susceptibility may be studied by using the determinental expression for the correlation function. The simplest result is obtained (for the isotropic case, $E_v = E_h$) by using the scaling form [27] to find for $T \sim T_c$ that

$$k_B T \chi_{\pm}(T) \sim M_{\pm}^2 \xi^2 2\pi \int_0^\infty \mathrm{d}r\, r\{G_{\pm} - \Theta_{\pm}\} \qquad [38]$$

where $\Theta_{+} = 0$ and $\Theta_{-} = 1$. and thus $\chi_{\pm}(T)$ diverges at $T \to T_c$ as

$$\chi_{\pm}(T) \sim C_{\pm}|T - T_c|^{-7/4} \qquad [39]$$

where $C_{\pm}$ are transcendental constants given as integrals over the scaling function $G_{\pm}(r)$, which were first evaluated by Barouch *et al.* in 1973 as

$$C_{-} = 0.0255369719\ldots, \quad C_{+} = 0.9625817322\ldots \qquad [40]$$

## Critical-Exponent Phenomenology

From the behavior for the Ising model of the specific heat, magnetization, susceptibility, correlation length, and the correlation at $T_c$ given above we abstract for general systems the phenomenological critical-exponent parametrization for $T \to T_c\pm$ of

$$c \sim A_C^{\pm}|T - T_c|^{-\alpha_{\pm}} \qquad [41]$$

$$M \sim A_M|T_c - T|^{\beta} \qquad [42]$$

$$\chi \sim A_{\chi}^{\pm}|T - T_c|^{-\gamma_{\pm}} \qquad [43]$$

$$\xi \sim A_{\xi}^{\pm}|T - T_c|^{-\nu_{\pm}} \qquad [44]$$

and at $T = T_c$ for $R \to \infty$

$$<\sigma_0\sigma_R> \sim A_{\sigma}/R^{d-2+\eta} \quad \text{where } d \text{ is the dimension} \qquad [45]$$

The exponents $\alpha_{\pm}, \gamma_{\pm}, \nu_{\pm}$ above and below $T_c$ are usually found to be equal, and the exponent $\eta$ is usually called the anomalous dimension. If it is assumed that the scaling function [27] exists and that one length scale scaling holds then the exponents are related by what are called scaling laws, such as

$$2\beta = \nu_{-}(d - 2 + \eta) \qquad [46]$$

$$\alpha_{-} + 2\beta - \gamma_{-} = 2 \qquad [47]$$

$$d\nu_{-} = 2 - \alpha_{-} \qquad [48]$$

Thus, from the properties of the Ising model near $T_c$, we have obtained a phenomenology for use on all systems near the critical point.

## Fuchsian Equations and Natural Boundaries for Susceptibility

This critical phenomenology, however, has not taken into account the fact that the susceptibility is a much more complicated function than either the spontaneous magnetization [11] or the free energy [5], which have only isolated singularities at $k^2=1$, and that there is more structure to the susceptibility than the singularity of [39].

For arbitrary $T$, the susceptibility was shown by Wu, McCoy, Tracy, and Barouch to be expressible in the form

$$\chi_{\pm}(T) = M_{\pm}^2 \sum_j \tilde{\chi}^{(j)}(T) \qquad [49]$$

where in the sum $j$ is odd (even) for $T$ above (below) $T_c$. The quantities $\tilde{\chi}^{(j)}(T)$ are explicitly given as $j$-fold integrals of algebraic functions and thus will satisfy linear differential equations with polynomial coefficients. Such functions can have only isolated singularities. The function $\tilde{\chi}^{(1)}(T)$ is elementary and has a double pole at $T_c$ and $\tilde{\chi}^{(2)}(T)$ is given in terms of complete elliptic integrals. Quite recently, remarkable Fuchsian linear differential equations for $\tilde{\chi}^{(3)}(T)$ and $\tilde{\chi}^{(4)}(T)$ of seventh and tenth orders, respectively, have been obtained by Zenine, Boukraa, Hassani, and Maillard for the isotropic lattice.

Furthermore, it was shown by Orrick *et al.* (2001) that $\tilde{\chi}^{(j)}$ has singularities in the complex $T$ plane at

$$\begin{aligned} &\cosh(2E_v/kT)\cosh(2E_h/kT) \\ &\quad - \sinh(2E_v/kT)\cos(2\pi/j) \\ &\quad - \sinh(2E_h/kT)\cos(2\pi m'/j) = 0 \end{aligned} \qquad [50]$$

with $m, m' = 1, 2, \ldots, j$. The form of the singularity in $\tilde{\chi}^{(j)}(T)$ for $T > T_c$ is as

$$\epsilon^{(j^2-3)/2} \ln \epsilon \qquad [51]$$

and, for $T < T_c$, it is as

$$\epsilon^{(j^2-3)/2} \qquad [52]$$

where $\epsilon$ measures the deviation from the singular point [50]. These singularities become dense as $j \to \infty$ and, therefore, the singularity at $T = T_c$ is not isolated and instead the critical point is embedded in a natural boundary. Such a function cannot satisfy a linear differential equation of finite order with polynomial coefficients.

The existence of the natural boundary in the susceptibility is a new phenomenon which is not seen in either the free energy or magnetization and leads to the speculation that in the presence of a magnetic field the one length scale scaling property of the model at $H = 0$ may fail. If this proves to be correct, there will be physical effects which are not incorporated in the phenomenological scaling theory of critical phenomena.

## Impure Ising Models

The Ising model may also be studied when the interaction energies at sites $j, k$ are not chosen to be independent of position but are allowed to vary from site to site. When these interactions are chosen randomly out of some probability distribution, this is a model of a ferromagnet with frozen (quenched) impurities. All real systems will be impure to some extent, so the study of such dirty systems is of great practical importance.

The special case where the interactions are translationally invariant in the horizontal direction but are allowed to vary in a layered fashion from row to row was introduced by McCoy and Wu in 1968 and found to be dramatically different from the pure Ising model described above. In particular, what is a critical temperature $T_c$ in the pure case is now spread out into a region bounded by the temperatures the pure model would be critical if all the bonds took on the minimum or maximum value allowed by the probability distribution. In this new region, the correlations (in the direction of translational invariance) are found to decay as a power law which depends on the temperature; the specific heat is never infinite but the susceptibility is infinite in an entire temperature region that includes the temperature at which the spontaneous magnetization first appears as $T$ is lowered. The existence of this new region for Ising models with a general randomness in two and three dimensions has been demonstrated by Griffiths. More recently, this effect has been reinterpreted in terms of impurities in quantum spin chains.

## Quantum Field Theory

The Ising model of [1] may be reinterpreted as a two-dimensional lattice gauge theory of the gauge field

$s_{j+1/2,k} = \pm 1$

on the vertical link between $(j, k)$ and $(j+1, k)$

$s_{j,k+1/2} = \pm 1$

on the horizontal link between $(j, k)$

and $(j, k+1)$ [53]

and a “Higgs” field

$$\phi_{j,k} = \pm 1 \quad \text{on the site } (j, k) \qquad [54]$$

with the action

$$S_g = -E_g \sum_{j,k} s_{j+1/2,k}s_{j+1,k+1/2}s_{j+1/2,k+1}s_{j,k+1/2} - E_h \sum_{j,k} (\phi_{j,k}s_{j+1/2,k}\phi_{j+1,k} + \phi_{j,k}s_{j,k+1/2}\phi_{j,k+1}) \qquad [55]$$

If we define

$$z_{g,h} = \tanh E_{g,h}/k_B T \qquad [56]$$

the partition function of the gauge theory is expressed in terms of the Ising model partition function as

$$Z_g = [8\cosh(E_g/k_B T)\cosh^2 \times (E_h/k_B T) z_g^{1/2} z_h]^{\mathcal{N}} Z_I(H) \qquad [57]$$

where we make the identification

$$H/k_B T = \tfrac{1}{2}\ln z_g \quad \text{and} \quad E/k_B T = \tfrac{1}{2}\ln z_h \qquad [58]$$

This identification may be extended to correlation functions. Of particular interest for the gauge theory is the plaquette–plaquette correlation $< P_{0,0}P_{j,l} >$, where

$$P_{j,k} = s_{j+1/2,k}s_{j+1,k+1/2}s_{j+1/2,k+1}s_{j,k+1/2} \qquad [59]$$

which is expressed in terms of the Ising correlations at $H \neq 0$ as

$$< P_{0,0}P_{j,k} > - < P_{0,0} >^2 = \sinh^2(2H/k_B T)(< \sigma_{0,0}\sigma_{j,k} > - < \sigma_{0,0} >^2) \qquad [60]$$

To study this correlation further, we need to study the correlations of the Ising model in nonzero magnetic field. This has been done by McCoy and Wu in the scaling limit $H \to 0, T \to T_c$ with

$$h = \frac{H}{|T - T_c|^{15/8}} \text{ fixed} \qquad [61]$$

for $T < T_c$, where it is found that the scaling function $G(r,h)$ for small $h$ and large $r$ if

$$G(r,h) \sim \sum_l ahK_0\left[(2 + h^{2/3}\lambda_l)r\right] \sim \pi^{1/2} r^{-1/2} e^{-2r} \sum_l hae^{-rh^{2/3}\lambda_l} \qquad [62]$$

where $\lambda_l$ are the solutions of

$$J_{1/3}\left(\tfrac{1}{3}\lambda^{3/2}\right) + J_{-1/3}\left(\tfrac{1}{3}\lambda^{3/2}\right) = 0 \qquad [63]$$

with $J_n(z)$ the Bessel function of order $n$ and $K_0(z)$ the modified Bessel function of the third kind.

A field theory is said to possess a particle spectrum if the Fourier transform of the two-point function

$$G(k,h) = \int d^2 r e^{ik\cdot r} G(r,h) \qquad [64]$$

has poles of the form $A_l/(k^2 + m_l^2)$, where $m_l$ is the mass of the $l$th particle. If we note that the Fourier transform of $K_0(r)$ is

$$\int d^2 r e^{ik\cdot r} K_0(r) = \frac{2\pi}{k^2 + 1} \qquad [65]$$

we see that the Fourier transform of [62] is the sum of an infinite number of poles. This is to be compared with the Fourier transform of the scaled correlation function $G_-(r)$ at $H = 0$ and $T < T_c$ [34], which does not contain any poles at all and may instead be interpreted as having a two-particle cut. This phenomenon of a cut at $h = 0$ breaking up into an infinite number of poles for $h > 0$ is a signal that at $h = 0$ the theory has free unconfined two-particle states which become weakly confined by a linear confining potential for $h > 0$. This confinement is thought to be a characteristic of most gauge theories.

# Two-Dimensional Models

**B Schroer**, Freie Universität Berlin, Berlin, Germany

## History and Motivation

Local quantum physics of systems with infinitely many interacting degrees of freedom leads to situations whose understanding often requires new physical intuition and mathematical concepts beyond that acquired in quantum mechanics and perturbative constructions in quantum field theory. In this situation, two-dimensional soluble models turned out to play an important role. On the one hand, they illustrate new concepts and sometimes remove misconceptions in an area where new physical intuition is still in the process of being formed. On the other hand, rigorously soluble models confirm that the underlying physical postulates are mathematically consistent, a task which for interacting systems with infinite degrees of freedom is mostly beyond the capability of pedestrian methods or brute force application of hard analysis on models whose natural invariances have been mutilated by a cutoff.

In order to underline these points and motivate the interest in two-dimensional QFT, let us briefly look at the history, in particular at the physical significance of the three oldest two-dimensional models of relevance for statistical mechanics and relativistic particle physics, in chronological order: the Lenz–Ising (L–I) model, Jordan's model of bosonization/fermionization, and the Schwinger model ($QED_2$). (A more detailed account of the changeful history concerning their correct physical interpretation and generalizations to higher dimensions of these models and the increasing conceptual role of low-dimensional models in QFT can be found in Schroer (2005).)

The L–I model was proposed in 1920 by Wihelm Lenz (see Lenz (1925)) as the simplest discrete statistical mechanics model with a chance to go beyond the P Weiss phenomenological ansatz involving long-range forces and instead explain ferromagnetism in terms of nonmagnetic short-range interactions. Its one-dimensional version was solved four years later by his student Ernst Ising. Its changeful history reached a temporary conceptual climax when Onsager succeeded to rigorously establish a second-order phase transition in two dimensions.

Another conceptually rich model which lay dormant for almost two decades as a result of a misleading speculative higher-dimensional generalization by its protagonist is the bosonization/fermionization model first proposed by Jordan (1937). This model establishes a certain equivalence between massless two-dimensional fermions and bosons and is related to Thirring's massless 4-fermion coupling model and also to Luttinger's one-dimensional model of an electron gas (Schroer). One reason why even nowadays hardly anybody knows Jordan's contribution is certainly the ambitious but unfortunate title "the neutrino theory of light" under which he published a series of papers.

Both discoveries demonstrate the usefulness of having controllable low-dimensional models; at the same time, their complicated history also illustrates the danger of rushing to premature "intuitive" conclusions about extensions to higher dimensions.

A review of the early historical benchmarks of conceptual progress through the study of solvable two-dimensional models would be incomplete without mentioning Schwinger's (1962) proposed solution of two-dimensional quantum electrodynamics, afterwards referred to as the Schwinger model. He used this model in order to argue that gauge theories are not necessarily tied to zero-mass vector particles. Some work was necessary (Schroer) to unravel its physical content with the result that the would-be charge of that $QED_2$ model was "screened" and its apparent chiral symmetry broken; in other words, the model exists only in the so-called Schwinger–Higgs phase with massive free scalar particles accounting for its physical content. Another closely related aspect of

this model which also arose in the Lagrangian setting of four-dimensional gauge theories was that of the $\theta$-angle parametrizing, an ambiguity in the quantization.

A coherent and systematic attempt at a mathematical control of two-dimensional models came in the wake of Wightman's first rigorous programmatic formulation of QFT (Schroer 2005). This formulation stayed close to the physical ideas underlying the impressive success of renormalized QED perturbation theory, although it avoided the direct use of Lagrangian quantization. The early attempts towards a "constructive QFT" found their successful realization in two-dimensional QFT (the $P\varphi_2$ models (Glimm and Jaffe 1987)); the restriction to low dimensions is related to the mild short-distance singularity behavior (super-renormalizability) which these methods require. We will focus our main attention on alternative constructive methods which, even though not suffering from such short-distance restrictions, also suffer from a lack of mathematical control in higher spacetime dimensions; the illustration of the constructive power of these new methods comes presently from massless $d=1+1$ conformal and chiral QFT as well as from massive factorizing models.

There are several books and review articles (Furlan *et al.* 1989, Ginsparg 1990, Di Francesco *et al.* 1996) on $d=1+1$ conformal as well as on massive factorizing models (Abdalla *et al.* 1991). To the extent that concepts and mathematical structures are used which permit no extension to higher dimensions (Kac–Moody algebras, loop groups, integrability, presence of an infinite number of conservation laws), this line of approach will not be followed in this article since our primary interest will be the use of two-dimensional models of QFT as "theoretical laboratories" of general QFT. Our aim is twofold; on the one hand, we intend to illustrate known principles of general QFT in a mathematically controllable context and on the other hand, we want to identify new concepts whose adaptation to QFT in $d=1+1$ lead to their solvability (Schroer).

## General Concepts and Their Two-Dimensional Manifestation

The general framework of QFT, to which the rich world of controllable two-dimensional models contributes as an important testing ground, exists in two quite different but nevertheless closely related formulations: the 1956 approach in terms of pointlike covariant fields due to Wightman (see Streater and Wightman (1964)) (*see* Axiomatic Quantum Field Theory), and the more algebraic setting which can be traced back to ideas which Haag (1992) developed shortly after and which are based on spacetime-indexed operator algebras and related concepts which developed over a long period of time, with contributions of many other authors to what is now referred to as algebraic QFT (AQFT) or simply local quantum physics (LQP). Whereas the Wightman approach aims directly at the (not necessarily observable) quantum fields, the operator-algebraic setting (*see* Algebraic Approach to Quantum Field Theory) is more ambitious. It starts from physically well-motivated assumptions about the algebraic structure of local observables and aims at the reconstruction of the full field theory (including the operators carrying the superselected charges) in the spirit of a local representation theory of (the assumed structure of the) local observables. This has the advantage that the somewhat mysterious concept of an inner symmetry (as opposed to outer (spacetime) symmetry) can be traced back to its physical roots which is the representation-theoretical structure of the local observable algebra (*see* Symmetries in Quantum Field Theory of Lower Spacetime Dimensions). In the standard Lagrangian quantization approach, the inner symmetry is part of the input (multiplicity indices of field components on which subgroups of U($n$) or O($n$) act linearly) and hence it is not possible to problematize this fundamental question. When in low-dimensional spacetime dimensions the sharp separation (the Coleman–Mandula theorems) of inner versus outer symmetry becomes blurred as a result of the appearance of braid group statistics, the standard Lagrangian quantization setting of most of the textbooks is inappropriate and even the Wightman framework has to be extended. In that case, the algebraic approach is the most appropriate.

The important physical principles which are shared between the Wightman approach (see Streater and Wightman (1964)) and the operator algebra (AQFT) setting (Haag 1992) are the spacelike locality or Einstein causality (in terms of pointlike fields or algebras localized in causally disjoint regions) and the existence of positive-energy representations of the Poincaré group implementing covariance and the stability of matter. In the algebraic approach, the observable content of the theory is encoded into a family of (weakly closed) operator algebras $\{\mathcal{A}(\mathcal{O})\}_{\mathcal{O}\in\mathcal{K}}$ indexed by a family of convex causally closed spacetime regions $\mathcal{O}$ (with $\mathcal{O}'$ denoting the spacelike complement and $\mathcal{A}'$ the von Neumann commutant) which act in one common Hilbert space. Covariant local fields lose their distinguished role

which they have in the classical setting and which (via Lagrangian quantization) was at least partially inherited by the Wightman approach and, apart in their role as local generators of symmetries (conserved currents), became mere "field coordinatizations" of local algebras. (There is a denumerable set of such pointlike field generators which form a local equivalence (Borchers) class of fields and in the absence of interactions permits a neat description in terms of Wick-ordered free-field polynomials (Haag 1992). Certain properties cannot be naturally formulated in the pointlike field setting (e.g., Haag duality for convex regions $\mathcal{A}(\mathcal{O}') = \mathcal{A}(\mathcal{O})'$), but apart from those properties the two formulations are quite close; in particular for two-dimensional theories there are convincing arguments that one can pass between the two without imposing additional technical requirements. (Haag duality holds for observable algebras in the vacuum sector in the sense that any violation can be explained in terms of a spontaneously broken symmetry; in local theories, it can always be enforced by dualization and the resulting Haag dual algebra has a charge superselection structure associated with the unbroken subgroup.) Haag duality is the statement that the commutant of observables not only contains the algebra of the causal complement that is, $\mathcal{A}(\mathcal{O}') \subset \mathcal{A}(\mathcal{O})'$ (Einstein causality) but is even exhausted by it; it is deeply connected to the measurement process and its violation in the vacuum sector for convex causally complete regions signals spontaneous symmetry breaking in the associated charge-carrying field algebra (Haag 1992). It can always be enforced (assuming that the wedge-localized algebras fulfill [1] below) by symmetry-reducing extension called Haag dualization. Its violation for multilocal region reveals the charge content of the model via charge–anticharge splitting in the neutral observable algebra (Schroer).

Another physically important property which has a natural algebraic formulation is the split property: for regions $\mathcal{O}_i$ separated by a finite spacelike distance, one finds $\mathcal{A}(\mathcal{O}_1 \cup \mathcal{O}_2) \simeq \mathcal{A}(\mathcal{O}_1) \otimes \mathcal{A}(\mathcal{O}_2)$ which can be derived from the Buchholz–Wichmann "nuclearity property" (Haag 1992) (an appropriate adaptation of the "finiteness of phase-space cell" property of QM to QFT). Related to the Haag duality is the local version of the "time slice property" (the QFT counterpart of the classical causal dependency property) sometimes referred to as "strong Einstein causality" $\mathcal{A}(\mathcal{O}'') = \mathcal{A}(\mathcal{O})''$.

One of the most astonishing achievements of the algebraic approach (which justifies its emphasis on properties of "local observables") is the DHR theory of superselection sectors (Doplicher *et al.* 1971), that is, the realization that the structure of charged (nonvacuum) representations (with the superposition principle being valid only within one representation) and the spacetime properties of the generating fields which are the carriers of these generalized charges (including their spacelike commutation relations which lead to the particle statistics and also to their internal symmetry properties) are already encoded in the structure of the Einstein causal observable algebra (Symmetries in Quantum Field Theory: Algebraic Aspects). The intuitive basis of this remarkable result (whose prerequisite is locality) is that one can generate charged sectors by spatially separating charges in the vacuum (neutral) sector and disposing of the unwanted charges at spatial infinity (Haag 1992).

An important concept which especially in $d = 1 + 1$ has considerable constructive clout is "modular localization." It is a consequence of the above algebraic setting if either the net of algebras have pointlike field generators, or if the one-particle masses are separated by spectral gaps so that the formalism of time-dependent scattering can be applied (Schroer 2005); in conformal theories, this property holds automatically in all spacetime dimensions. It rests on the basic observation (Tomita–Takesaki Modular Theory) that a standard pair $(\mathcal{A}, \Omega)$ of a von Neumann operator algebra and a standard vector (standardness means that the operator algebra of the pair $(\mathcal{A}, \Omega)$ acts cyclic and separating on the vector $\Omega$) gives rise to a Tomita operator $S$ through its star-operation whose polar decomposition yield two modular objects, a one-parametric subgroup $\Delta^{it}$ of the unitary group of operators in Hilbert space whose Ad-action defines the modular automorphism of $(\mathcal{A}, \Omega)$ whereas the angular part $J$ is the modular conjugation which maps $\mathcal{A}$ into its commutant $\mathcal{A}'$

$$\begin{aligned} &SA\Omega = A^*\Omega,\ S = J\Delta^{1/2} \\ &J_W = U(j_W) = S_{\mathrm{scat}}J_0, \Delta_W^{it} = U(\Lambda_W(2\pi t)) \\ &\sigma_W(t) := \mathrm{Ad}\Delta_W^{it} \end{aligned} \qquad [1]$$

The standardness assumption is always satisfied for any field-theoretic pair $(A(\mathcal{O}), \Omega)$ of a $O$-localized algebra and the vacuum state (as long as $\mathcal{O}$ has a nontrivial causal disjoint $\mathcal{O}'$), but it is only for the wedge region $W$ that the modular objects have a physical interpretation in terms of the global symmetry group of the vacuum as specified in the second line of [1]; the modular unitary $\Delta_W^{it}$ represents the $W$-associated boost $\Lambda_W(\chi)$ and the modular conjugation $J_W$ implements the TCP-like reflection along the edge of the wedge (Bisognano

and Wichmann 1975). The third line is the definition of the modular group. The importance of this theory for local quantum physics results from the fact that it leads to the concept of modular localization, an intrinsic new scenario for field-theoretic constructions which is different from the Lagrangian quantization schemes (Schroer 2005).

A special feature of $d = 1 + 1$ Minkowski spacetime is the disconnectedness of the right/left spacelike region leading to a right–left ordering structure. So in addition to the Lorentz-invariant timelike ordering $x \prec y$ ($x$ earlier than $y$, which is independent of spacetime dimensions), there is an invariant spacelike ordering $x < y$ ($x$ to the left of $y$) in $d = 1 + 1$ which opens the possibility of more general Lorentz-invariant spacelike commutation relations than those implemented by Bose/Fermi fields (Rehren and Schroer 1987) of fields with a spacelike braid group commutation structure. The appearance of such exotic statistics fields is not compatible with their Fourier transforms being creation/annihilation operators for Wigner particles; rather, the state vectors which they generate from the vacuum contain in addition to the one-particle contribution a vacuum polarization cloud (Schroer 2005). This close connection between new kinematic possibilities and interactions is one of the reasons why, (different from higher dimensions where interactions are prescribed by the recipe of local couplings of free fields) low-dimensional QFT offers a more intrinsic access to the central issue of interactions.

## Boson/Fermion Equivalence and Superselection Theory in a Special Model

The simplest and oldest but conceptually still rich model is obtained, as first proposed by Jordan (1937), by using a two-dimensional massless Dirac current and showing that it may be expressed in terms of scalar canonical Bose creation/annihilation operators

$$j_\mu =: \overline{\psi}\gamma_\mu\psi := \partial_\mu\phi,\ \phi := \int_{-\infty}^{+\infty} \{e^{ipx}a^*(p) + h.c.\}\frac{dp}{2|p|} \qquad [2]$$

Although the potential $\phi(x)$ of the current as a result of its infrared divergence is not a field in the standard sense of an operator-valued distribution in the Fock space of the $a(p)^{\#}$ (It becomes an operator after smearing with test functions whose Fourier transform vanishes at $p = 0$), the formal exponential defined as the zero-mass limit of a well-defined exponential free massive field

$$: e^{i\alpha\phi(x)} := \lim_{m\to 0} m^{\alpha^2/2} : e^{i}\alpha\phi_m(x) : \qquad [3]$$

turns out to be a *bona fide* quantum field in a larger Hilbert space (which extends the Fock space generated from applying currents to the vacuum). The power in front is determined by the requirement that all Wightman functions (computed with the help of free-field Wick combinatorics) stay finite in this massless limit; the necessary and sufficient condition for this is the charge conservation rule

$$\left\langle \prod_i : e^{i\alpha_i\phi(x)} : \right\rangle = \begin{cases} \prod_{i<j}\left(\dfrac{-1}{(\xi_{+ij})_\varepsilon(\xi_{-ij})_\varepsilon}\right)^{(1/2)\alpha_i\alpha_j}, & \Sigma\alpha_i = 0 \\ 0, & \text{otherwise} \end{cases} \qquad [4]$$

where the resulting correlation function has been factored in terms of light-ray coordinates $\xi_{\pm ij} = x_{\pm i} - x_{\pm j}, x_\pm = t \pm x$, and the $\varepsilon$-prescription stands for taking the standard Wightman boundary value $t \to t + i\varepsilon$, $\lim_{\varepsilon\to 0}$ which insures the positive-energy condition. The finiteness of the limit insures that the resulting zero-mass limiting theory is a *bona fide* quantum field theory that is, its system of Wightman functions permits the construction of an operator theory in a Hilbert space with a distinguished vacuum vector.

The factorization into light-ray components [4] shows that the exponential charge-carrying operators inherit this factorization into two independent chiral components $:\exp i\alpha\,\phi(x) : = \exp i\alpha\,\phi_+(x_+):$ $:\exp i\alpha\,\phi_-(x_-):$, each one being covariant under scaling $\xi \to \lambda\xi$ if one assigns the scaling dimension $d = \alpha^2/2$ to the chiral exponential field and $d = 1$ to the current. As any Wightman field, this is a singular object which only after smearing with Schwartz test functions yields an (unbounded) operator. But the above form of the correlation function belongs to a class of distributions which admits a much larger test-function space consisting of smooth functions which instead of decreasing rapidly only need to be bounded so that they stay finite on the compactified light-ray line $\dot{R} = S^1$. To make this visible, one uses the Cayley transform (now $x$ denotes either $x_+$ or $x_-$)

$$z = \frac{1 + ix}{1 - ix} \in S^1 \qquad [5]$$

This transforms the Schwartz test function into a space of test functions on $S^1$ which have an infinite order zero at $z = -1$ (corresponding to $x = \pm\infty$) but the rotational transformed fields $j(z)$, $:\exp i\alpha\,\phi(z):$ permit the smearing with all smooth functions on $S^1$, a characteristic feature of all conformal invariant

theories as the present one turns out to be. There is an additional advantage in the use of this compactification. Fourier transforming the circular current actually allows for a quantum-mechanical zero mode whose possible nonzero eigenvalues indicate the presence of additional charge sectors beyond the charge-zero vacuum sector. For the exponential field, this leads to a quantum-mechanical pre-exponential factor which automatically insures the charge selection rules so that unrestricted (by charge conservation) Wick contraction rules can be applied. In this approach, the original chiral Dirac fermion $\psi(x)$ (from which the current was formed as the $:\psi\bar{\psi}:$ composite) reappears as a charge-carrying exponential field for $\alpha = 1$ and thus illustrates the meaning of bosonization/fermionization. (It is interesting to note that Jordan's (1937) original treatment of fermionization had such a pre-exponential quantum-mechanical factor.) Naturally, this terminology has to be taken with a grain of salt in view of the fact that the bosonic current algebra only generates a superselected subspace into which the charge-carrying exponential field does not fit. Only in the case of massive two-dimensional QFT fermions can be incorporated into a Fock space of bosons (see last section). At this point, it should however be clear to the reader that the physical content of Jordan's paper had nothing to do with its misleading title "neutrino theory of light" but rather was an early illustration about charge superselection rules in two-dimensional QFT.

A systematic and rigorous approach consists in solving the problem of positive-energy representation theory for the Weyl algebra on the circle (which is the rigorous operator-algebraic formulation of the abelian current algebra). (The Weyl algebra originated in quantum mechanics around 1927; its use in QFT only appeared after the cited Jordan paper. By representation we mean here a regular representation in which the exponentials can be differentiated in order to obtain (unbounded) smeared current operators.) It is the operator algebra generated by the exponential of a smeared chiral current (always with real test functions) with the following relation between the generators

$$\begin{aligned} W(f) &= \mathrm{e}^{\mathrm{i}j(f)} \\ j(f) &= \int \frac{\mathrm{d}z}{2\pi\mathrm{i}} j(z) f(z), [j(z), j(z')] \\ &= -\delta'(z - z') \end{aligned} \quad [6a]$$

$$\begin{aligned} W(f)W(g) &= \mathrm{e}^{-(1/2)s(f,g)} W(f+g) \\ W^*(f) &= W(-f) \end{aligned} \quad [6b]$$

$$\begin{aligned} \mathcal{A}(S^1) &= \mathrm{alg}\{W(f), f \in C_\infty(S^1)\} \\ \mathcal{A}(I) &= \mathrm{alg}\{W(f), \mathrm{supp} f \subset I\} \end{aligned} \quad [6c]$$

where

$$s(.\,,.) = \int \frac{\mathrm{d}z}{2\pi\mathrm{i}} f'(z) g(z)$$

is the symplectic form which characterizes the Weyl algebra structure and [6c] denotes the unique $C^*$ algebra generated by the unitary objects $W(f)$. A particular representation of this algebra is given by assigning the vacuum state to the generators $\langle W(f)\rangle_0 = e^{-(1/2)\|f\|_0^2}$, $\|f\|_0^2 = \sum_{n\geq 1} n|f_n|^2$. Starting with the vacuum Hilbert space representation $\mathcal{A}(S^1)_0 = \pi_0(\mathcal{A}(S^1))$, one easily checks that the formula

$$\langle W(f)\rangle_\alpha := \mathrm{e}^{\mathrm{i}\alpha f_0} \langle W(f)\rangle_0 \quad [7a]$$

$$\pi_\alpha(W(f)) = \mathrm{e}^{\mathrm{i}\alpha f_0} \pi_0(W(f)) \quad [7b]$$

defines a state with positive energy, that is, one whose GNS representation for $\alpha \neq 0$ is unitarily inequivalent to the vacuum representation. Its incorporation into the vacuum Hilbert space [7b] is part of the DHR formalism. It is convenient to view this change as the result of an application of an automorphism $\gamma_\alpha$ on the $C^*$-Weyl algebra $\mathcal{A}(S^1)$ which is implemented by a unitary charge-generating operator $\Gamma_\alpha$ in a larger (nonseparable) Hilbert space which contains all charge sectors $H_\alpha = \Gamma_\alpha H_0$, $H_0 \equiv H_{\mathrm{vac}} = \overline{\mathcal{A}(S^1)\Omega}$:

$$\begin{aligned} \langle W(f)\rangle_\alpha &= \langle \gamma_\alpha(W(f))\rangle_0 \\ \gamma_\alpha(W(f)) &= \Gamma_\alpha W(f) \Gamma_\alpha^* \end{aligned} \quad [8]$$

$\Gamma_\alpha \Omega = \Omega_\alpha$ describes a state with a rotational homogeneous charge distribution; arbitrary charge distributions $\rho_\alpha$ of total charge $\alpha$ that is, $\int (\mathrm{d}z/\ 2\pi\mathrm{i})\rho_\alpha = \alpha$ are obtained in the form

$$\psi^\zeta_{\rho_\alpha} = \eta(\rho_\alpha) W(\hat{\rho}^\zeta_\alpha) \Gamma_\alpha \quad [9]$$

where $\eta(\rho_\alpha)$ is a numerical phase factor and the net effect of the Weyl operator is to change the rotational homogeneous charge distribution into $\rho_\alpha$. The necessary charge-neutral compensating function $\rho^\zeta_\alpha$ in the Weyl cocycle $W(\rho^\zeta_\alpha)$ is uniquely determined in terms of $\rho_\alpha$ up to the choice of one point $\zeta \in S^1$ (the determining equation involves the $\ln z$ function which needs the specification of a branch cut (Schroer 2005)). From this formula, one derives the commutation relations $\psi^\zeta_{\rho_\alpha} \psi^\zeta_{\rho_\beta} = \mathrm{e}^{\pm\mathrm{i}\pi\alpha\beta} \psi^\zeta_{\rho_\beta} \psi^\zeta_{\rho_\alpha}$ for spacelike separations of the $\rho$ supports; hence, these fields are relatively local (bosonic) for $\alpha\beta = 2\mathbb{Z}$. In particular, if only one

type of charge is present, the generating charge is $\alpha_{\mathrm{gen}} = \sqrt{2N}$ and the composite charges are multiples, that is, $\alpha_{\mathrm{gen}}\mathbb{Z}$. This locality condition providing bosonic commutation relations does not yet ensure the $\zeta$-independence. Since the equation which controls the $\zeta$-change turns out to be

$$\psi_{\rho_\alpha}^{\zeta_1}\left(\psi_{\rho_\alpha}^{\zeta_2}\right)^* = \mathrm{e}^{\pm \mathrm{i}\pi\alpha\beta}\mathrm{e}^{2\pi \mathrm{i} Q\alpha} \qquad [10]$$

one achieves $\zeta$-independence by restricting the Hilbert space charges to be "dual" to that of the operators, that is,

$$Q = \left\{\frac{1}{\sqrt{2N}}\mathbb{Z}\right\}$$

The localized $\psi_{\rho_\alpha}^{\zeta_1}$ operators acting on the restricted separable Hilbert space $H_{\mathrm{res}}$ generate a $\zeta$-independent extended observable algebra $\mathcal{A}_N(S^1)$ (Schroer) and it is not difficult to see that its representation in $H_{\mathrm{res}}$ is reducible and that it decomposes into $2N$ charge sectors

$$\left\{\frac{1}{\sqrt{2N}}n, n = 0, 1, \ldots, N-1\right\}$$

Hence, the process of extension has led to a charge quantization with a finite ("rational") number of charges relative to the new observable algebra which is neutral in the new charge counting

$$\frac{1}{\alpha_{\mathrm{gen}}}\mathbb{Z}/\alpha_{\mathrm{gen}}\mathbb{Z} = \mathbb{Z}/\alpha_{\mathrm{gen}}^2 = \mathbb{Z}_{2N}$$

The charge-carrying fields in the new setting are also of the above form [9], but now the generating field carries the charge

$$\int \frac{\mathrm{d}z}{2\pi \mathrm{i}}\rho_{\mathrm{gen}} = Q_{\mathrm{gen}}$$

which is a $(1/2N)$ fraction of the old $\alpha_{\mathrm{gen}}$. Their commutation relations for disjoint charge supports are "braidal" (or better "plektonic" which is more on par with being bosonic/fermionic). (In the abelian case like the present, the terminology "anyonic" enjoys widespread popularity, but in the present context the "any" does not go well with charge quantization.) These objects considered as operators localized on $S^1$ do depend on the cut $\zeta$, but using an appropriate finite covering of $S^1$ this dependence is removed (Schroer 2005). So the field algebra $\mathcal{F}_{\mathbb{Z}2N}$ generated by the charge-carrying fields (as opposed to the bosonic observable algebra $\mathcal{A}_N$) has its unique localization structure on a finite covering of $S^1$. An equivalent description which gets rid of $\zeta$ consists in dealing with operator-valued sections on $S^1$. The extension $\mathcal{A} \to \mathcal{A}_N$, which renders the Hilbert space separable and quantizes the charges, seems to be characteristic for abelian current algebra; in all other models which have been constructed up to now the number of sectors is at least denumerable and in the more interesting ones even finite (rational models). An extension is called maximal if there exists no further extension which maintains the bosonic commutation relation. For the case at hand, this would require the presence of another generating field of the same kind as above, which belongs to an integer $N'$ is relatively local to the first one. This is only possible if $N$ is divisible by a square.

In passing, it is interesting to mention a somewhat unexpected relation between the Schwinger model, whose charges are screened, and the Jordan model. Since the Lagrangian formulation of the Schwinger model is a gauge theory, the analog of the four-dimensional "asymptotic freedom" wisdom would suggest the possibility of "charge liberation" in the short-distance limit of this model. This seems to contradict the statement that the intrinsic content of the Schwinger model ($QED_2$ with massless Fermions) (after removing a classical degree of freedom) is the QFT of a free massive Bose field and such a simple free field is at first sight not expected to contain subtle information about asymptotic charge liberation. (In its original gauge-theoretical form, the Schwinger model has an infinite vacuum degeneracy. The removal of this degeneracy (restoration of the cluster property) with the help of the "$\theta$-angle formalism" leaves a massive free Bose field (the Schwinger–Higgs mechanism). As expected in $d = 1 + 1$ the model only possesses this phase.) Well, as we have seen above, the massless limit really does have liberated charges and the short-distance limit of the massive free field is the massless model (Schroer).

As a result of the peculiar bosonization/fermionization aspect of the zero-mass limit of the derivative of the massive free field, Jordan's model is also closely related to the massless Thirring model (and the related Luttinger model for an interacting one-dimensional electron gas) whose massive version is in the class of factorizing models (see later section). (Another structural consequence of this aspect leads to Coleman's theorem (Schroer 2005) which connects the Mermin–Wagner no-go theorem for two-dimensional spontaneous continuous symmetry breaking with these zero-mass peculiarities.) The Thirring model is a special case in a vast class of "generalized" multi-coupling multicomponent Thirring models, that is, models with 4-fermion interactions. Under this name they were studied in the early 1970s (Schroer) with the aim to identify massless subtheories for which the currents form chiral current algebras.

The counterpart of the potential of the conserved Dirac current in the massive Thirring model is the sine-Gordon field, that is, a composite field which in the attractive regime of the Thirring coupling again obeys the so-called sine-Gordon equation of motion. Coleman gave a supportive argument (Schroer 2005) but some fine points about the range of its validity in terms of the coupling strength remained open. (It was noticed that the current potential of the free massive Dirac Fermion ($g=0$) does not obey the sine-Gordon equation (Schroer 2005).) A rigorous confirmation of these facts was recently given in the bootstrap form-factor setting (Schroer 2005). Massive models which have a continuous or discrete internal symmetry have "disorder" fields which implement a "half-space" symmetry on the charge-carrying field (acting as the identity in the other half-axis) and together with the basic pointlike field form composites which have exotic commutation relations (see the last section).

## The Conformal Setting, Structural Results

Chiral theories play a special role within the setting of conformal quantum fields. General conformal theories have observable algebras which live on compactified Minkowski space ($S^1$ in the case of chiral models) and fulfill the Huygens principle, which in an even number of spacetime dimension means that the commutator is only nonvanishing for lightlike separation of the fields. The fact that this classically expected behavior breaks down for nonobservable conformal fields (e.g., the massless Thirring field) was noticed at the beginning of the 1970s and considered paradoxical at that time ("reverberation" in the timelike (Huygens) region). Its resolution around 1974–75 confirmed that such fields are genuine conformal covariant objects but that some fine points about their causality needed to be addressed. The upshot was the proposal of two different but basically equivalent concepts about globally causal fields. They are connected by the following global decomposition formula:

$$A(x_{\rm cov}) = \sum A_{\alpha,\beta}(x),\ A_{\alpha,\beta}(x) = P_\alpha A(x) P_\beta,\ Z = \sum e^{id_\alpha} P_\alpha \qquad [11]$$

On the left-hand side, the spacetime point of the field is a point on the universal covering of the conformal compactified Minkowski space. These are fields (Lüescher and Mack 1975) (Schroer 2005) which "live" in the sense of quantum (modular) localization on the universal covering spacetime (or on a finite covering, depending on the "rationality" of the model) and fulfill the global causality condition previously discovered by I Segal (Schroer 2005). They are generally highly reducible with respect to the center of the covering group. The family of fields on the right-hand side, on the other hand, are fields which were introduced (Schroer and Swieca 1974; Schroer *et al.* 1975) with the aim to have objects which live on the projection $x(x_{\rm cov})$, that is, on the spacetime of the physics laboratory instead of the "hells and heavens" of the covering (Schroer 2005). They are operator-distributional valued sections in the compactification of ordinary Minkowski spacetime. The connection is given by the above decomposition formula into irreducible conformal blocks with respect to the center $\mathbf{Z}$ of the noncompact covering group $\widetilde{\mathrm{SO}(2,n)}$ where $\alpha, \beta$ are labels for the eigenspaces of the generating unitary $Z$ of the abelian center $\mathbf{Z}$. The decomposition [11] is minimal in the sense that in general there generally will be a refinement due to the presence of additional charge superselection rules (and internal group symmetries). The component fields are not Wightman fields since they annihilate the vacuum if the right-hand projection differs from $P_0 = P_{\rm vac}$.

Note that the Huygens (timelike) region in Minkowski spacetime has a timelike ordering structure $x \prec y$ or $x \succ y$ (earlier or later). In $d=1+1$, the topology allows in addition a spacelike left–right ordering $x \lessgtr y$. In fact, it is precisely the presence of these two orderings in conjunction with the factorization of the vacuum symmetry group $\widetilde{\mathrm{SO}(2,2)} \simeq \widetilde{\mathrm{PSL}(2R)}_l \otimes \widetilde{\mathrm{PSL}(2,R)}_r$, in particular $\mathbf{Z} = \mathbf{Z}_l \otimes \mathbf{Z}_r$, which is at the root of a significant simplification. This situation suggested a tensor factorization into chiral components and led to an extremely rich and successful construction program of two-dimensional conformal QFT as a two-step process: the classification of chiral observable algebras on the light ray and the amalgamation of left–right chiral theories to two-dimensional local conformal QFT. The action on the circular coordinates $z$ is through fractional $\mathrm{SU}(1,1)$ transformations

$$g(z) = \frac{\alpha z + \beta}{\bar\beta z + \bar\alpha}$$

whereas the covering group acts on the Mack–Luescher covering coordinates.

The presence of an ordering structure permits the appearance of more general commutation relations for the above $A_{\alpha\beta}$ component fields namely

$$A_{\alpha,\beta}(x) B_{\beta,\gamma}(y) = \sum_{\beta'} R^{\alpha,\gamma}_{\beta,\beta'} B_{\alpha,\beta'}(y) A_{\beta',\gamma}(x), \quad x > y \qquad [12]$$

with numerical $R$-coefficients which, as a result of associativity and relative commutativity with respect to observable fields, have to obey certain structure relations; in this way, Artin braid relations emerge as a new manifestation of the Einstein causality principle for observables in low-dimensional QFT (Rehren and Schroer 1989) (see Schroer 2005). Indeed, the DHR method to interpret charged fields as charge superselection carriers (tied by local representation theory to the bosonic local structure of observable algebras) leads precisely to such a plektonic statistics structure (Fredenhagen *et al.* 1992, Gabbiani and Froehlich 1993) for systems in low spacetime dimension (*see* Symmetries in Quantum Field Theory of Lower Spacetime Dimensions). With an appropriately formulated adjustment to observables fulfilling the Huygens commutativity, this plektonic structure (but now disconnected from particle/field statistics) is also a possible manifestation of causality for the higher-dimensional timelike structure (Schroer 2005).

The only examples known up to the appearance of the seminal BPZ work (Belavin *et al.* 1984) were the abelian current models of the previous section which furnish a rather poor man's illustration of the richness of the decomposition theory. The floodgates of conformal QFT were only opened after the BPZ discovery of "minimal models," which was preceded by the observation (Friedan *et al.* 1984) that the algebra of the stress–energy tensor came with a new representation structure which was not compatible with an underlying internal group symmetry (*see* Symmetries in Quantum Field Theory: Algebraic Aspects).

An important step in the structural study of chiral models was the recognition that the energy–momentum tensor has the commutation structure of a Lie field (Schroer 2005); in the next section, its algebraic structure and its representation theory will be presented.

## Chiral Fields and Two-Dimensional Conformal Models

Let us start with a family which generalizes the abelian model of the previous section. Instead of a one-component abelian current we now take $n$ independent copies. The resulting multicomponent Weyl algebra has the previous form except that the current is $n$-component and the real function space underlying the Weyl algebra consists of functions with values in an $n$-component real vector space $f \in LV$ with the standard Euclidean inner product denoted by $(\,,)$. The local extension now leads to $(\alpha, \beta) \in 2\mathbb{Z}$, that is, an even-integer lattice $\mathcal{L}$ in $V$, whereas the restricted Hilbert subspace $H_{\mathcal{L}^*}$ which ensures $\zeta$-independence is associated with the dual lattice $L^*$: $(\lambda_i, \alpha_k) = \delta_{ik}$ which contains $\mathcal{L}$. The resulting superselection structure (i.e., the $Q$-spectrum) corresponds to the finite factor group $\mathcal{L}^*/\mathcal{L}$. For self-dual lattices $\mathcal{L}^* = \mathcal{L}$ (which only can occur if $\dim \mathrm{V}$ is a multiple of 8), the resulting observable algebra has only the vacuum sector; the most famous case is the Leech lattice $\Lambda_{24}$ in $\dim V = 24$, also called the "moonshine" model. The observation that the root lattices of the Lie algebras of types $A$, $B$, or $E$ (e.g., su($n$) corresponding to $A_{n-1}$) also appear among the even-integral lattices suggests that the nonabelian current algebras associated to those Lie algebras can also be implemented. This turns out to be indeed true as far as the level-1 representations are concerned which brings us to the second family: the nonabelian current algebras of level $k$ associated to those Lie algebras; they are characterized by the commutation relation

$$[J_\alpha(z), J_\beta(z')] = \mathrm{i} f^\gamma_{\alpha\beta} j_\gamma(z)\delta(z - z') - \tfrac{1}{2} k g_{\alpha\beta}\delta'(z - z') \qquad [13]$$

where $f^\gamma_{\alpha\beta}$ are the structure constants of the underlying Lie algebra, $g$ their Cartan–Killing form, and $k$, the level of the algebra, must be an integer in order that the current algebra can be globalized to a loop group algebra. The Fourier decomposition of the current leads to the so-called affine Lie algebras, a special family of Kac–Moody algebras. For $k = 1$, these currents can be constructed as bilinears in terms of the multicomponent chiral Dirac field; there exists also the mentioned possibility to obtain them by constructing their maximal Cartan currents within the above abelian setting and representing the remaining nondiagonal currents as certain charge-carrying ("vertex" algebra) operators. Level-$k$ algebras can be constructed from reducing tensor products of $k$ level-1 currents or directly via the representation theory of infinite-dimensional affine Lie algebras. (The global exponentiated algebras (the analogs to the Weyl algebra) are called loop group algebras.) Either way one finds that, for example, the SU(2) current algebra of level $k$ has (together with the vacuum sector) $k + 1$ sectors (inequivalent representations). The different sectors are already distinguished by the structure of their ground states of the conformal Hamiltonian $L_0$. Although the computation of higher point correlation functions for $k > 1$, there is no problem in securing the existence of the algebraic nets which define these chiral models as well as their $k + 1$

representation sectors and to identify their generating charge-carrying fields (primary fields) including their $R$-matrices appearing in their plektonic commutation relations. It is customary to use the notation $SU(2)_k$ for the abstract operator algebras associated with the current generators [13] and we will denote their $k+1$ equivalence classes of representations by $\mathcal{A}_{SU(2)_k,n}, n=0,\ldots,k$, whereas representations of current algebras for higher rank groups require a more complicated labeling (in terms of Weyl chambers).

The third family of models are the so-called minimal models which are associated with the Lie-field commutation structure of the chiral stress–energy tensor which results from the chiral decomposition of a conformally covariant two-dimensional stress–energy tensor

$$[T(z), T(z')] = \mathrm{i}(T(z) + T(z'))\delta'(z - z') + \frac{\mathrm{i}c}{24\pi}\delta'''(z - z') \qquad [14]$$

whose Fourier decomposition yields the Witt–Virasoro algebra, that is, a central extension of the Lie algebra of the $\mathrm{Diff}(S^1)$. (The presence of the central term in the context of QFT (the analog of the Schwinger term) was noticed later; however, the terminology Witt–Virasoro algebra in the physics literature came to mean the Lie algebra of diffeomorphisms of the circle including the central extension.) The first two coefficients are determined by the physical role of $T(z)$ as the generating field density for the Lie algebra of the Poincaré group whereas the central extension parameter $c > 0$ (positivity of the two-point function) for the connection with the generation of the Moebius transformations and the undetermined parameter $c > 0$ (the central extension parameter) is easily identified with the strength of the two-point function. Although the structure of the $T$-correlation functions resembles that of free fields (in the sense that is an algebraically computable unique set of correlation functions once one has specified the two-point function), the realization that $c$ is subject to a discrete quantization if $c < 1$ came as a surprise. As already mentioned, the observation that the superselection sectors (the positive-energy representation structure) of this algebra did not at all follow the logic of a representation theory of an inner symmetry group generated a lot of attention and stimulated a flurry of publications on symmetry concepts beyond groups (quantum groups). A concept of fundamental importance is the DHR theory of localized endomorphisms of operator algebras and the concept of operator-algebraic inclusions (in particular, inclusions with conditional expectations – V Jones inclusions).

The $SU(2)_k$ current coset construction (Goddard *et al.* 1985) revealed that the proof of existence and the actual construction of the minimal models is related to that of the $SU(2)_k$ current algebras. Constructing a chiral model does not necessarily mean the explicit determination of the $n$-point Wightman functions of their generating fields (which for most chiral models remains a prohibitively complicated task) but rather a proof of their existence by demonstrating that these models are obtained from free fields by a series of computational complicated but mathematically controlled operator-algebraic steps as reduction of tensor products, formation of orbifolds under group actions, coset constructions, and a special kind of extensions. The generating fields of the models are nontrivial in the sense of not obeying free-field equations (i.e., not being “on-shell”). The cases where one can write down explicit $n$-point functions of generating fields are very rare; in the case of the minimal family this is limited to the field theory of the Ising model (Schroer 2005).

To show the power of inclusion theory for the determination of the charge content of theory, let us look at a simple illustration in the context of the above multicomponent abelian current algebra. The vacuum representation of the corresponding Weyl algebra is generated from smooth $V$-valued functions on the circle modulo constant functions (i.e., functions with vanishing total integral) $f \in LV_0$. These functions equipped with the aforementioned complex structure and scalar product yield a Hilbert space. The $I$-localized subalgebra is generated by the Weyl image of $I$-supported functions (class functions whose representing functions are constant in the complement $I'$)

$$\begin{aligned} \mathcal{A}(I) &:= \mathrm{alg}\{W(f) | f \in K(I)\} \\ K(I) &= \{f \in LV_0 | f = \mathrm{const.in}\, I'\} \end{aligned} \qquad [15]$$

The one-interval Haag duality $\mathcal{A}(I)' = \mathcal{A}(I')$ (the commutant algebra equals the algebra localized in the complement) is simply a consequence of the fact that the symplectic complement $K(I)'$ in terms of $\mathrm{Im}(f, g)$ consists of real functions in that space which are localized in the complement, that is, $K(I)' = K(I')$. The answer to the same question for a double interval $I = I_1 \cup I_3$ (think of the first and third quadrant on the circle) does not lead to duality but rather to a genuine inclusion

$$\begin{aligned} K((I_1 \cup I_3)') = K(I_2 \cup I_4) &\subset K(I_1 \cup I_3)' \\ K(I_1 \cup I_3) &\subset K((I_1 \cup I_3)')' \end{aligned} \qquad [16]$$

The meaning of the left-hand side is clear; these are functions which are constant in $I_1 \cup I_3$ with the same constant in the two intervals whereas the functions on the right-hand side are less restrictive in that the constants can be different. The conversion of real subspaces into von Neumann algebras by the Weyl functor leads to the algebraic inclusion $\mathcal{A}(I_1 \cup I_3) \subset \mathcal{A}((I_1 \cup I_3)')'$. In physical terms, the enlargement results from the fact that within the charge neutral vacuum algebra a charge split with one charge in $I_1$ and the compensating charge in $I_2$ for all values of the (unquantized) charge occurs. A more realistic picture is obtained if one allows a charge split to be subjected to a charge quantization implemented by a lattice condition $f(I_2) - f(I_4) \in 2\pi L$ which relates the two multicomponent constant functions (where $f(I)$ denotes the constant value $f$ takes in $I$). As in the previous one-component case, the choice of even lattices corresponds to the local (bosonic) extensions. Although imposing such a lattice structure destroys the linearity of the $K$, the functions still define Weyl operators which generated operator algebras $\mathcal{A}_L(I_1 \cup I_2)$. (The linearity structure is recovered on the level of the operator algebra.) But now the inclusion involves the dual lattice $L^*$ (which of course contains the original lattice),

$$\begin{aligned} &\mathcal{A}_L(I_1 \cup I_2) \subset \mathcal{A}_{L^*}(I_1 \cup I_2) \\ &\operatorname{ind}\{\mathcal{A}_L(I_1 \cup I_2) \subset \mathcal{A}_L((I_1 \cup I_2)')'\} = |G| \\ &\mathcal{A}_L(I_1 \cup I_2) = \operatorname{inv}_G \mathcal{A}_{L^*}(I_1 \cup I_2) \end{aligned}$$

This time the possible charge splits correspond to the factor group $G = L^*/L$, that is, the number of possibilities is $|G|$ which measures the relative size of the bigger algebra in terms of the smaller. This is a special case of the general concept of the so-called Jones index of an inclusion which is a numerical measure of its depth. A prerequisite is that the inclusion permits a conditional expectation which is a generalization of the averaging under the "gauge group" $G$ on $\mathcal{A}_{L^*}(I_1 \cup I_2)$ in the third equation above, which identifies the invariant smaller algebra with the fix-point algebra (the invariant part) under the action of $G$. In fact, using the conceptual framework of Jones, one can show that the two-interval inclusion is independent of the position of the disjoint intervals characterized by the group $G$.

There exists another form of this inclusion which is more suitable for generalizations. One starts from the charge quantized extended local algebra $\mathcal{A}_L^{\text{ext}} \supset \mathcal{A}$ described earlier in terms of an even-integer lattice $L$ (which lives in the separable Hilbert space $H_{L^*}$) as our observable algebra. Again the Haag duality is violated and converted into an inclusion $\mathcal{A}_L^{\text{ext}}(I_1 \cup I_2) \subset \mathcal{A}_L^{\text{ext}}((I_1 \cup I_2)')'$ which turns out to have the same $G = L^*/L$ charge structure (it is in fact isomorphic to the previous inclusion). In the general setting (current algebras, minimal model algebras, ...), this double interval inclusion is particularly interesting if the associated Jones index is finite. One finds Kawahigashi *et al.* (2001) (Schroer 2005).

**Theorem 1** *A chiral theory with finite Jones index* $\mu = \operatorname{ind}\{\mathcal{A}((I_1 \cup I_2)')' : \mathcal{A}(I_1 \cup I_2)\}$ *for the double interval inclusion (always assuming that* $A(S^1)$ *is strongly additive and split) is a rational theory and the statistical dimensions* $d_\rho$ *of its charge sectors are related to* $\mu$ *through the formula*

$$\mu = \sum_\rho d_\rho^2 \qquad [17]$$

Instead of presenting more constructed chiral models, it may be more informative to mention some of the algebraic methods by which they are constructed and explored. The already mentioned DHR theory provides the conceptual basis for converting the notion of positive-energy representation sectors of the chiral model observable algebras $\mathcal{A}$ (equivalence classes of unitary representations) into localized endomorphisms $\rho$ of this algebra. This is an important step because contrary to group representations which have a natural tensor product composition structure, representations of operator algebras generally do not come with a natural composition structure. The DHR endomorphisms theory of $\mathcal{A}$ leads to fusion laws and an intrinsic notion of generalized statistics (for chiral theories: plektonic in addition to bosonic/fermionic). The chiral statistics parameters are complex numbers (Haag 1992) whose phase is related to a generalized concept of spin via a spin-statistics theorem and whose absolute value (the statistics dimension) generalized the notion of multiplicities of fields known from the description of inner symmetries in higher-dimensional standard QFTs. The different sectors may be united into one bigger algebra called the exchange algebra $\mathcal{F}_{\text{red}}$ in the chiral context (the "reduced field bundle" of DHR) in which every sector occurs by definition with multiplicity 1 and the statistics data are encoded into exchange (commutation) relations of charge-carrying operators or generating fields ("exchange algebra fields") (Schroer 2005). Even though this algebra is useful in that all properties concerning fusion and statistics are nicely encoded, it lacks some cherished properties of standard field theory

namely there is no unique state–field relation, that is, no Reeh–Schlieder property (a field $A_{\alpha\beta}$ whose source projection $P_\beta$ does not coalesce with the vacuum projection annihilates the vacuum); in operator-algebraic terms, the local algebras are not factors. This poses the question of how to manufacture from the set of all sectors natural (not necessarily local) extensions with these desired properties. It was found that this problem can be characterized in operator-algebraic terms by the existence of the so-called DHR triples (Schroer). In case of rational theories, the number of such extensions is finite and in the aforementioned "classical" current algebra and minimal models they all have been constructed by this method (thus confirming existing results completing the minimal family by adding some missing models). The same method adapted to the chiral tensor product structure of $d = 1 + 1$ conformal observables classifies and constructs all two-dimensional local (bosonic/ fermionic) conformal QFT $\mathcal{B}_2$ which can be associated with the observable chiral input. It turns out that this approach leads to another of those pivotal numerical matrices which encode structural properties of QFT: the coupling matrix $Z$,

$$\mathcal{A} \otimes \mathcal{A} \subset \mathcal{B}_2$$
$$\sum_{\rho\sigma} Z_{\rho,\sigma}\rho(\mathcal{A}) \otimes \sigma(\mathcal{A}) \subset \mathcal{A} \otimes \mathcal{A} \qquad [18]$$

where the second line is an inclusion solely expressed in terms of observable algebras from which the desired (isomorphic) inclusion in the first line follows by a canonical construction, the so-called Jones basic construction. The numerical matrix $Z$ is an invariant closely related to the so-called "statistics character matrix" (Schroer 2005) and in case of rational models it is even a modular invariant with respect to the modular $\mathrm{SL}(2, Z)$ group transformations (which are closely related to the matrix $S$ in the final section).

## Integrability, the Bootstrap Form-Factor Program

Integrability in QFT and the closely associated bootstrap form-factor construction of a very rich class of massive two-dimensional QFTs can be traced back to two observations made during the 1960s and 1970s ideas. On the one hand, there was the time-honored idea to bypass the "off-shell" field-theoretic approach to particle physics in favor of a pure on-shell $S$-matrix setting which (in particular recommended for strong interactions), as a result of the elimination of short distances via the mass-shell restriction, would be free of ultraviolet divergencies. This idea was enriched in the 1960s by the crossing property which in turn led to the bootstrap idea, a highly nonlinear seemingly self-consistent proposal for the determination of the $S$-matrix. However, the protagonists of this $S$-matrix bootstrap program placed themselves into a totally antagonistic fruitless position with respect to QFT so that the strong return of QFT in the form of gauge theory undermined their credibility. On the other hand, there were rather convincing quasiclassical calculations in certain two-dimensional massive QFTs as, for example, the sine-Gordon model which indicated that the obtained quasiclassical mass spectrum is exact and hence suggested that the associated QFTs are integrable (Dashen *et al.* 1975) and have no real particle creation. These provocative observations asked for a structural explanation beyond quasiclassical approximations, and it soon became clear that the natural setting for obtaining such mass formulas was that of the "fusion" of boundstate poles of unitary crossing-symmetric purely elastic $S$-matrices; first in the special context of the sine-Gordon model (Schroer *et al.* 1976) and later as a classification program from which factorizing $S$-matrices can be determined by solving well-defined equations for the elastic two-particle $S$-matrix (Karowski *et al.* 1977). (It was incorrectly believed that the "nontrivial elastic scattering implies particle creation" statement of Aks (Aks, 1963) is also valid for low-dimensional QFTs.) Some equations in this bootstrap approach resembled mathematical structures which appeared in C N Yang's work on nonrelativistic $\delta$-function particle interactions as well as relations for Boltzmann weights in Baxter's work on solvable lattice models; hence, they were referred to as Yang–Baxter relations. These results suggested that the old bootstrap idea, once liberated from its ideological dead freight (in particular from the claim that the bootstrap leads to a unique "theory of everything" (minus gravity)), generates a useful setting for the classification and construction of factorizing two-dimensional relativistic $S$-matrices. Adapting certain known relations between two-particle form factors of field operators and the $S$-matrix to the case at hand (Karowski and Weisz 1978), and extending this with hindsight to generalized (multiparticle) form factors, one arrived at the axiomatized recipes of the bootstrap form-factor program of $d = 1 + 1$ factorizable models (Smirnov 1992). Although this approach can be formulated within the

setting of the LSZ scattering formalism, the use of a certain algebraic structure (Zamolodchikov and Zamolodchikov 1979) which in the simplest version reads

$$Z(\theta)Z^*(\theta') = S^{(2)}(\theta - \theta')Z^*(\theta')Z(\theta) + \delta(\theta - \theta')$$
$$Z(\theta)Z(\theta') = S^{(2)}(\theta' - \theta)Z(\theta')Z(\theta) \quad [19]$$

(the $\delta$-term Faddeev is due to Faddeev) brought significant simplifications. In the general case, the $Z's$ are vector valued and the $S^{(2)}$-structure function is matrix valued. (The identification of the Z–F structure coefficients with the elastic two-particle $S$-matrix $S^{(2)}$ (which is prenempted by our notation) can be shown to follow from the physical interpretation of the Z-F structure in terms of localization.) In that case the associativity of the Z–F algebra is equivalent to the Yang–Baxter equations. Recently, it became clear that this algebraic relation has a deep physical interpretation; it is the simplest algebraic structure which can be associated with generators of nontrivial wedge-localized operator algebras (see the next section).

Conceptually as well as computationally it is much simpler to identify the intrinsic meaning of integrability in QFT with the factorization of its $S$-matrix or a certain property of wedge-localized algebras (see next section) than to establish integrability (*see* Integrability and Quantum Field Theory).

The first step of the bootstrap form-factor program namely the classification and construction of model $S$-matrices follows a combination of two patterns: prescribing particle multiplets transforming according to group symmetries and/or specifying structural properties of the particle spectrum. The simplest illustration for the latter strategy is supplied by the $\mathbb{Z}_N$ model. In terms of particle content, $\mathbb{Z}_N$ demands the identification of the $N$th bound state with the antiparticle. Since the fusion condition for the bound mass $m_b^2 = (p_1 + p_2)^2 = m_1^2 + m_2^2 + 2m_1 m_2 ch(\theta_1 - \theta_2)$ is only possible for a pure imaginary rapidity difference $\theta_{12} = \theta_1 - \theta_2 = \mathrm{i}\alpha$ ("binding angle"). Hence, the binding of two "elementary" particles of mass $m$ gives

$$m_2 = m\frac{\sin 2\alpha}{\sin \alpha}$$

and more generally of $k$ particles with

$$m_k = m\frac{\sin k\alpha}{\sin \alpha}$$

so that the antiparticle mass condition $m_N = \bar{m} = m$ fixes the binding angle to $\alpha = 2\pi/N$. (The quotation mark is meant to indicate that in contrast to the Schrödinger QM there is "nuclear democracy" on the level of particles. The inexorable presence of interaction-caused vacuum polarization limits a fundamental/fused hierarchy to the fusion of charges.) The minimal (no additional physical poles) two-particle $S$-matrix in terms of which the $n$-particle $S$-matrix factorizes is therefore

$$S^{(2)}_{\min} = \frac{\sin(1/2)(\theta + (2\pi \mathrm{i})/N)}{\sin(1/2)(\theta - (2\pi \mathrm{i})/N)} \quad [20]$$

(minimal = without so-called CDD poles) The SU($N$) model as compared with the U($N$) model requires a similar identification of bound states of $N - 1$ particles with an antiparticle. This $S$-matrix enters as in the equation for the vacuum to $n$-particle meromorphic form factor of local operators; together with the crossing and the so-called "kinematical pole equation," one obtains a recursive infinite system linking a certain residue with a form factor involving a lower number of particles. The solutions of this infinite system form a linear space from which the form factors of specific tensor fields can be selected by a process which is analogous but more involved than the specification of a Wick basis of composite free fields. Although the statistics property of two-dimensional massive fields is not intrinsic but a matter of choice, it would be natural to realize, for example, the $\mathbb{Z}_N$ fields as $\mathbb{Z}_N$-anyons.

Another rich class of factorizing models are the Toda theories of which the sine-Gordon and sinh–Gordon are the simplest cases. For their descriptions, the quasiclassical use of Lagrangians (supported by integrability) turns out to be of some help in setting up their more involved bootstrap form-factor construction.

The unexpected appearance of objects with new fundamental (solitonic) charges (e.g., the Thirring field as the carrier of a solitonic sine-Gordon charge) and the unexpected confinement of charges (e.g., the CP(1) model as a confined SU(2) model) turn out to be opposite sides of the same coin and both cases have realizations in the setting of factorizing models (Schroer 2005).

## Recent Developments

There are two ongoing developments which place the two-dimensional bootstrap form-factor program into a more general setting which permits to understand its position in the general context of local quantum physics.

One of these starts from the observation that the smallest spacetime localization region in which it is possible to find vacuum-polarization-free generators (PFG) in the presence of interactions is the wedge

region. If one demands in addition that these generators (necessarily unbounded operators) have the standard domain properties of QFT (which include stability of the domain under translations), then one finds that this leads precisely to the two-dimensional Z–F algebraic structure which in turn in this way a spacetime interpretation for the first time acquires. In these investigations (Schroer 2005), modular localization theory plays a prominent role and there are strong indications that with these methods one can show the nontriviality of intersections of wedge algebras which is the algebraic criterion for the existence of a model within local quantum physics.

There is a second constructive idea based on light-front holography which uses the radical reorganization of spacetime properties of the algebraic structure while maintaining the physical content including the Hilbert space. Since spacetime localization aspects (apart from the remark about wedge algebras and their PFG generators made before) are traditionally related to the concept of fields, holographic methods tend to de-emphasize the particle structure in favor of "field properties." Indeed, the transversely extended chiral theories which arise as the holographic image lead to simplification of many interesting properties with very similar aims to the old "light-cone quantization" except that light-front holography is another way of looking at the original local ambient theory without subjecting it to another quantization. (The price for this simplification is that as a result of the nonuniqueness of the holographic inversion certain problems cannot be formulated.)

Actually, as a result of the absence of a transverse direction in the two-dimensional setting, the family of factorizing models provides an excellent theoretical laboratory to study their rigorous "chiral encoding" which is conceptually very different from Zamolodchikov's perturbative relation (which is based on identifying a factorizing model in terms of a perturbation on a chiral theory).

It turns out that the issue of statistics of particles loses its physical relevance for two-dimensional massive models since they can be changed without affecting the physical content. Instead such notions as order/disorder fields and soliton take their place (Schroer 2005).

In accordance with its historical origin, the theory of two-dimensional factorizing models may also be viewed as an outgrowth of the quantization of classical integrable systems (Integrability and Quantum Field Theory). But in comparison with the rather involved structure of integrabilty (verifying the existence of sufficiently many commuting conservation laws), the conceptual setting of factorizing models within the scattering framework (factorization follows from existence of wedge-localized tempered PFGs) is rather simple and intrinsic (Schroer 2005).

Among the additional ongoing investigations in which the conceptual relation with higher-dimensional QFT is achieved via modular localization theory, we will select three which have caught our, active attention. One is motivated by the recent discovery of the adaptation of Einsteins classical principle of local covariance to QFT in curved spacetime. The central question raised by this work (*see* Algebraic Approach to Quantum Field Theory) is if all models of Minkowski spacetime QFTs permit a local covariant extension to curved spacetime and if not which models do? In the realm of chiral QFT, this would amount to ask if all Moebius-invariant models are also Diff($S^1$)-covariant. It has been known for sometime that a QFT with all its rich physical content can be uniquely defined in terms of a carefully chosen relative position of a finite number of copies of one unique von Neumann operator algebra within one common Hilbert space. This is a perfect quantum field-theoretical illustration for Leibnitz's philosophical proposal that reality results from the relative position of "monades" (As opposed to the more common (Newtonian) view that the material reality originates from a material content being placed into a spacetime vessel) if one takes the step of identifying the hyperfinite typ $III_1$ Murray von Neumann factor algebra with an abstract monade from which the different copies result from different ways of positioning in a shared Hilbert space (Schroer 2005). In particular, Moebius-covariant chiral QFTs arise from two monades with a joint intersection defining a third monade in such a way that the relative positions are specified in terms of natural modular concepts (without reference to geometry). This begs the question whether one can extend these modular-based algebraic ideas to pass from the global vacuum preserving Moebius invariance to local Diff(S) covariance Moeb $\rightarrow$ Diff($S^1$). This would be precisely the two-dimensional adaptation of the crucial problem raised by the recent successful generalization of the local covariance principle underlying Einstein's classical theory of gravity to QFT in curved spacetime: does every Poincaré covariant Minkowski spacetime QFT allow a unique correspondence with one curved spacetime (having the same abstract algebraic substrate but with a totally different spacetime encoding)? In the chiral context, one is led to the notion of "partially geometric modular groups" which only act geometrically if restricted to specific subalgebras (Schroer

2005). It is hard to imagine how one can combine quantum theory and gravity without understanding first the still mysterious links between spacetime geometry, thermal properties, and relative positioning of monades in a joint Hilbert space.

A second important umbilical cord with higher-dimensional theories is the issue of "Euclideanization" in particular the chiral counterpart of Osterwalder–Schrader localization and the closely related Nelson–Symanzik duality. In concrete chiral models (e.g., the models in the section "Chiral fields and two-dimensional conformal models"), it has been noted as a result of explicit calculations that the analytic continuation in the angular parametrization for thermal correlation functions leads to a duality relation in

$$\langle A(\varphi_1, \ldots, \varphi_n) \rangle_{\alpha, 2\pi\beta_t} = \left(\frac{\mathrm{i}}{\beta_t}\right)^a \sum_\gamma S_{\alpha\gamma} \left\langle A\left(\frac{\mathrm{i}}{\beta_t}\varphi_1, \ldots, \frac{\mathrm{i}}{\beta_t}\varphi_n\right)\right\rangle_{\gamma,(2\pi/\beta_t)} \qquad [21]$$

where the thermal correlation function is defined as

$$\begin{aligned} \langle A(\varphi_1, \ldots, \varphi_n) \rangle_{\rho_\alpha, 2\pi\beta_t} &:= \mathrm{tr}_{H_{\rho_\alpha}} \mathrm{e}^{-2\pi\beta_t \left(L_0^{\rho_\alpha} - (c/24)\right)} \pi_{\rho_\alpha}(A(\varphi_1, \ldots, \varphi_n)) \\ A(\varphi_1, \ldots, \varphi_n) &= \prod_{i=1}^n A_i(\varphi_i) \end{aligned} \qquad [22]$$

Compared with the thermally extended Nelson–Symanzik relation for two-dimensional QFT one notices that in addition to the expected behavior of real coordinates becoming imaginary and the $2\pi$-periodicity changing role with the (suitably normalized) KMS inverse temperature, there is a rotation in the space of superselected charges in terms of a unitary matrix $S$ whose origin lies in the braid group statistics (the statistics character matrix). The deeper structural explanation which shows that this relation is not just a property of special models, but rather a generic property of chiral QFT, comes from a very deep angular Euclideanization which is based on modular theory (Schroer). Specializing $A =$ identity, one obtains a relation for the partition function, the famous Verlinde identity which is part of the transformation law of the thermal angular correlation functions under the $\mathrm{SL}(2, \mathrm{R})$ modular group.

There are many additional important observations on factorizing models whose relation to the physical principles of QFT, unlike the bootstrap form-factor program, is not yet settled. The meaning of the $c$-parameter outside the chiral setting and ideas on its renormalization group flow as well as the various formulations of the thermodynamic Bethe ansatz belong to a series of interesting observations whose final relation to the principles of QFT still needs clarification.

## Universality and Renormalization

**M Lyubich**, University of Toronto, Toronto, ON, Canada and Stony Brook University, Stony Brook, NY, USA

### Introduction

Discovery of the universality phenomenon and the underlying renormalization mechanism by Feigenbaum and independently by Coullet and Tresser in late 1970s was one of the most influential events in the dynamical systems theory in the last quarter of the twentieth century. It was numerically observed that the cascades of doubling bifurcations leading to chaotic regimes in one-parameter families of interval maps, as well as the dynamical attractors that appear in the limits, exhibit the universal small-scale geometry. To explain this surprising observation, a "Renormalization Conjecture" was formulated which asserted that a natural renormalization operator acting in the space of dynamical systems has a unique hyperbolic fixed point.

It took about two decades to prove this conjecture rigorously (and without the help of computers). The proof revealed rich mathematical structures behind the universality phenomenon that linked it tightly to holomorphic dynamics and conformal and hyperbolic geometry.

Besides the universality *per se*, the renormalization theory led to many other important results. It includes the proof of the regular or stochastic dichotomy that gives us a complete understanding of the real quadratic family (and more general families of one-dimensional maps) from measure-theoretic point of view, as well as deep advances in several key problems of holomorphic dynamics.

Since the original discovery, many other manifestations of the universality have been observed, experimentally, numerically, and theoretically, in various classes of dynamical systems. However, in this article we will focus on mathematical aspects of the original phenomenon.

#### General Terminology and Notations

We will use general notations and terminology from Holomorphic Dynamics.

### Unimodal Maps

#### Definitions and Conventions

Let us consider a smooth interval map $f: I \to I$. It is called *unimodal* if it has a single critical point $c$ and this point is an extremum. We assume that the critical point is nondegenerate, unless otherwise it is explicitly stated. A unimodal map is called $S$-unimodal if it has a negative Schwarzian derivative:

$$Sf = \frac{f'''}{f'} - \frac{3}{2}\left(\frac{f''}{f'}\right)^2 < 0$$

For simplicity, we also assume that the map $f$ is even, and normalize it so that $c = 0$ and one of the endpoints of $I$ is a fixed point.

#### Topological Dynamics

Let $J \ni 0$ be a 0-symmetric periodic interval, that is, $f^p(J) \subset J$ for some $p \in \mathbb{N}$, such that the intervals $J_k = f^k(J), k = 0, 1, \ldots, p-1$, have disjoint interiors. Then we refer to $\cup J_k$ as a *cycle of intervals* of period $p$.

According to their topological dynamics, $S$-unimodal maps can be divided into three possible types (Sharkovskii, Singer, Guckenheimer, Misiurewicz, van Strien, Blokh, etc.):

- *Regular maps*. Such a map has an attracting or parabolic cycle $\boldsymbol{\alpha}$. In this case, almost all trajectories of $f$ converge to $\boldsymbol{\alpha}$. In case $\boldsymbol{\alpha}$ is attracting, the map $f$ is also called *hyperbolic* (*see* Holomorphic Dynamics).
- *Topologically chaotic maps*. For such a map, there is a cycle of intervals $\cup J_k$ such that the restriction $f | \cup J_k$ is *topologically transitive* (i.e., it has a dense orbit). Moreover, for almost all $z \in I$, $\operatorname{orb} z$ eventually lands in this cycle.
- *Infinitely renormalizable maps*. For such a map, there is a nested sequence of periodic intervals $J^1 \supset J^2 \supset \cdots \ni 0$ of periods $p_n \to \infty$. Then the

intersection of the corresponding cycles of intervals,

$$A = A_f = \bigcap_{n=0}^{\infty} \bigcup_{k=0}^{p_n - 1} f^k(J^n) \qquad [1]$$

is a Cantor set endowed with a natural group structure (inverse limit of cyclic groups $\mathbb{Z}/p_n\mathbb{Z}$) such that $f|A$ becomes a group translation. Moreover, $f^n z \to A$ for a.e. $z \in I$. This Cantor set is also called the *Feigenbaum attractor* of $f$.

### Kneading Theory

Kneading theory (Milnor and Thurston, mid-1970s) gives a complete topological classification of $S$-unimodal maps (and more general one-dimensional maps). Let $I_+$ and $I_-$ stand for the components of $I \backslash \{0\}$, where $I_+ \ni f(0)$. To any point $x \in I$, let us associate its *itinerary* $(\varepsilon_n)_{n=0}^{N}$, where $\varepsilon_n \in \{+, -, 0\}$, $N \in \mathbb{Z}_+ \cup \infty$, in the following way. If $x$ is precritical then $N \in \mathbb{Z}_+$ is the smallest number such that $f^N x = 0$, and we let $\varepsilon_N = 0$. Otherwise, $N = \infty$. For $n < N, \varepsilon_n = +$ if $f^n x \in I_+$, and $\varepsilon_n = -$ if $f^n x \in I_-$.

The *kneading sequence* of $f$ is the itinerary of the critical value $f(0)$. It essentially classifies $S$-unimodal maps: *two nonregular S-unimodal maps are topologically conjugate if and only if they have the same kneading sequence*. (In the regular case, one should state if the map is hyperbolic or parabolic and specify the sign of the multiplier of the corresponding cycle.)

The kneading theory completely describes *admissible* kneading sequences (realizable by some unimodal maps), and order them linearly in such a way that a bigger sequence corresponds to a more "complicated" map. The minimal admissible kneading sequence, $+ + +$, is realized by the parabolic map $x \mapsto x^2 + 1/4$, while the maximal one, $+ - - - -$, is realized by the Chebyshev map $x \mapsto x^2 - 2$.

A central result of the kneading theory is the *Intermediate Value Theorem* asserting that a smooth one-parameter family of $S$-unimodal maps $f_t$ containing two kneading sequences also contains all intermediate kneading sequences. In particular, a family that contains the above maximal and the minimal kneading sequences, contains *all* admissible kneading sequences. Such a family is called *full*. We see that the real quadratic family $P_c, c \in [-2, 1/4]$, is full: *any S-unimodal map is topologically equivalent to some quadratic polynomial*. This indicates dynamical significance of the quadratic family.

We say that a one-parameter family of unimodal maps $f_t$ is *almost full* if it contains all admissible kneading sequences except possibly the minimal one.

## Universality Phenomenon

### Universal Geometry of Doubling Bifurcations and the Feigenbaum Attractor

Let us consider the real quadratic family $P_c : x \mapsto x^2 + c$, $c \in [-2, 1/4]$. As the parameter $c$ moves down from 1/4, we observe a sequence of doubling bifurcations $c_n$ where the attracting cycle of period $2^n$ gives birth to an attracting cycle of period $2^{n+1}, n = 0, 1, \ldots$ (*see* Holomorphic Dynamics and Figure 1). This sequence converges to the *Feigenbaum parameter* $c_\infty$ at exponential rate: $c_n - c_\infty \sim \lambda^{-n}$, where $\lambda \approx 4.6$. It turns out that if we consider a similar one-parameter family of unimodal maps, say $x \mapsto a \sin x$, we observe a similar sequence of doubling bifurcations converging to the limit exponentially at the *same* rate $\lambda^{-n}$, independently of the family under consideration.

In the dynamical space, let us consider the Feigenbaum attractor $A_f$ [1] of an infinitely renormalizable $S$-unimodal map $f$ that appear in the limit of doubling bifurcations (so that the periods of periodic intervals $J^n$ are equal to $2^n$). Let us consider the *scaling factors* $\sigma_n = |J^n|/|J^{n-1}|$. Then $\sigma_n \to \sigma_\infty$, where the limiting scaling factor $\sigma_\infty \approx 2.6$ is

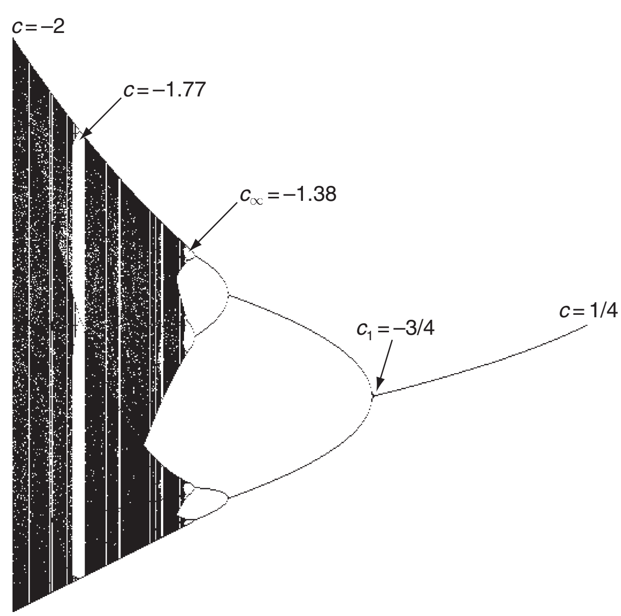

**Figure 1** Real quadratic family $P_c : x \mapsto x^2 + c$. This picture presents how the limit set of the orbit $\{P_c^n(0)\}_{n=0}^{\infty}$ bifurcates as the parameter $c$ changes from 1/4 on the right to −2 on the left. Three topological types of regimes are intertwined in an intricate way. The gaps correspond to the regular regimes. The black regions correspond to the chaotic regimes (though, of course, there are many narrow invisible gaps therein). In the beginning (on the right) one can see the cascade of doubling bifurcations. This picture became symbolic for one-dimensional dynamics.

*independent* of the particular map $f$ under consideration. Thus, the small-scale geometry of $A_f$ is universal.

This was historically the first observed manifestation of the *quantitative universality* of dynamical and parameter structures.

#### Feigenbaum–Coullet–Tresser Renormalization Conjecture

To explain the above universality phenomenon, Feigenbaum and independently Coullet and Tresser, formulated the following Renormalization Conjecture. Let us consider the space $\mathcal{U}$ of $S$-unimodal maps $f:[-1,1]\to[-1,1]$. A map $f\in\mathcal{U}$ is called *(doubling) renormalizable* if it has a cycle of intervals $J\to J_1\to J$ of period 2. Then, for any $n\in\mathbb{Z}_+\cup\{\infty\}$, we can naturally define $n$-times renormalizable maps, where $n=0$ corresponds to the *non-renormalizable* case, while $n=\infty$ corresponds to the *infinitely renormalizable* case.

Let $\mathcal{U}'\subset\mathcal{U}$ be the space of doubling renormalizable maps. If $f\in\mathcal{U}'$ then $f^2:J\to J$ is an $S$-unimodal map as well, and we define the *(doubling) renormalization operator* $R:\mathcal{U}'\to\mathcal{U}$ as the rescaling of this map:

$$Rf(x)=\sigma^{-1}f^2(\sigma x)$$

where $\sigma=|J|/2$.

The Renormalization Conjecture asserted that:

- The renormalization operator $R$ has a unique fixed point $f_*$, and this point is hyperbolic;
- the stable manifold $W^s(f_*)$ consists of infinitely renormalizable unimodal maps;
- the unstable manifold $W^u(f_*)$ is one dimensional and represents an almost full family of unimodal maps (see the section "Kneading theory"); and
- the quadratic family $\{P_c\}$ transversally intersects $W^s(f_*)$ (see Figure 2).

Assuming this conjecture, one can see that for any curve $t\mapsto g_t$ in $\mathcal{U}$ that transversally intersects the stable manifold $W^s(f_*)$ at some moment $t_*$, the doubling bifurcations parameters $t_n$ converge to $t_*$ at exponential rate $\lambda^{-n}$, where $\lambda$ is the unstable eigenvalue of the differential $DR(f_*)$. This explains the universal geometry of doubling bifurcations.

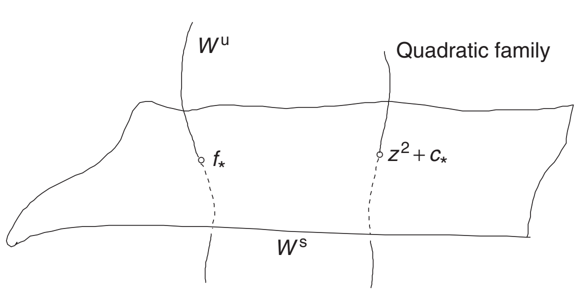

**Figure 2** Renormalization fixed point.

One can also show that the Feigenbaum attractor $A_f$ of any map $f\in W^s(f_*)$ is *smoothly equivalent* to $A_{f_*}$, which explains the universal small-scale geometry of these attractors.

#### Full Renormalization Horseshoe

Along with period doublings, one can consider period triplings, quadruplings, etc. A unimodal map $f\in\mathcal{U}$ is said to be *renormalizable with period* $p$ if it has a cycle of intervals $J\to J_1\to\cdots\to J_{p-1}\to J$ of period $p$. The corresponding renormalization operator is defined as $Rf(x)=\sigma^{-1}f^p(\sigma x)$, where $\sigma=|J|/2$.

The *combinatorics* or *type* $\tau$ of the renormalization operator is the order of the intervals $J_k, k=0,1,\ldots,p-1$, on the real line (up to reversal). (For instance, there are three admissible combinatorics $\tau$ of period 5.) If we want to specify combinatorics of the renormalization operator under consideration, we use notation $R_\tau$. This operator is defined on the "renormalization strip" $\mathcal{U}^\tau$ of unimodal maps $f\in\mathcal{U}$ that are renormalizable with combinatorics $\tau$.

The Renormalization Conjecture admits a straightforward generalization to any renormalization operator $R_\tau$. More interestingly, one can formulate a stronger version of it by putting all the admissible renormalization types together. Let $\mathcal{T}$ stand for the set of all *minimal* renormalization types, that is, the types that cannot be factored through other types. Then the renormalization strips $\mathcal{U}^\tau, \tau\in\mathcal{T}$, are pairwise disjoint, and we can define the *full renormalization operator*

$$R:\bigcup_{\tau\in\mathcal{T}}\mathcal{U}^\tau\to\mathcal{U} \qquad [2]$$

by letting $R|\mathcal{U}^\tau=R_\tau$. Then the strong version of the renormalization conjecture asserted that:

- there is an $R$-invariant hyperbolic subset $\mathcal{A}\subset\mathcal{U}$ called the *full renormalization horseshoe* such that the restriction $R|\mathcal{A}$ is topologically conjugate to the full shift $\sigma$ on the space $\Sigma$ of bi-infinite sequences $(\ldots,\tau_{-1},\tau_0,\tau_1,\ldots)$ of symbols $\tau_n\in\mathcal{T}$;
- for any $f_*\in\mathcal{A}$, the stable manifold $W^s(f_*)$ consists of infinitely renormalizable maps $f\in\mathcal{U}$ with the same combinatorics as $f_*$;
- for any $f_*\in\mathcal{A}$, the unstable manifold $W^u(f_*)$ is one-dimensional and represents an almost full family of unimodal maps; and
- the real quadratic family $\{P_c\}$ transversally intersects all stable manifolds $W^s(f_*)$.

## Complex Renormalization

### Polynomial-Like Maps

A *polynomial-like map* is a holomorphic branched covering of finite degree $f: U \to U'$, where $U \Subset U' \subset \mathbb{C}$ are topological disks (In other words, the maps $f$ is *proper*, that is, full preimages $f^{-1}(K)$ of compact sets $K \subset U'$ are compact). For instance, if $f$ is a polynomial of degree $d$ then for a sufficiently large radius $R > 0$, the map $f: f^{-1}(\mathbb{D}_R) \to \mathbb{D}_R$ is a polynomial-like map of the same degree $d$. We refer to such polynomial-like maps as "polynomials."

The *filled Julia set* of $f$ is the set of nonescaping points:

$$K(f) = \{z\colon f^n z \in U, n = 0, 1, \ldots\}$$

The Julia set of $f$ is the boundary of its filled Julia set: $J(f) = \partial K(f)$.

A polynomial-like map of degree $d$ has $d-1$ critical points counted with multiplicities. The Julia set (and the filled Julia set) is connected if and only if all the critical points $c_i$ are nonescaping, that is, $c_i \in K(f)$.

A polynomial-like map of degree 2 is called *quadratic-like*. The Julia set of a quadratic-like map is either connected or a Cantor set, depending on whether its critical point is nonescaping or otherwise.

The domain of a polynomial-like map is allowed to be slightly adjusted by taking $V'$ to be a topological disk such that $U \subset V' \subset U'$ and letting $V = f^{-1}(V')$. We say that two polynomial-like maps represent the same germ if one can be obtained from the other by a sequence of such adjustments.

We will be mostly interested in the quadratic case; so let $\mathcal{Q}$ be the space of quadratic-like germs considered up to affine conjugacy, and let $\mathcal{C}$ be the *connectedness locus* in $\mathcal{Q}$, that is, the subset of $f \in \mathcal{Q}$ with connected Julia set. The space $\mathcal{Q}$ has a natural complex analytic structure such that holomorphic curves in $\mathcal{Q}$ are represented by holomorphic families $f_\lambda(z)$ of quadratic-like maps.

Two polynomial-like maps are called *hybrid* equivalent if they are conjugate by a quasiconformal map $h$ such that $\bar{\partial} h = 0$ a.e. on $K(f)$ (in particular, $h$ is conformal on int $K(f)$). By the *Straightening Theorem*, any polynomial-like map is hybrid equivalent (after an adjustment of its domain) to a polynomial of the same degree (called the "straightening" of $f$). The straightening depends only on the germ of $f$.

For a quadratic-like map $f$ with connected Julia set, the straightening $P_c: z \mapsto z^2 + c$ is *unique*, $c = \chi(f)$. Thus, we obtain the straightening map $\chi: \mathcal{C} \to M$, where $M$ is the Mandelbrot set (*see* Holomorphic Dynamics). We let $\mathcal{H}_c = \chi^{-1}(c)$ be the hybrid class passing through a point $c \in M$. One can show that $\mathcal{H}_c$ is a *codimension-one submanifold* in $\mathcal{Q}$.

Any quadratic-like map has two fixed points counted with multiplicity. In the case of connected Julia set, these fixed points have a different dynamical meaning: one of them, called $\alpha$, is either attracting, or neutral, or repelling *separating*, that is, $J(f) \setminus \{\alpha\}$ is disconnected. Another one, called $\beta$, is either parabolic with multiplier 1 (and then it coincides with $\alpha$) of repelling *nonseparating*.

In what follows, we normalize quadratic-like maps so that 0 is their critical point.

### Complex Renormalization and Little Mandelbrot Sets

A quadratic-like map $f: U \to U'$ with connected Julia set is called *renormalizable* if there is a topological disk $V \ni 0$ and a natural number $p \geq 2$ called the *renormalization period* such that:

- letting $g = f^p | V$ and $V' = g(V)$, the map $g: V \to V'$ is quadratic-like;
- the *little Julia set* $K(g)$ is connected; and
- the sets $g^n(K(g)), n = 1, \ldots, p-1$, can intersect $K(g)$ only at the $\beta$-fixed point of $g$.

Under these circumstances, the quadratic-like germ $g$ considered up to affine conjugacy is called the *renormalization* of the quadratic-like germ $f$; $g = Rf$. Moreover, one says that $f$ is *primitively* renormalizable if the little Julia sets $g^n(K(g)), n = 1, \ldots, p-1$, are pairwise disjoint. Otherwise, $f$ is *satellite* renormalizable.

As in the unimodal case, one can define *combinatorics* or *type* $\tau$ of the complex renormalization. Roughly speaking, renormalizable maps with the same combinatorics have the same renormalization period and the "same position" of the little Julia sets $f^k(K(g))$ in $\hat{\mathbb{C}}$ (the rigorous definition is based on the notion of Thurston's equivalence from Holomorphic Dynamics).

**Theorem 1** (Douady and Hubbard 1986). *The set of parameters $c$ for which a quadratic map $P_c: z \mapsto z^2 + c$ is renormalizable with a given combinatorics $\tau$ assemble a homeomorphic copy $M^\tau$ of the Mandelbrot set $M$.*

This theorem explains the presence of many little Mandelbrot sets that are observable on the computer pictures of $M$ (see Figures 3 and 4). Moreover, the copies corresponding to the primitive renormalization originate at primitive hyperbolic components (*see* Holomorphic Dynamics), while the copies obtained by a satellite renormalization originate at satellite hyperbolic components attached to some

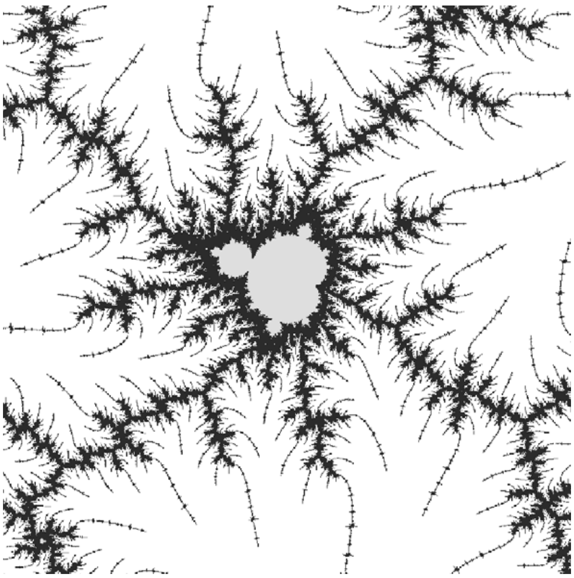

**Figure 3** A primitive copy of the Mandelbrot set.

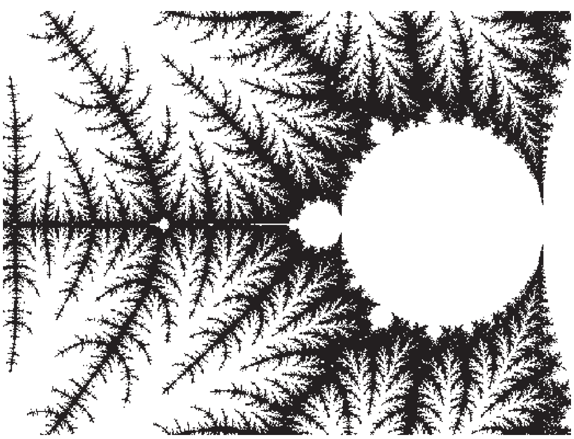

**Figure 4** The satellite copy of the Mandelbrot set attached to the main cardioid at the point of doubling bifurcation.

"mother" hyperbolic component. (Satellite copies attached to the main cardioid are particularly prominent on the pictures of $M$.)

Given a combinatorial type $\tau$, the set $\mathcal{Q}^\tau$ of quadratic-like germs $f \in \mathcal{Q}$ that are renormalizable with combinatorics $\tau$ (the complex renormalization strip) is the union of hybrid classes passing through the little copy $M^\tau$. As in the real case, let us consider the set $\mathcal{T}_{\mathbb{C}}$ of all minimal combinatorial types. Then the corresponding renormalization strips $\mathcal{Q}^\tau$ are pairwise disjoint, and we can define the *full* complex renormalization operator $R : \bigcup_{\tau \in \mathcal{T}_{\mathbb{C}}} \mathcal{Q}^\tau \to \mathcal{Q}$.

## Renormalization Theorem

The first proof of the Renormalization Conjecture in the period-doubling case was based on rigorous computer estimates (Lanford 1982). It followed, in the 1980s, by works of Epstein, Eckmann, Khanin, Sinai, among others, which gave a better conceptual understanding and provided proofs of many ingredients of the picture (without computer assistance).

The turning point in this development occurred when methods of holomorphic dynamics and conformal geometry were introduced into the subject (Douady and Hubbard 1985, Sullivan 1986). This led to the proof of the renormalization conjecture in the space of quadratic-like germs:

**Theorem 2** (Sullivan–McMullen–Lyubich, the 1990s). *For any real combinatorics $\tau \in \mathcal{T}$, the operator $R_\tau$ has a unique fixed point $f_\tau$ in the space $\mathcal{Q}$. Moreover, $f_\tau$ is hyperbolic, its stable manifold $W^s(f_\tau)$ coincides with the hybrid class $\mathcal{H}_c, c = \chi(f_\tau)$, while the real slice of the unstable manifold represents an almost full family of unimodal maps.*

This result was further extended to the smooth category by de Faria, de Melo, and Pinto.

## MLC, Density of Hyperbolicity, and Geometry of Feigenbaum Julia Sets

The "Mandelbrot set is locally connected" (MLC) conjecture (*see* Holomorphic Dynamics) is intimately related to the renormalization phenomenon. This connection was first revealed by the following result:

**Theorem 3** (Yoccoz 1990, unpublished). *Let us consider a nonrenormalizable quadratic polynomial $P_c : z \mapsto z^2 + c$ with connected Julia set and both fixed points repelling. Then the Julia set $J(P_c)$ is locally connected and the Mandelbrot set is locally connected at $c$.*

This result was recently extended to higher-degree unicritical polynomials $z \mapsto z^d + c$ (Kahn–Lyubich, preprint 2005).

The MLC Conjecture is still open for general infinitely renormalizable parameters. However, the similar problem for the real quadratic family has been resolved. It implies the real version of the Fatou conjecture in the quadratic case (*see* Holomorphic Dynamics):

**Theorem 4** (Lyubich 1997). *Hyperbolic maps are dense in the real quadratic family.*

This result was recently extended to higher-degree polynomials by Kozlovskii, Shen, and van Strien (preprint 2003).

Infinitely renormalizable quadratic maps of bounded combinatorial type (i.e., with bounded relative periods $p_{n+1}/p_n$) supply us with a rich class of fractals with very interesting geometry. These

Julia sets are "hairy" at the origin, that is, their blow-ups fill in densely the whole plane (this phenomenon is related to the universal geometry of the Feigenbaum attractors; McMullen (1996)). However, some of them have zero Lebesgue measure (Yarrington, thesis 1995) and Hausdorff dimension smaller than 2 (Avila–Lyubich, preprint 2004). It is unknown whether this happens for all of them or not (in particular, the answer is unknown for the Feigenbaum map born in the cascade of doubling bifurcations).

## Regular or Stochastic Dichotomy

### Stochastic Maps

An $S$-unimodal map $f$ is called *stochastic* if it has an absolutely continuous invariant measure $\mu$. In this case, $f$ is topologically chaotic (see the section "Topological dynamics") and $\mu$ is supported on the transitive cycle of intervals $\cup J_k$. Moreover, $\mu$ has a positive characteristic exponent,

$$\chi = \int \log|Df| \mathrm{d}\mu > 0$$

and Lebesgue almost all orbits are equidistributed with respect to $\mu$, that is, for Lebesgue a.e. $x \in I$,

$$\frac{1}{n}\sum \phi(f^n x) \to \int \phi \, \mathrm{d}\mu$$

for any continuous function $\phi$. The map $f^p \mid J$ is mixing with respect to $\mu$, and in fact, is *weakly Bernoulli*.

Here are two important criteria for stochasticity:

- *Collet–Eckmann condition* (*see* Holomorphic Dynamics). These maps have extra strong stochastic properties, notably, the exponential decay of correlations.
- *Martens–Nowicki condition*. To state it, we need to define the principal nest of intervals, $I^0 \supset I^1 \supset \cdots \ni 0$. Here $I^0 = [-\alpha, \alpha]$, where $\alpha$ is the fixed point with negative multiplier, and $I^{n+1}$ is inductively defined as the component of $f^{-l_n}(I^n)$ containing 0, where $l_n$ is the moment of first return of the orbit of 0 to $I^n$. Let us consider the scaling factors $\sigma_n = |I^n|/|I^{n-1}|$. If $\sum \sqrt{\sigma_n} < \infty$ *then* $f$ *is stochastic*.

Let $\mathcal{N} \subset [-2, 1/4]$ be the set of parameters $c$ for which the quadratic map $P_c$ is topologically chaotic. Not every such map is stochastic. However, *the set of stochastic parameters has positive Lebesgue measure* (Jakobson 1981), and in fact,

**Theorem 5** (Lyubich 2000). *For a.e.* $c \in \mathcal{N}$, *the map* $P_c$ *satisfies the Martens–Nowicki condition, and thus, is stochastic.*

Avila and Moreira (2005) went on to prove that *for a.e.* $c \in \mathcal{N}$, *the map* $P_c$ *is Collet–Eckmann.*

### Renormalization Horseshoe

Let us consider the complexification of the renormalization operator [2],

$$R : \bigcup_{\tau \in \mathcal{T}} \mathcal{Q}^\tau \to \mathcal{Q} \qquad [3]$$

acting in the space of quadratic-like maps.

**Theorem 6** (Lyubich 2002). *The "Strong Renormalization Conjecture" is valid for the operator* [3].

Let $\mathcal{I} \subset [-2, 1/4]$ be the set of parameters for which the quadratic map $P_c$ is infinitely renormalizable. The above theorem implies that this set has *zero Lebesgue measure*. (Avila and Moreira went on to prove that $\mathrm{HD}(\mathcal{I}) < 1$.)

### Regular or Stochastic Dichotomy

Putting together Theorems 5 and 6, we obtain:

**Theorem 7** *For a.e.* $c \in [-2, 1/4]$, *the quadratic map* $P_c$ *is either regular or stochastic.*

This result gives a complete probabilistic picture of dynamics in the real quadratic family. It has been later transferred to any nondegenerate real analytic family of $S$-unimodal maps (Avila–Lyubich–de Melo), and further to a generic smooth family of $S$-unimodal maps (Avila–Moreira).

Palis has formulated a strong general conjecture (in all dimensions) asserting that a typical (from the probabilistic point of view) smooth dynamical system $f$ has finitely many attractors supporting SRB measures (*see* Lyapunov Exponents and Strange Attractors) that govern the behavior of Lebesgue a.e. trajectories of $f$. The above results confirm the *Palis Conjecture* in the setting of $S$-unimodal maps.

## Other Universality Classes

From a more general point of view, renormalization is an appropriately rescaled return map to a relevant piece of the phase space, viewed as an operator in some class of dynamical systems. From this point of view, most dynamical systems are "renormalizable," and the renormalization approach often provides a deep insight into the nature of the systems in question.

Here is a partial list of classes of nonlinear systems that exhibit universality with an underlying renormalization mechanism (we provide a few

relevant names, but there are many more people who contributed to the corresponding theories):

- Holomorphic germs near indifferent equilibria (Yoccoz, Shishikura, McMullen);
- critical circle maps (Kadanoff, Feigenbaum, Rand, Lanford, Swiatek, de Faria, Yampolsky);
- non-renormalizable quadratic-like maps of Fibonacci type (Lyubich–Milnor);
- conservative two-dimensional diffeomorphisms near the point of breaking of KAM tori (MacKay, Koch); and
- dissipative Hénon-like maps (Collet–Eckmann–Koch, de Carvalho–Lyubich–Martens).

## Variational Methods in Turbulence

**F H Busse**, Universität Bayreuth, Bayreuth, Germany

### Introduction

The problem of fluid turbulence is commonly regarded as one of the most challenging problems of theoretical physics and mathematics. There is general agreement that the Navier–Stokes equations (NSEs) provide a satisfactory basis for the description of turbulent motions of homogeneous Newtonian fluids such as gases and most liquids. But the difficulty of generating solutions of these equations for high-Reynolds-number flows has prevented accurate answers to simple questions such as the question of the discharge of turbulent pipe flow as a function of the pressure head or the question of the heat transport by turbulent convection in a fluid layer heated from below. In view of this difficulty, it has become an attractive idea to obtain rigorous bounds on turbulent transports. Variational methods have played an important role in the derivation of such bounds.

There is another motivation for the use of variational methods for the understanding of turbulent fluid systems. Experimenters have sometimes noted the tendency of turbulent flows to maximize transports under given external conditions. In his pioneering paper, Howard (1963) mentions that the Malkus hypothesis of a maximum heat transport by thermal convection had motivated him to derive upper bounds through the use of variational methods. The techniques developed by Howard have later been applied to other kinds of turbulent transports by Busse. While relatively simple ordinary differential equations are obtained when the equation of continuity is not imposed as a constraint, the Euler–Lagrange equations for a stationary value of the variational functional lead to nonlinear partial differential equations when solenoidal extremalizing vector fields are required. Nevertheless, using boundary layer methods one can derive approximate analytical solutions even in the limit of asymptotically large Rayleigh and Reynolds numbers (Busse 1969, 1978).

In the following, we shall first discuss the energy method which provides necessary conditions for the existence of turbulent solutions of the underlying equations and then turn to the problem of upper bounds for the turbulent momentum transport in the plane Couette flow configuration as a particular example. The properties and physical relevance of the extremalizing vector fields will be discussed in a final section.

### Energy Method

For simplicity, we consider the NSEs for a homogeneous incompressible fluid with a constant kinematic viscosity $\nu$ in an arbitrary fixed domain $\mathcal{D}$. Using the diameter $d$ of the domain as length scale and $d^2/\nu$ as timescale, we can write the NSEs of motion in dimensionless form,

$$\frac{\partial}{\partial t}\boldsymbol{v} + \boldsymbol{v}\cdot\nabla\boldsymbol{v} = -\nabla p + \boldsymbol{f} + \nabla^2\boldsymbol{v} \qquad [1a]$$

$$\nabla\cdot\boldsymbol{v} = 0 \qquad [1b]$$

where $\boldsymbol{f}$ denotes some given steady distribution of a force density. On the boundary $\partial\mathcal{D}$ of the domain $\mathcal{D}$, steady velocities parallel to the boundary may be specified. We assume that the basic steady solution of the problem is given by $\boldsymbol{v}_s = Re\,\hat{\boldsymbol{v}}$ where the average of $(\hat{\boldsymbol{v}})^2/2$ over the domain $\mathcal{D}$ (indicated by angular brackets) is unity, $\langle|\hat{\boldsymbol{v}}|^2\rangle = 2$. Any velocity field $\boldsymbol{v}_t$ different from $\boldsymbol{v}_s$, that is, with $\boldsymbol{u} \equiv \boldsymbol{v}_t - \boldsymbol{v}_s \not\equiv 0$, must obey the equations

$$\frac{\partial}{\partial t}\boldsymbol{u} + \boldsymbol{v}_s\cdot\nabla\boldsymbol{u} + \boldsymbol{u}\cdot\nabla\boldsymbol{v}_s + \boldsymbol{u}\cdot\nabla\boldsymbol{u} = -\nabla\tilde{p} + \nabla^2\boldsymbol{u} \qquad [2a]$$

$$\nabla\cdot\boldsymbol{u} = 0 \qquad [2b]$$

together with the homogeneous boundary conditions for $\boldsymbol{u}$ on $\partial\mathcal{D}$. By multiplying eqn [2a] by $\boldsymbol{u}$ and averaging the result over the domain $\mathcal{D}$ we obtain the relationship

$$\frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\langle\boldsymbol{u}\cdot\boldsymbol{u}\rangle = -\langle|\nabla\boldsymbol{u}|^2\rangle - Re\langle\boldsymbol{u}\cdot(\boldsymbol{u}\cdot\nabla)\hat{\boldsymbol{v}}\rangle \qquad [3]$$

where the vanishing of $\boldsymbol{u}$ on $\partial\mathcal{D}$ and equations such as

$$\langle \boldsymbol{u}\cdot(\boldsymbol{v}_\mathrm{s}\cdot\nabla)\boldsymbol{u}\rangle = \tfrac{1}{2}\langle \boldsymbol{v}_\mathrm{s}\cdot\nabla\boldsymbol{u}\cdot\boldsymbol{u}\rangle = \tfrac{1}{2}\langle\nabla\cdot(\boldsymbol{v}_\mathrm{s}\boldsymbol{u}\cdot\boldsymbol{u})\rangle = 0$$

have been used to prove that the terms $\boldsymbol{v}_\mathrm{s}\cdot\nabla\boldsymbol{u}$, $\boldsymbol{u}\cdot\nabla\boldsymbol{u}$ and $\nabla\tilde{p}$ do not enter the balance [3]. This balance is called the Reynolds–Orr energy equation and is the basis for the application of the energy method. The lowest value $Re$ for which the right-hand side of [3] is non-negative is called the energy Reynolds number $Re_\mathrm{E}$. For $Re < Re_\mathrm{E}$ the steady solution $\boldsymbol{v}_\mathrm{s}$ is absolutely stable and the energy of any disturbance $\boldsymbol{u}$ must decay exponentially in time. $Re > Re_\mathrm{E}$ is a necessary condition for the existence of a persistent turbulent state of fluid flow. $Re_\mathrm{E}$ is determined as the solution of the variational problem:

*For a given flow $\hat{\boldsymbol{v}}$ in $\mathcal{D}$ find the minimum $Re_\mathrm{E}$ of the functional*

$$\mathcal{R}_\mathrm{E} \equiv \frac{\langle|\nabla\breve{\boldsymbol{u}}|^2\rangle}{\langle-\breve{\boldsymbol{u}}\cdot(\breve{\boldsymbol{u}}\cdot\nabla)\hat{\boldsymbol{v}}\rangle} \qquad [4]$$

*among all vector fields $\breve{\boldsymbol{u}}$ which satisfy the conditions $\nabla\cdot\breve{\boldsymbol{u}}=0$ in $\mathcal{D}$, $\breve{\boldsymbol{u}}=0$ on $\partial\mathcal{D}$, and $\langle\breve{\boldsymbol{u}}\cdot(\breve{\boldsymbol{u}}\cdot\nabla)\hat{\boldsymbol{v}}\rangle < 0$.*

For $Re \geq Re_\mathrm{E}$ there will exist at least one vector field $\boldsymbol{u}$, namely the minimizing solution $\breve{\boldsymbol{u}}$ of the variational problem [4], the energy of which does not decay, at least not initially. In the derivation of the Euler–Lagrange equations as necessary conditions for stationary values of the variational functional [4],

$$\tfrac{1}{2}G(\breve{u}_\kappa\partial_\kappa\hat{v}_i + \breve{u}_\kappa\partial_i\hat{v}_\kappa) = -\partial_i\breve{\pi} + \partial_\kappa\partial_\kappa\breve{u}_i \qquad [5a]$$

$$\partial_\kappa\breve{u}_\kappa = 0 \qquad [5b]$$

the constraint $\nabla\cdot\breve{\boldsymbol{u}}=0$ has been taken into account through the Lagrange multiplying function $\breve{\pi}$. $G$ is a stationary value of the functional [4] and in general there exist many of those which are determined as eigenvalues of the linear boundary value problem [5] together with its boundary condition $\breve{u}_i=0$ on $\partial\mathcal{D}$. Only the infinum of all $G$ provides the energy Reynolds number $Re_\mathrm{E}$. Many details on the energy method can be found in Joseph's book (1976). Here we just wish to remark that the Reynolds–Orr balance [3] remains valid when the problem is considered in a system rotating with a constant angular velocity $\Omega_D$ since the Coriolis force does not contribute to the energy balance [3]. The values of $Re_\mathrm{E}$ are usually much smaller than the critical values $Re_\mathrm{c}$ for the onset of infinitesimal disturbances as can be seen from Table 1. Here the experimentally determined values

**Table 1** Reynolds numbers for shear flows

| | $Re_\mathrm{E}$ | $Re_\mathrm{G}$ (from exp.) | $Re_\mathrm{c}$ |
|---|---|---|---|
| Plane Couette flow | 82.6 | ≈1300 | ∞ |
| Poiseuille flow (channel flow) | 99.2[a] | ≈2000[a] | 5772[a] |
| Hagen–Poiseuille flow (pipe flow) | 81.5[a] | ≈2100[a] | ∞ |
| Circular Couette flow with $\Omega_D = Re_\mathrm{E}/2$ | 82.6 | ≈82.6 | 82.6 |

[a] The maximum velocity and the channel width $d$ (radius $d$ in the case of pipe flow) have been used in definition of $Re$.

$Re_\mathrm{G}$ for the instability of the basic flow state have also been listed. A unique situation occurs in the small gap limit of the Taylor–Couette system where $Re_\mathrm{E}$ and $Re_\mathrm{c}$ coincide for a special value of the dimensionless mean rotation rate $\Omega_D$ (Busse 2002).

## Variational Problem for Turbulent Momentum Transport

In order to introduce the variational method for bounds on turbulent transports we consider the simplest configuration for which a nontrivial solution of the NSEs of motion exists: the configuration of plane Couette flow (Figure 1). The Reynolds number is defined in this case in terms of the constant relative motion $U_0\boldsymbol{i}$ between the plates, $Re = U_0 d/\nu$, where $\boldsymbol{i}$ is the unit vector parallel to the plates and $\nu$ is the kinematic viscosity of the fluid. Using the distance $d$ between the plates as length scale and $d^2/\nu$ as timescale, the basic equations can be written in the form

$$\frac{\partial}{\partial t}\boldsymbol{v} + \boldsymbol{v}\cdot\nabla\boldsymbol{v} = -\nabla p + \nabla^2\boldsymbol{v} \qquad [6]$$

$$\nabla\cdot\boldsymbol{v} = 0 \qquad [7]$$

We use a Cartesian system of coordinates with the $x$, $z$-coordinates in the directions of $\boldsymbol{i}$ and $\boldsymbol{k}$,

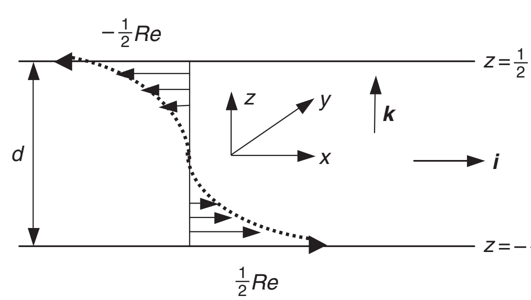

**Figure 1** Geometrical configuration of the plane Couette flow problem.

respectively, where $\boldsymbol{k}$ is the unit vector normal to the plates such that the boundary conditions are given by

$$\boldsymbol{v} = \mp \frac{1}{2} Re\, \boldsymbol{i} \quad \text{at } z = \pm \frac{1}{2} \qquad [8]$$

After separating the velocity field $\boldsymbol{v}$ into its mean and fluctuating parts, $\boldsymbol{v} = U + \check{\boldsymbol{v}}$ with $\bar{\boldsymbol{v}} = U$, $\bar{\check{\boldsymbol{v}}} = 0$, where the bar denotes the average over planes $z = \text{const.}$, we obtain by multiplying eqn [6] by $\check{\boldsymbol{v}}$ and averaging it over the entire fluid layer (indicated by angular brackets)

$$\frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\langle|\check{\boldsymbol{v}}|^2\rangle = -\left\langle \overline{\boldsymbol{u}w} \cdot \frac{\partial}{\partial z} U \right\rangle - \langle|\nabla\check{\boldsymbol{v}}|^2\rangle \qquad [9]$$

Here $\boldsymbol{u}$ denotes the component of $\check{\boldsymbol{v}}$ perpendicular to $\boldsymbol{k}$ and $w$ is its $z$-component. We define fluid turbulence under stationary conditions by the property that quantities averaged over planes $z = \text{const.}$ are time independent. Accordingly, the equation for the mean flow $U$ can be integrated to yield

$$\frac{\mathrm{d}}{\mathrm{d}z} U = \overline{w\boldsymbol{u}} - \langle w\boldsymbol{u}\rangle - Re\, \boldsymbol{i} \qquad [10]$$

where the boundary condition [8] has been employed. With this relationship, $U$ can be eliminated from the problem and the energy balance

$$\langle|\nabla\boldsymbol{u}|^2\rangle + \langle|\overline{\boldsymbol{u}w} - \langle\boldsymbol{u}w\rangle|^2\rangle = Re\langle u_x w\rangle \qquad [11]$$

is obtained where the identity $\langle\overline{\boldsymbol{u}w}^2\rangle - \langle\boldsymbol{u}w\rangle^2 = \langle|\overline{\boldsymbol{u}w} - \langle\boldsymbol{u}w\rangle|^2\rangle$ has been used.

Since the momentum transport in the $x$-direction between the moving rigid plates is described by $M = -\mathrm{d}U_x/\mathrm{d}z\,|_{z=\pm 1/2} = \langle u_x w\rangle + Re$, we can conclude immediately that the momentum transport by turbulent flow always exceeds the corresponding laminar value because $\langle u_x w\rangle$ is positive according to the relationship [11]. Since a lower bound on $M$ thus exists, an upper bound $\mu$ on $\langle u_x w\rangle$ as a function of $Re$ is of primary interest. Following Howard (1963), it can be shown that $\mu(Re)$ is a monotonous function and it is therefor equivalent to ask for a lower bound $R$ of $Re$ at a given value $\mu$ of $\langle u_x w\rangle$. We are thus led to the following formulation of the variational problem:

*Find the minimum $R(\mu)$ of the functional*

$$\mathcal{R}(\tilde{\boldsymbol{v}}, \mu) \equiv \frac{\langle|\nabla\tilde{\boldsymbol{v}}|^2\rangle}{\langle\tilde{u}_x\check{w}\rangle} + \mu\frac{\langle|\overline{\tilde{\boldsymbol{u}}\tilde{w}} - \langle\tilde{\boldsymbol{u}}\tilde{w}\rangle|^2\rangle}{\langle\tilde{u}_x\tilde{w}\rangle^2} \qquad [12]$$

*among all solenoidal vector fields $\tilde{\boldsymbol{v}} \equiv \tilde{\boldsymbol{u}} + \boldsymbol{k}\tilde{w}$ (with $\tilde{\boldsymbol{u}} \cdot \boldsymbol{k} = 0$) that satisfy the boundary condition $\tilde{\boldsymbol{v}} = 0$ at $z = \pm 1/2$ and the condition $\langle\tilde{u}_x\tilde{w}\rangle > 0$.*

The Euler–Lagrange equations as necessary conditions for an extremal value of the functional are given by

$$\tilde{w}\frac{\mathrm{d}}{\mathrm{d}z}U^* + \boldsymbol{k}\tilde{\boldsymbol{u}} \cdot \frac{\mathrm{d}}{\mathrm{d}z}U^* = -\nabla\pi + \nabla^2\tilde{\boldsymbol{v}} \qquad [13]$$

$$\nabla \cdot \tilde{\boldsymbol{v}} = 0 \qquad [14]$$

where $\mathrm{d}U^*/\mathrm{d}z$ is defined by

$$\frac{\mathrm{d}}{\mathrm{d}z}U^* = \overline{\tilde{\boldsymbol{u}}\tilde{w}} - \langle\tilde{\boldsymbol{u}}\tilde{w}\rangle - \boldsymbol{i}\left(R - \frac{\langle|\nabla\tilde{\boldsymbol{v}}|^2\rangle}{2\langle\tilde{\boldsymbol{v}}_x\tilde{w}\rangle}\right) \qquad [15]$$

and where $\mu = \langle\tilde{\boldsymbol{u}}_x\tilde{w}\rangle$ has been set. When eqns [13]–[15] are compared with the equations for $\check{\boldsymbol{v}}$ and for $\boldsymbol{U}$, a strong similarity can be noticed. The variational problem does not exhibit any time dependence, but the Euler–Lagrange equations may still be regarded as the symmetric analogue of the NSEs for steady flow.

## Upper Bounds on the Turbulent Momentum Transport

A simple analytical solution of the variational problem can be obtained when the constraint $\nabla \cdot \tilde{\boldsymbol{v}} = 0$ is dropped. In that case it is evident that the minimum of the functional [12] is reached when $\tilde{\boldsymbol{v}}$ is independent of $x$, $y$, and when $\tilde{u}_x = \tilde{w} = f(z)$ holds. The Euler–Lagrange equations then assume the form of an ordinary differential equation,

$$f'' = [\mu(f^2/\langle f^2\rangle - 1) - R + \langle f'^2\rangle/\langle f^2\rangle]f \qquad [16]$$

Since the variational functional [12] is homogeneous in $\tilde{\boldsymbol{v}}$, we are free to use a normalization condition for which we choose $\max[f(z)] = 1$. Multiplication of eqn [16] by $f'$ and integration yield

$$f'^2 = \frac{\mu}{2k^2\langle f^2\rangle}(1 - k^2f^2)(1 - f^2)$$
$$\text{with } k^2 = \mu/[2(R+\mu)\langle f^2\rangle - 2\langle f'^2\rangle - \mu] \qquad [17]$$

This equation can be solved in terms of elliptical integrals. The minimum $R(\mu)$ is determined by the relationships

$$R = \frac{8}{3}[K^2(1+k^2) + K^3/D - 3k^2KD)]$$
$$\mu = 8k^2\,KD \qquad [18]$$

where $D(k)$ and $K(k)$ are the complete elliptical integrals usually labeled by these letters. For details, see the analysis by Howard (1963) of an analogous problem. In the asymptotic case of large

Reynolds numbers, relationships [18] yield the upper bound

$$\mu(Re) = \frac{8}{128} Re^2 \qquad [19]$$

In solving the full eqns [13]–[15], it is convenient to eliminate eqn [14] through the general representation of the solenoidal vector field $\tilde{\boldsymbol{v}}$,

$$\tilde{\boldsymbol{v}} = \nabla \times (\nabla\phi \times \boldsymbol{k}) + \nabla\psi \times \boldsymbol{k} \qquad [20]$$

We assume that the minimizing vector field $\tilde{\boldsymbol{v}}$ does not depend on $x$, although a rigorous proof for this property can be given only for small values of $\mu$. Introducing the notations $\theta \equiv \partial\psi/\partial y$ and $w \equiv -\partial^2\phi/\partial y^2$ we are thus led to the general ansatz

$$w = w^{(N)} \equiv \sum_{n=1}^{N} \alpha_n^{-2} w_n(z)\phi_n(y) \qquad [21a]$$

$$\theta = \theta^{(N)} \equiv \sum_{n=1}^{N} \theta_n(z)\phi_n(y) \qquad [21b]$$

where $N$ may tend to infinity and the functions $\phi_n(y)$ satisfy the equation

$$\frac{\partial^2}{\partial y^2}\phi_n = -\alpha_n^2\phi_n \qquad [22]$$

In the following, it will be assumed that the positive wavenumbers $\alpha_n$ are ordered according to their size, $\alpha_{n-1} < \alpha_n < \alpha_{n+1}$. The solutions of the form [21] of the Euler–Lagrange equations exhibit a boundary layer structure for large $\mu$ as sketched in Figure 2. Accordingly, the $N$–$\alpha$ solutions are characterized by a hierarchy of $N$ boundary layers at each plate and provide the upper bound sequentially with increasing $\mu$ starting with $N = 1$. The extremalizing vector fields thus exhibit a bifurcation structure similar to that found in many cases of the transition to turbulence. The thicknesses of the boundary layers decrease with increasing $\mu$ and their ratio from one layer to the next approaches the factor 4 as indicated in Figure 3. The typical scale of motion increases linearly with

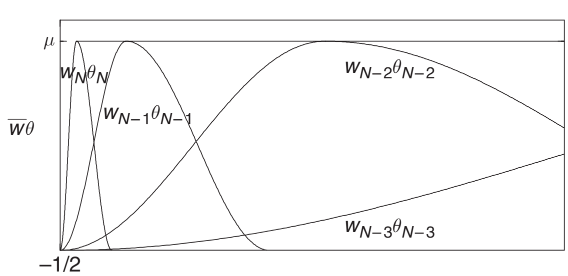

**Figure 2** Qualitative sketch of the boundary layer structure of the extremalizing $N-\alpha$ solution.

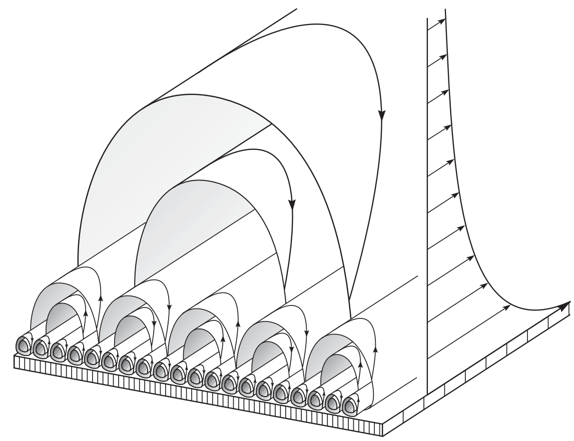

**Figure 3** Qualitative sketch of the nested boundary layers that characterize the vector field of maximum transport. The profile of the mean shear is shown on the right side.

distance from the wall as assumed in Prandtl's mixing-length theory. But the discreteness of the scales reflects the fact that effective transports require preferred scales. Asymptotically, the upper bound for the momentum transport approaches

$$\mu(Re) = 0.010\, Re^2 \qquad [23]$$

which represents a significant improvement over the relationship [19]. Nevertheless, the upper bound still exceeds the measured values of the momentum transport by more than a factor 10.

## Discussion

Bounds like those for the momentum transport have been obtained for many other kinds of turbulent transports. For details we refer to the review articles listed below. Usually, the formulation of the upper bound problem requires that the external conditions are homogeneous in two spatial dimensions such that a separation of the turbulent velocity, temperature, or magnetic fields into mean and fluctuating parts is possible. In this respect, the variational methods for upper bounds are more restricted than those used for determination of the energy Reynolds number $Re_E$. The latter problem, incidentally, corresponds to the limit $\mu \to 0$ of variational problems of the type [12] as can be seen from a comparison with expression [4].

In recent years, the background field method has been introduced by Doering and Constantin (1994) as an alternative way for obtaining bounds on properties of turbulent flows. When optimized, it becomes equivalent to the variational method discussed in this article as has been demonstrated by Kerswell (1998). The fact that not optimized bounds can be obtained

relatively easily emphasizes the point that the extremalizing vector fields are the most interesting aspect of the variational problems. They often exhibit similarities with the observed turbulent velocity fields, in particular as far as the mean flows are concerned. In the case of convection in a layer heated from below, the transition of the bound from the $1-\alpha$ solution to the $2-\alpha$ solution corresponds closely to the experimentally observed transition from convection rolls to bimodal convection (Busse 1969).

The close similarities between variational functionals for rather different physical systems suggest corresponding similarities between the respective turbulent fields. For example, the analogy between the fluctuating component of the temperature in turbulent convection and the streamwise component of the fluctuating velocity field in shear flow turbulence has been demonstrated and employed in a theory of the atmospheric boundary layer (Busse 1978). Better bounds and more physically realistic properties of the extremalizing vector fields can be expected when additional constraints are imposed. For example, the energy balances for poloidal and toroidal components of the velocity field can be applied separately. But these developments are still in their initial stages.

# Variational Techniques for Ginzburg–Landau Energies

**S Serfaty**, New York University, New York, NY, USA

Ginzburg–Landau-type problems are variational problems which consider a Dirichlet-type energy posed on complex-valued functions, penalized by a potential term which has a well in the unit circle of the complex plane. The denomination comes from the physical model of superconductivity of Ginzburg and Landau. They are phase-transition-type models in the sense that they describe the state of the material according to different "phases" which can coexist in a sample and be separated by various types of interfaces. We start by presenting the physical model (readers familiar with it may wish to skip the next two sections and go straight to the section "The simplified model").

## Introduction to the Ginzburg–Landau Model

The Ginzburg–Landau model was introduced by Ginzburg and Landau in the 1950s as a phenomenological model to describe superconductivity, and was later justified as a limit of the quantum BCS theory of Bardeen–Cooper–Schrieffer. It is a model of great importance and recognition in physics (with several Nobel prizes awarded for it: Landau, Ginzburg, Abrikosov). In addition to its importance in the modeling of superconductivity, the Ginzburg–Landau model turns out to be mathematically extremely close to the Gross–Pitaevskii model for superfluidity, and models for rotating Bose–Einstein condensates, which all have in common the appearance of topological defects called "vortices."

Superconductivity, which was discovered in 1911 by Kammerling Ohnes, consists in the complete loss of resistivity of certain metals and alloys at very low temperatures: the two most striking consequences of it being the possibility of permanent superconducting currents and the particular behavior that an external magnetic field applied to the sample gets expelled from the material and can generate vortices, through which it penetrates the sample.

### The Energy Functional

After a series of dimension reductions, the Ginzburg–Landau model describes the state of the superconducting sample occupying a region $\Omega$ and submitted to the external magnetic field $h_{\text{ex}}$,

below the critical temperature, through its Gibbs energy:

$$G_\varepsilon(\psi, A) = \frac{1}{2}\int_\Omega |\nabla_A\psi|^2 + \frac{(1-|\psi|^2)^2}{2\varepsilon^2} + \frac{1}{2}\int_{\mathbb{R}^3} |\mathrm{curl}\, A - h_{\mathrm{ex}}|^2 \qquad [1]$$

In this expression, the first unknown $\psi$ is the "order parameter" in physics. It is a complex-valued condensed wave function, indicating the local state of the material, or the phase (in the Landau theory approach of phase transitions): $|\psi|^2$ is the density of the "Cooper pairs" of superconducting electrons explaining superconductivity in the BCS approach. With our normalization $|\psi| \le 1$ and where $|\psi| \sim 1$ the material is in the superconducting phase, while where $|\psi| \sim 0$, it is in the normal phase (i.e., behaves like a normal conductor), the two phases being able to coexist in the sample.

The second unknown $A$ is the electromagnetic vector potential of the magnetic field, a function from $\Omega$ to $\mathbb{R}^3$. The induced magnetic field in the sample is deduced by $h = \mathrm{curl}\, A$. The notation $\nabla_A$ denotes the covariant derivative $\nabla - \mathrm{i}A$. The superconducting current is the vector $j$ of components

$$j_k = \langle \mathrm{i}\psi, (\nabla_A)_k \psi\rangle \qquad [2]$$

where $\langle .,.\rangle$ denotes the scalar product in $\mathbb{C}$ identified with $\mathbb{R}^2$.

Finally, the parameter $\varepsilon$ is the inverse of the "Ginzburg–Landau parameter" $\kappa$, a dimensionless parameter (ratio of the penetration depth and the coherence length) depending on the material only.

Most variational studies of Ginzburg–Landau focus on the regime of large $\kappa$ or small $\varepsilon$, corresponding to "extreme type-II" superconductors, also called the London limit. In this limit, the potential term acts as a singular perturbation, and the characteristic size of the vortices is $\varepsilon \to 0$; vortices become line-like topological singularities, which makes it easier to extract and describe them.

This model is a $\mathbb{U}(1)$-gauge theory, that is, it is invariant under the gauge transformations:

$$\begin{aligned} \psi &\mapsto \psi e^{\mathrm{i}\Phi} \\ A &\mapsto A + \nabla\Phi \end{aligned} \qquad [3]$$

where $\Phi$ is a smooth real-valued function. The physically relevant quantities are those that are gauge invariant, such as the energy $G_\varepsilon, |\psi|, h$, and the superconducting current $j$.

For more on the model, we refer to the physics literature (e.g., DeGennes (1966) and Tinkham (1996)).

### Reductions of the Model

The goal of variational studies of the Ginzburg–Landau model is to relate the energy to the vortices and the applied field. In three dimensions (3D), vortices are filaments, or lines of zeros of the order parameter $\psi$, around which $\psi$ has a nonzero winding number. These are quite delicate to describe in 3D (we will mention some results below), so a simplification that is commonly made consists in reducing to a two-dimensional model.

When reducing to 2D, one assumes that everything is independent of the vertical direction, and that the applied magnetic field is also vertical. The domain $\Omega$ is then a two-dimensional, bounded and (for simplicity) simply connected open set, which is the horizontal section of an infinite vertical cylinder. One can also imagine it represents a thin film.

In 2D, the energy is written the same way:

$$G_\varepsilon(\psi, A) = \frac{1}{2}\int_\Omega |\nabla_A\psi|^2 + \frac{(1-|\psi|^2)^2}{2\varepsilon^2} + |\mathrm{curl}\, A - h_{\mathrm{ex}}|^2 \qquad [4]$$

where this time $A$ is $\mathbb{R}^2$-valued, and the induced magnetic field $h = \mathrm{curl}\, A = \partial_1 A_2 - \partial_2 A_1$ is now a real-valued function, which can be taken to be equal to $h_{\mathrm{ex}}$ (now a real positive number) in $\mathbb{R}^2 \backslash \Omega$.

The stationary states of the system are the critical points of $G_\varepsilon$, or the solutions of the Ginzburg–Landau equations:

$$\begin{aligned} -(\nabla_A)^2\psi &= \frac{1}{\varepsilon^2}\psi(1-|\psi|^2) && \text{in } \Omega \\ -\nabla^\perp h &= \langle \mathrm{i}\psi, \nabla_A\psi\rangle && \text{in } \Omega \\ h &= h_{\mathrm{ex}} && \text{on } \partial\Omega \\ \nabla_A\psi\cdot\nu &= 0 && \text{on } \partial\Omega \end{aligned} \qquad [5]$$

where $\nabla^\perp$ denotes $(-\partial_{x_2}, \partial_{x_1})$.

A common simplification consists in suppressing the magnetic field, and thus in studying the simplified energy

$$E_\varepsilon(u) = \frac{1}{2}\int_\Omega |\nabla u|^2 + \frac{(1-|u|^2)^2}{2\varepsilon^2} \qquad [6]$$

where the order parameter is commonly denoted by $u$, and is still complex valued. This energy, which can be seen as a complex analog of the real-valued Allen–Cahn model of phase transitions, has been extensively studied, especially since the work of Bethuel–Brezis–Hélein, where the domain $\Omega$ is assumed to be two dimensional and simply connected. The higher-dimensional case has also been considered.

### Vortices and Critical Fields

We now need to explain more precisely what a vortex is. In two dimensions, a vortex is an object centered at an isolated zero of $u$ (or $\psi$), around which the phase of $u$ has a nonzero winding number called the "degree of the vortex." It is the simplest example of a topological defect. If the zero is located at $x_0$, the winding number or degree is the integer that can be computed by

$$\frac{1}{2\pi}\int_{\partial B(x_0,r)}\frac{\partial\varphi}{\partial\tau}=d\in\mathbb{Z} \qquad [7]$$

where $r$ is small enough, and $\varphi$ is the phase of $u$, that is, $u$ can be written $u=|u|e^{i\varphi}$. For example, the phase $\varphi=d\theta$, where $\theta$ is the polar angle centered at $x_0$, yields a vortex of degree $d$. Observe that the phase $\varphi$ is not a well-defined function, it is multivalued (and defined up to $2\pi$); however, we have the important relation

$$\operatorname{curl}\nabla\varphi=2\pi\sum_i d_i\delta_{a_i} \qquad [8]$$

where the $a_i$'s are the zeros of $u$, $d_i$'s the associated degrees, and $\delta_x$ denotes the Dirac mass at $x$.

When $\varepsilon$ is small, it is clear from [4] or [6] that $|u|$ prefers to be close to 1, and a scaling argument hints that $|u|$ is different from 1 in regions of characteristic size $\varepsilon$. Of course this is an intuitive picture and several mathematical notions are used to describe the vortices.

Vortices appear due to the applied field $h_{ex}$. For type-II superconductors there are essentially three critical fields, $H_{c_1}$, $H_{c_2}$, $H_{c_3}$, critical values of $h_{ex}$ for which phase transitions occur. For $h_{ex}\le H_{c_1}=O(|\log\varepsilon|)$, there are no vortices and the superconductor is in the superconducting phase $|\psi|\simeq 1$ everywhere. At $H_{c_1}$ the first vortices appear, and their number increases as $h_{ex}$ is raised. When they become numerous they tend to arrange in triangular lattices called Abrikosov lattices, as observed in experiments and predicted by Abrikosov from the Ginzburg–Landau model, in a very influential work. At the second critical field $H_{c_1}=O(1/\varepsilon^2)$ bulk superconductivity is destroyed, and surface superconductivity remains until $H_{c_3}=O(1/\varepsilon^2)$, the third critical field, above which $\psi\equiv 0$ and the material is normal.

## Issues and Methods

The variational approach to Ginzburg–Landau consists in expressing the energy in terms of reduced quantities or objects, in particular in terms of the vortices. This requires to develop mathematical tools to describe and characterize the vortices (in particular give some suitable definitions of a "vortex structure" for a given $u$ or $\psi$), and estimate precisely the energetic cost of each vortex and of their interaction. This allows us to obtain results of variational convergence of the energy $G_\varepsilon, E_\varepsilon$ (or their variants), that is, to derive $\Gamma$-limits, or "reduced problems" posed in terms of the vortices, which are easier to minimize than the original ones. These limits depend on the regime of applied field, and allow to characterization of, in turn, the critical fields, and the optimal repartition and number of the vortices, if any.

Variational methods also serve to solve some inverse problems, that is, to prove the existence of solutions of the equation which have some given properties, such as a given repartition of vortices, through local minimization procedures, or the use of topological methods based on investigating the topology of the energy levels.

Nonvariational approaches of Ginzburg–Landau are also very useful, in particular to identify the profiles of the solutions, to describe vortices of nonminimizing critical points, or to perform a bifurcation analysis around the normal solution at $H_{c_3}$.

## The Simplified Model

We first present the variational study of $E_\varepsilon$ [6] in dimension 2, together with the mathematical tools used for both [6] and [4]. We will restrict to the asymptotics $\varepsilon\to 0$, since this is the situation where the most results are known.

Let us present informally the essential ingredients of the analysis.

### Tracing the Vortices

The easiest way to trace the vortices is to use the current $\langle iu, \nabla u\rangle$ (or the "superconducting current" $j=\langle i\psi, \nabla_A\psi\rangle$ for the case with magnetic field). Here we recall $\langle .,. \rangle$ denotes the scalar product in $\mathbb{C}$ as identified with $\mathbb{R}^2$, that is, $\langle iu, \nabla u\rangle=(u\times\partial_1 u, u\times\partial_2 u)$ with $\times$ the vector product in $\mathbb{R}^2$.

The curl of the current is the vorticity of the map $u$, exactly like in fluid mechanics. Writing $u=\rho e^{i\varphi}$ we have (at least formally) $\langle iu, \nabla u\rangle=\rho^2\nabla\varphi$ and since $\rho=|u|$ is close to 1 (other than in the small vortex regions), we have the approximation

$$\begin{aligned}\operatorname{curl}\langle iu,\nabla u\rangle &=\operatorname{curl}(\rho^2\nabla\varphi)\simeq\operatorname{curl}\nabla\varphi\\ &=2\pi\sum_i d_i\delta_{a_i}\end{aligned} \qquad [9]$$

where the $a_i$'s are the zeros of $u$ (or its vortices) and the $d_i$'s their degrees, or

$$\operatorname{curl}\langle i\psi,\nabla_A\psi\rangle+\operatorname{curl}A\simeq\operatorname{curl}\nabla\varphi$$

in the case with magnetic field. This can be made rigorous (see Jerrard and Soner (2002) and Sandier and Serfaty (to appear)), that is, one can express that

$$\operatorname{curl}\langle \mathrm{i}u, \nabla u\rangle - 2\pi \sum_i d_i \delta_{a_i} \to 0 \quad \text{as } \varepsilon \to 0 \qquad [10]$$

(or respectively $\operatorname{curl}\langle \mathrm{i}\psi, \nabla_A \psi\rangle + \operatorname{curl} A - 2\pi \sum_i d_i \delta_{a_i} \to 0$) in some weak functional norm, thus giving a rigorous use of [8]. The quantity

$$\mu(u) = \operatorname{curl}\langle \mathrm{i}u, \nabla u\rangle \qquad [11]$$

or

$$\mu(\psi, A) = \operatorname{curl}\langle \mathrm{i}\psi, \nabla_A \psi\rangle + \operatorname{curl} A = \operatorname{curl} j + h \qquad [12]$$

in the case with magnetic field, will thus be called the vorticity and be used to trace the vortices, in this limit $\varepsilon \to 0$. The relation

$$\mu - 2\pi \sum_i d_i \delta_{a_i} \to 0 \quad \text{as } \varepsilon \to 0 \qquad [13]$$

states that it is close to being a measure.

This is also called the Jacobian determinant if written (with differential forms) $Ju = \mathrm{d}\langle \mathrm{i}u, \mathrm{d}u\rangle = \langle \mathrm{i}\mathrm{d}u, \mathrm{d}u\rangle = 2(u_{x_1} \times u_{x_2})\mathrm{d}x_1 \wedge \mathrm{d}x_2$, and under this form it can be used in higher dimensions.

### The Cost of Each Vortex

Here we investigate informally the cost of a vortex of degree $d$. We know already that the characteristic length scale of variation of $u$ is $\varepsilon$, and that $(1 - |u|^2)^2$ is strongly penalized. Thus, we may expect that $|u|$ is close to 1 at a distance $\gg \varepsilon$ of the zeros. Assuming that $x_0$ is a zero of $u$, and taking formally $|u| = 1$ for $|x - x_0| \geq \varepsilon$, we may write $u = \mathrm{e}^{\mathrm{i}\varphi}$ and $|\nabla u| = |\nabla \varphi|$ for $|x - x_0| \geq \varepsilon$.

Then, we have

$$\begin{aligned} &\frac{1}{2}\int_{R \geq |x - x_0| \geq \varepsilon} |\nabla u|^2 \\ &\geq \frac{1}{2}\int_\varepsilon^R \left(\int_{\partial B(x_0, r)} \left|\frac{\partial \varphi}{\partial \tau}\right|^2\right) \mathrm{d}r \\ &\geq \frac{1}{2}\int_\varepsilon^R \left(\left(\int_{\partial B(x_0, r)} \frac{\partial \varphi}{\partial \tau}\right)^2 \frac{1}{2\pi r}\right) \mathrm{d}r \qquad [14] \\ &\geq \frac{1}{2}\,\frac{4\pi^2 d^2}{2\pi}\int_\varepsilon^R \frac{\mathrm{d}r}{r} = \pi d^2 \log\frac{R}{\varepsilon} \qquad [15] \end{aligned}$$

where we have used the Cauchy–Schwarz inequality for [14], and the characterization of the degree [7]. We may also observe that this lower bound is sharp if $\partial\varphi/\partial\tau$ is constant, that is, if the phase is $d\theta$ (and the vortex radial). The cost associated to $|u|$ in the energy imposes the length scale $\varepsilon$ and is generally of order 1 ($|\nabla u| \leq C/\varepsilon$), thus negligible compared to the cost associated to the phase, which blows up as $\log 1/\varepsilon$ as $\varepsilon \to 0$.

The above estimate is only valid as long as $B(x_0, R)$ does not contain any other zero of $u$. If vortices get close to each other or become numerous, one needs refined techniques to estimate their cost. This can be done through a "ball-construction method" introduced independently by Jerrard and Sandier.

### Evaluating the Total Interaction Cost of Vortices

In a first approach, one studies configurations which satisfy the upper bound $E_\varepsilon(u) \leq C|\log \varepsilon|$. Then, lower bounds of the type [15] show that the total sum of the degrees (hence the total number of vortices of nonzero degree) remains bounded as $\varepsilon \to 0$. Up to extraction, we may assume these zeros $a_i$ converge as $\varepsilon \to 0$ to a finite set of points $p_i$, with a total degree still denoted $d_i$. This can also be expressed as $\mu(u_\varepsilon) \to 2\pi \sum_i d_i \delta_{p_i}$ as $\varepsilon \to 0$.

This is not the only case of interest, since unbounded numbers of vortices do arise, especially in the physical situation of the energy with magnetic field, as we will see in the next section. However, this hypothesis, which was made in the work of Bethuel–Brezis–Hélein, makes the analysis easier and already allows us to exhibit the main phenomena.

Vortices in superconductors are generated by the presence of the external magnetic field $h_{\mathrm{ex}}$. For the energy without magnetic field, this has to be replaced by some boundary condition which forces some degree. Bethuel–Brezis–Hélein considered the fixed Dirichlet boundary condition $u_\varepsilon = g$ on $\partial\Omega$, where $g$ is a fixed unit-valued map on $\partial\Omega$, of degree $d > 0$. This forces $u$ to have a total degree $d$ in $\Omega$. However, the Neumann boundary condition, for instance, can also be considered (the minimizers of $E_\varepsilon$ are then simply constants, they are trivial, but one can still look for other critical points).

Let us return to lower bounds in order to look for the next order term in the energy (still with formal arguments). Cutting out holes $\cup_i B(p_i, \rho)$ of fixed size $\rho$ around the limiting vortices $p_i$, we may assume that $u = \mathrm{e}^{\mathrm{i}\varphi}$ in $\Omega \setminus \cup_i B(p_i, \rho) = \Omega_\rho$, with $\varphi$ a real-valued function, defined modulo $2\pi$. Minimizing the energy outside of the holes amounts to solving

$$\min_{\substack{u:\, \Omega_\rho \to \mathbb{S}^1 \\ u = g \text{ on } \partial\Omega \\ \deg(u, \partial B(p_i, \rho)) = d_i}} \frac{1}{2}\int_{\Omega_\rho} |\nabla u|^2$$

This is a harmonic map problem, whose solution is given in terms of $\varphi$ by

$$\begin{aligned} \Delta\varphi &= 0 \qquad \text{in } \Omega_\rho \\ \frac{\partial\varphi}{\partial\tau} &= \left\langle \mathrm{i}g, \frac{\partial g}{\partial\tau}\right\rangle \quad \text{on } \partial\Omega \\ \int_{\partial B(p_i,\rho)} \frac{\partial\varphi}{\partial\tau} &= 2\pi d_i \end{aligned}$$

and in terms of the harmonic conjugate $\Phi$ which is the function (up to a constant) such that $\nabla\varphi = \nabla^\perp\Phi$,

$$\begin{aligned} \Delta\Phi &= 0 \qquad \text{in } \Omega_\rho \\ \frac{\partial\Phi}{\partial\nu} &= \left\langle \mathrm{i}g, \frac{\partial g}{\partial\tau}\right\rangle \quad \text{on } \partial\Omega \\ \int_{\partial B(p_i,\rho)} \frac{\partial\Phi}{\partial\nu} &= 2\pi d_i \end{aligned} \qquad [16]$$

As $\rho \to 0$, $\Phi$ behaves like the solution of

$$\begin{aligned} \Delta\Phi_0 &= 2\pi\sum_i d_i\delta_{p_i} \quad \text{in } \Omega \\ \frac{\partial\Phi_0}{\partial\nu} &= \left\langle \mathrm{i}g, \frac{\partial g}{\partial\tau}\right\rangle \qquad \text{on } \partial\Omega \end{aligned} \qquad [17]$$

Hence, we have

$$\begin{aligned} \frac{1}{2}\int_{\Omega_\rho} |\nabla\varphi|^2 &= \frac{1}{2}\int_{\Omega_\rho} |\nabla\Phi|^2 \\ &\simeq \frac{1}{2}\int_{\Omega_\rho} |\nabla\Phi_0|^2 \\ &= \pi\sum_i d_i^2\log\frac{1}{\rho} + W_d(p_1,\ldots,p_n) \\ &\quad + o(1) \quad \text{as } \rho\to 0 \end{aligned} \qquad [18]$$

where

$$\begin{aligned} W_d(a_1,\ldots,a_n) = &-\pi\sum_{i\neq j} d_i d_j \log|p_i - p_j| \\ &-\pi\sum_i d_i R(a_i) \\ &+\frac{1}{2}\int_{\partial\Omega}\Phi_0\left(\mathrm{i}g, \frac{\partial g}{\partial\tau}\right) \end{aligned} \qquad [19]$$

and $R(x) = \Phi_0(x) - \sum_i d_i\log|x - p_i|$. The function $W$ was introduced by Bethuel–Brezis–Hélein and called the renormalized energy, since it consists in the part of the energy that is left after subtracting the "infinite part" in $|\log\varepsilon|$ from $E_\varepsilon$. It contains the (logarithmic) interaction energy between the vortices: we see that vortices with degrees of same sign repel one another while vortices with degrees of opposite signs attract one another. The $\pi d_i^2 \log 1/\rho$ term corresponds to the self-interaction, or cost of the vortex of core of size $\rho$; it is what replaces the infinite term in the formal calculation.

Now [18] is a good estimate for the optimal energy outside of the holes, while the energy in holes of size $\rho$ can be bounded below by [15]. Given the degree $d_i$ on the boundary $\partial B(p_i,\rho)$ of the small hole, $B(p_i,\rho)$ contains one or several zeros of $u$ of degrees $\delta_k$ with total degree $\sum_k \delta_k = d_i$. In view of [15], since the cost of a vortex of degree $d$ grows like $\pi d^2|\log\varepsilon|$, and since the infimum of $\sum_k \delta_k^2$ under the constraint $\sum_k \delta_k = d_i$ is $\delta_k = \mathrm{sign}(d_i)$, the least costly way to achieve this is to have $|d_i|$ vortices of degree $\mathrm{sign}(d_i)$. The smallest lower bound possible is thus

$$\frac{1}{2}\int_{B(p_i,\rho)} |\nabla u|^2 + \frac{(1-|u|^2)^2}{2\varepsilon^2} \geq \pi|d_i|\log\frac{\rho}{\varepsilon} + C \qquad [20]$$

where the constant $C$ can be described explicitly. Adding up the results of [20] and [18], we find

$$\begin{aligned} E_\varepsilon(u) \geq\ &\pi\sum_i d_i^2\log\frac{1}{\rho} \\ &+\pi\sum_i |d_i|\log\frac{\rho}{\varepsilon} + W_d(p_1,\ldots,p_n) \\ &+ nC + o_\rho(1) + o_\varepsilon(1) \\ \geq\ &\pi\sum_i |d_i|\log\frac{1}{\varepsilon} + W_d(p_1,\ldots,p_n) \\ &+ nC + o_\varepsilon(1) \end{aligned} \qquad [21]$$

with equality only if $u$ has $|d_i|$ zeros of degree $\mathrm{sign}(d_i)$ in each $B(p_i,\rho)$.

This provides a lower bound of the energy in terms of the vortices. Moreover, this bound is sharp: one can construct test configurations which have the given limiting vortices $(p_i, d_i)$, and an energy equal to the right-hand side of [21].

One can thus deduce the behavior of global minimizers of the energy. Given the total degree $d = \deg(g) > 0$ on $\partial\Omega$, we need $\sum_i d_i = d$, and the lowest value achievable under this constraint in the right-hand side of [21] is to have $d_i = 1$ for every $i$, and thus to have exactly $d$ vortices of degree 1. Moreover, the limiting points $p_i$'s should minimize $W$. We thus are led to the first main result.

**Theorem 1** (Bethuel–Brezis–Hélein). *Minimizers of $E_\varepsilon$ under the boundary condition $u = g$, $\deg(g) = d > 0$, have $d$ zeros of degree 1, which converge as $\varepsilon \to 0$ to a minimizer of $W$.*

This result can be rephrased as a result of $\Gamma$-convergence of $E_\varepsilon - \pi d|\log\varepsilon|$. It reduces the minimization of $E_\varepsilon$ to one of $W$, which is a finite-dimensional problem (interaction of point charges).

Thus, we see again the interest of studying this asymptotic limit $\varepsilon \to 0$ because the vortices become pointlike and the problem reduces to a finite-dimensional one, or one of minimizing the vortex interaction.

#### Further Results

A nonvariational approach also allowed Bethuel–Brezis–Hélein to prove a further correspondence between $E_\varepsilon$ and $W$: they obtained that critical points of $E_\varepsilon$, under the upper bound $E_\varepsilon \le C|\log \varepsilon|$, have vortices which converge to a critical point of $W$. Other important results are the study of the blow-up profiles or solutions in the whole plane, by Brezis–Merle–Rivière and Mironescu.

In two dimensions, the variational approach is also used to solve inverse problems (construct solutions) and study variants of the energy with pinning (or weighted) terms.

The variational approach is also fruitful in higher dimensions. In dimension 3, for example, vortices are not points but vortex lines, and the Jacobian $Ju = d(\mathrm{i}u, \mathrm{d}u)$ can be seen as a current carried by the vortex line, with $\|Ju\|$ total mass of the current equal to $\pi$ times the length of the line, and it was established by Jerrard and Soner that $Ju_\varepsilon$ is compact in some weak sense, and converges, up to extraction, to some $\pi$ times integer-multiplicity rectifiable current $J$, with

$$\liminf_{\varepsilon\to 0} \frac{E_\varepsilon(u_\varepsilon)}{|\log \varepsilon|} \ge \|J\|$$

In fact, a complete $\Gamma$-convergence result of $E_\varepsilon/|\log \varepsilon|$ can be proved, see the work of Alberti–Baldo–Orlandi, and thus minimizing $E_\varepsilon$ reduces at the limit to minimizing the length of the line, leading to straight lines, or in higher dimensions, to codimension-2 minimal currents. This is a nontrivial problem, contrarily to dimension 2, where the $\Gamma$-limit of $E_\varepsilon/|\log \varepsilon|$ is trivial, which required to go to the lower-order term to find the nontrivial renormalized energy limit $W$.

### The Functional with Magnetic Field

The aim here is to achieve the same objective: express or bound from below the energy by terms which depend only on the vortices and their degrees. The method consists in transposing the type of analysis above taking into account the magnetic field contribution to see how the external field triggers the sudden appearance of vortices, and for what values they appear (thus retrieving the critical fields, etc.). One of the main difficulties consists in the fact that the number of vortices becomes divergent, which requires more delicate estimates. Also, it is then no longer possible to study the convergence of the individual zeros of $\psi$, so one studies instead the limit of rescalings of the vorticity measures $\mu(\psi, A)$.

#### Splitting of the Energy and Main Results

Let us recall that in the case with magnetic field, the vorticity is given by [12]. In addition, we may assume that the second set of equations in [5]

$$-\nabla^\perp h = j \ \text{ in } \Omega, \quad h = h_{\mathrm{ex}} \text{ on } \partial\Omega \qquad [22]$$

is satisfied (if not, keeping $\psi$ fixed and choosing $A$ which satisfies this equation always decreases the energy). Taking the curl of this equation, we find exactly

$$\begin{aligned} -\Delta h + h &= \mu(\psi, A) && \text{in } \Omega \\ h &= h_{\mathrm{ex}} && \text{on } \partial\Omega \end{aligned} \qquad [23]$$

Thus, the vorticity and the induced magnetic field are in one-to-one correspondence with each other. Combining it to the relation [13], we are led to the approximate relation

$$\begin{aligned} -\Delta h + h &\simeq 2\pi \sum_i d_i \delta_{a_i} && \text{in } \Omega \\ h &= h_{\mathrm{ex}} && \text{on } \partial\Omega \end{aligned} \qquad [24]$$

where again the $a_i$'s are the vortex centers and $d_i$'s their degrees, well known in physics as the "London equation." It shows how the magnetic field is induced by the vortices which act like "charges," and how the magnetic field "penetrates the sample" around the positive vortex locations. Of course this equation is only an approximation, because the singularities at the $a_i$'s, where $h$ would become infinite, are really smoothed out in $\mu(\psi, A)$; however, the approximation is good far from the vortex cores, just as [17] is an approximation for [16].

It is then natural to introduce the field corresponding to the vortex-free situation, which is $h_{\mathrm{ex}} h_0$ where $h_0$ solves

$$\begin{aligned} -\Delta h_0 + h_0 &= 0 && \text{in } \Omega \\ h_0 &= 1 && \text{on } \partial\Omega \end{aligned} \qquad [25]$$

$h_0$ is thus a fixed smooth function, depending only on $\Omega$, and when there are no vortices, we expect $h$ to be approximately $h_{\mathrm{ex}} h_0$. Moreover, $h' := h - h_{\mathrm{ex}} h_0$ then solves

$$\begin{aligned} -\Delta h' + h' &= \mu(\psi, A) \simeq 2\pi \sum_i d_i \delta_{a_i} && \text{in } \Omega \\ h' &= 0 && \text{on } \partial\Omega \end{aligned} \qquad [26]$$

Defining the Green kernel $G(.,y)$ by

$$\begin{aligned} -\Delta G + G &= \delta_y \quad \text{in } \Omega \\ G &= 0 \quad \text{on } \partial\Omega \end{aligned} \qquad [27]$$

and $S$ by $S(x,y) = 2\pi G(x,y) + \log|x-y|$, for $x$ far enough from the $a_i$'s, we may approximate $h'$ by

$$h'(x) = 2\pi \sum_i G(x, a_i) \qquad [28]$$

Using the second Ginzburg–Landau equation [22] and the fact that $|\psi| \leq 1$, we have $|\nabla_A \psi| \geq |j| = |\nabla h|$, thus $G_\varepsilon(\psi, A) \geq (1/2)\int_\Omega |\nabla h|^2 + |h - h_{\text{ex}}|^2$. Plugging in the decomposition $h = h_{\text{ex}} h_0 + h'$ and using an integration by parts and [26], one finds

$$\begin{aligned} G_\varepsilon(\psi, A) &= \frac{1}{2} h_{\text{ex}}^2 \int_\Omega |\nabla h_0|^2 + |h_0 - 1|^2 \\ &\quad + h_{\text{ex}} \int_\Omega \nabla h_0 \cdot \nabla h' + (h_0 - 1) h' \\ &\quad + \frac{1}{2} \int_\Omega |\nabla h'|^2 + |h'|^2 \\ &= h_{\text{ex}}^2 J_0 + h_{\text{ex}} \int_\Omega (h_0 - 1) \mu(\psi, A) \\ &\quad + \frac{1}{2} \int_\Omega |\nabla h'|^2 + |h'|^2 \end{aligned} \qquad [29]$$

where $J_0$ is the constant $(1/2)\int_\Omega |\nabla h_0|^2 + |h_0 - 1|^2$. The right-hand side of eqn [29] can be expressed in terms of the vortices. First, using [26], we have $\int_\Omega (h_0 - 1)\mu(\psi, A) \simeq 2\pi \sum_i d_i (h_0 - 1)(a_i)$. Second, the expression $\int_\Omega |\nabla h'|^2 + |h'|^2$ can be treated exactly like $E_\varepsilon(u)$ in the previous section, using lower bounds for the cost of vortices provided by the Jerrard–Sandier method, we are led to the (approximate) relation

$$\begin{aligned} \frac{1}{2} \int_\Omega |\nabla h'|^2 + |h'|^2 \geq \pi \sum_i |d_i| \log \frac{1}{\varepsilon} \\ - \pi \sum_{i \neq j} d_i d_j \log |a_i - a_j| \\ + \pi \sum_{i,j} d_i d_j S(a_i, a_j) \end{aligned} \qquad [30]$$

Combining this to [29] we find the decomposition

$$\begin{aligned} G_\varepsilon(\psi, A) \geq h_{\text{ex}}^2 J_0 + \pi \sum_i |d_i| |\log \varepsilon| \\ + 2\pi h_{\text{ex}} \sum_i d_i (h_0 - 1)(a_i) \\ - \pi \sum_{i \neq j} d_i d_j \log |a_i - a_j| \\ + \pi \sum_{i,j} d_i d_j S(a_i, a_j) \end{aligned} \qquad [31]$$

On the other hand, this inequality is sharp: as before, given vortices $a_i$, one can construct a configuration $(\psi, A)$ for which this is an equality, at leading order.

In that relation, $h_{\text{ex}}^2 J_0$ is a fixed energy, the energy of the vortex-free configuration. To it are added the intrinsic cost of each vortex $\pi |d_i| |\log \varepsilon|$, the interaction cost between vortices, and the interaction between the vortices and the external field $2\pi h_{\text{ex}} \sum_i d_i (h_0 - 1)(a_i)$.

It is then simple, by minimizing the right-hand side with respect to the vortices for a given $h_{\text{ex}}$, and observing that $h_0 - 1 \leq 0$, to deduce a few basic facts about vortices: vortices of positive degree (and of degree +1) are preferred, each vortex costs $\pi|\log \varepsilon|$, and allows to gain at best an energy $2\pi h_{\text{ex}} \max |h_0 - 1|$ when placed at the minimum of $h_0 - 1$. Therefore, vortices become favorable when their cost becomes smaller than the gain, that is, when $h_{\text{ex}}$ becomes larger than the "first critical field"

$$H_{c_1} \sim \frac{|\log \varepsilon|}{2|\min(h_0 - 1)|} \qquad [32]$$

We have the first main result.

**Theorem 2** (Sandier–Serfaty). *When $\varepsilon$ is small enough and $h_{\text{ex}} \leq H_{c_1}$, then minimizers of $G_\varepsilon$ have no vortices.*

On the other hand, if $h_{\text{ex}} \geq H_{c_1}$, the vortices cannot all be located at the same minimum point of $h_0 - 1$, because their repulsion $-\pi \sum_{i \neq j} \log |a_i - a_j|$ would be infinite. There is thus a trade-off between their repulsion and the cost for being far from the minimum of $h_0 - 1$. Only if $n$, the number of vortices, is small compared to $h_{\text{ex}}$ do the vortices tend to concentrate near the minimum of $h_0 - 1$. If so, then, assuming for simplicity that the minimum of $h_0 - 1$ is achieved at a unique point $p$, and denoting by $Q$ the Hessian of $h_0 - 1$ at $p$, in the relation above $(h_0 - 1)(a_i)$ can be approximated by $\min(h_0 - 1) + (1/2) Q(a_i - p)$ and thus $G_\varepsilon(\psi, A)$ by

$$\begin{aligned} G_\varepsilon(\psi, A) \sim h_{\text{ex}}^2 J_0 + \pi n |\log \varepsilon| + 2\pi n h_{\text{ex}} \min(h_0 - 1) \\ + \pi h_{\text{ex}} \sum_i Q(a_i - p) \\ - \pi \sum_{i \neq j} d_i d_j \log |a_i - a_j| + \pi n^2 S(p, p) \end{aligned} \qquad [33]$$

From this relation, optimizing on $\ell$, the characteristic distance to $p$ and characteristic distance between the vortices, we find that $\ell = \sqrt{n / h_{\text{ex}}}$ is optimal.

Moreover, optimizing with respect to $n$, we find that $n$ should remain bounded (as $\varepsilon \to 0$) when $h_{\text{ex}} \leq H_{c_1} + O(\log|\log \varepsilon|)$. In that regime, rescaling by setting $x_i = ((a_i - p)/\ell)$, we have the following result:

**Theorem 3** (Sandier–Serfaty). *There exist fields $H_n \sim H_{c_1} + C(n-1)\log|\log\varepsilon|$ such that when $H_n \le h_{ex} < H_{n+1}$, minimizers of $G_\varepsilon$ have n vortices of degree 1, and the rescaled vortices $x_i$'s tend to minimize*:

$$w_n(x_1, \ldots, x_n) = -\pi \sum_{i\neq j} \log|x_i - x_j| + \pi n \sum_{i=1}^{n} Q(x_i) \qquad [34]$$

If $h_{ex} - H_{c_1} \gg \log|\log\varepsilon|$, then the optimal number of vortices $n$ becomes unbounded as $\varepsilon \to 0$. The analysis above still holds, but in order to get a convergence of the vortices, one needs to rescale the vorticity measure by $n$. There is an intermediate regime, for $\log|\log\varepsilon| \ll h_{ex} - H_{c_1} \ll |\log\varepsilon|$ for which $n$ should be $\gg 1$ but still $n \ll h_{ex}$, so $\ell \ll 1$: vortices are numerous, but still concentrate around $p$. Rescaling by the scale $\ell$ as above, we prove that the density of vortices (after dividing it by $n$) converges to a probability measure, minimizer of the energy

$$I(\mu) = -\pi \int_{\mathbb{R}^2\times\mathbb{R}^2} \log|x-y|\, d\mu(x)\, d\mu(y) + \pi \int_{\mathbb{R}^2} Q(x)\, d\mu(x) \qquad [35]$$

This is an averaged/continuous form of [34].

If $h_{ex} - H_{c_1}$ is of order $|\log\varepsilon|$, then the optimal number $n$ becomes of order $h_{ex}$ and the vortices no longer concentrate around a single point.

The simplest approach is then to simply consider the vorticity measure $\mu(\psi, A)$ and to rescale it by the order $n$, hence by $h_{ex}$. Then $(1/h_{ex})\mu(\psi, A)$ converges, after extraction, to some measure $\mu_*$. A continuous version of [31] can thus be written, using [12], as

$$G_\varepsilon(\psi, A) \ge \frac{1}{2} h_{ex}|\log\varepsilon| \int_\Omega |\mu_*| + \frac{1}{2} h_{ex}^2 \int_\Omega |\nabla h_{\mu_*}|^2 + |h_{\mu_*}|^2 \qquad [36]$$

where $h_{\mu_*}$ solves

$$\begin{aligned} -\Delta h_{\mu_*} + h_{\mu_*} &= \mu_* \quad \text{in } \Omega \\ h_{\mu_*} &= 1 \quad \text{on } \partial\Omega \end{aligned}$$

Again, this inequality can be proved to be sharp (by a construction) and allows to show that minimizers of $G_\varepsilon$ have a vorticity $\mu(\psi, A)$ such that $\mu(\psi, A)/h_{ex}$ converges to a minimizer of

$$\mathcal{G}(\mu_*) = \frac{1}{2}\left(\lim_{\varepsilon\to 0} \frac{|\log\varepsilon|}{h_{ex}}\right) \int_\Omega |\mu_*| + \frac{1}{2}\int_\Omega |\nabla h_{\mu_*}|^2 + |h_{\mu_*}|^2$$

In fact the stronger result holds, in that sense:

**Theorem 4** (Sandier–Serfaty). *$G_\varepsilon/h_{ex}^2$ $\Gamma$-converges to $\mathcal{G}$.*

The limit problem of minimizing $\mathcal{G}$ turns out to have a simple solution in terms of an obstacle problem: the optimal $\mu_*$ is a uniform density of vortices on a subdomain of $\Omega$ determined through a free boundary problem (and depending on $h_{ex}$), which is nonzero.

In all these regimes, we have thus been able to identify the optimal number and repartition of vortices through a $\Gamma$-convergence-type approach, that is, by reducing the minimization of the energy to the minimization of a limiting problem: $w_n$ or $I$ or $\mathcal{G}$, according to the regime.

### Further Results

Concerning vortices, in the same spirit as what was done for $E_\varepsilon$, we can obtain necessary conditions characterizing limiting vorticities obtained from sequences of (nonminimizing) critical points of the energy $G_\varepsilon$. They consist in passing to the limit in the conservative form of the Ginzburg–Landau equations [5].

Most of the results concerning the phase transitions at the next critical fields $H_{c_2}$ and $H_{c_3}$ are also obtained by nonvariational methods, and often by linear analysis.

The study of the Ginzburg–Landau energy in non-simply-connected domains is also very interesting because it leads to nontrivial topological effects, since in such domains there exist unit-valued maps with nonzero degree (corresponding to permanent currents).

## Austenite–Martensite Transformations and the Shape Memory Effect

Microstructures in materials that typically form in response to phase transformations in the solid state, and their impact on the elastic properties of these materials have been known for centuries. The discovery of the complex phase diagram of iron revolutionized the production of steels at the end of the nineteenth century. Starting in the 1980s, the mathematical description of microstructures in the framework of nonlinear elasticity has led to deep analytical questions and surprising developments in the calculus of variations and in nonlinear partial differential equations.

The mathematical approach outlined here is based on the following fundamental assumptions:

1. The observed configurations correspond to minimizers of or elements of minimizing sequences for an energy functional.
2. The qualitative properties of low energy states are determined from the set of minima of the free energy density.

Under these assumptions one aims at explaining experimental observations and to predict material properties based on minimizing an energy functional of the form

$$I(u) = \int_\Omega W(Du)\,\mathrm{d}x$$

Here $\Omega$ is an ideal, unstressed reference configuration in $\mathbb{R}^n, u:\Omega\to\mathbb{R}^m$ is an elastic deformation, and $W:\mathbb{M}^{m\times n}\to\mathbb{R}$ is the stored energy density. In the case of physical interest, $m=n=2$ or $m=n=3$. For applications in elasticity we assume that $m=n$, but this assumption is not needed in the general theory. The energy density $W$ and its structure depend critically on the temperature. However, since we are interested in the analysis of the material at a given temperature, we do not include this dependence explicitly.

The key ingredient of this model is the stored energy density $W$ which has to reflect the properties of the specific material one wants to model. Frequently these are alloys, in particular shape memory alloys that undergo an austenite–martensite transformation. For most materials a closed analytic expression for $W$ is not available. In the spirit of the fundamental assumption (2) one therefore focuses on the structure of the set of minima of $W$ which is determined from general invariance and symmetry principles. We may assume that $W\geq 0$ and that $K=\{X: W(X)=0\}\neq\emptyset$. The principle of material frame indifference then asserts that

$$W(RF) = W(F) \quad \text{for all } R\in \mathrm{SO}(n)$$

Here $\mathrm{SO}(n)$ is the group of proper rotations, that is, the set of all matrices $R\in\mathbb{M}^{n\times n}$ with $R^TR=\mathrm{Id}$ and $\det R=1$.

The symmetry of the austenitic (high-temperature) phase implies that the energy density in the martensitic (low-temperature) phase is invariant under all changes of basis that leave the underlying lattice in the austenitic phase invariant. Therefore,

$$W(R^TFR) = W(F) \quad \text{for all } R\in\mathcal{P}_a$$

where $\mathcal{P}_a$ is the point group of the austenite. In the case of a cubic to tetragonal phase transformation, this leads to $K=\mathrm{SO}(3)$ in the austenitic phase and to

$$K = \mathrm{SO}(3)U_1\cup\mathrm{SO}(3)U_2\cup\mathrm{SO}(3)U_3 \qquad [1]$$

with

$$U_i = \eta^2 e_i\otimes e_i + \frac{1}{\eta}(I - e_i\otimes e_i) \qquad [2]$$

in the martensitic phase (see Figure 1). A set of the form $\mathrm{SO}(n)U_i$ is often referred to as an energy well.

The origin of the shape memory effect is the availability of a rich class of geometric patterns in which the martensitic phases can be arranged, thus leading to a great flexibility of the material to accommodate macroscopic deformations. Upon heating of the material above the transformation temperature, the martensitic phases lose their stability and the material returns to its unique shape in the

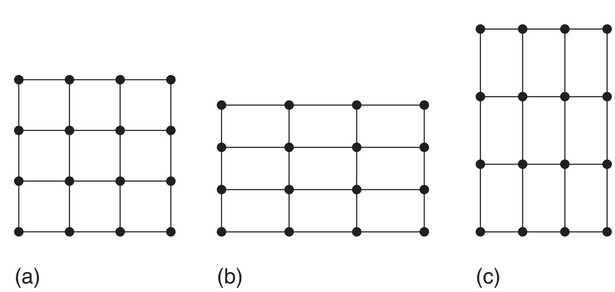

**Figure 1** Two-dimensional cartoon of a cubic to tetragonal phase transformation in a single crystal: (a) a cubic lattice, (b) and (c) tetragonal variants which are stretched in directions $e_1$ and $e_2$, respectively. (Sketch not to scale.)

(a) The upper right half of the lattice deforms into phase I with the constant deformation gradient $U_1$, the lower left half of the lattice deforms into phase II with constant deformation gradient $U_2$. (b) An additional rotation is needed to accomplish a continuous deformation, see formula [3]. (c) A different configuration with a different orientation of the interface. (Sketch not to scale.)

austenitic phase. The two solutions of Hadamard's compatibility condition

$$QU_2 - U_1 = a \otimes b, \quad Q \in SO(3)$$

are given by

$$Q_1 = \frac{1}{\eta^4+1}\begin{pmatrix} 2\eta^2 & \eta^4-1 & 0 \\ 1-\eta^4 & 2\eta^2 & 0 \\ 0 & 0 & \eta^4+1 \end{pmatrix} \qquad [3]$$

and $Q_2 = Q_1^T$ (see Figure 2). The normals (in the reference configuration) are given by $(1, \pm 1, 0)/\sqrt{2}$. It is one of the successes of the theory that it provides an analytical derivation of the normals to the twinning planes.

## The Direct Method in the Calculus of Variations

The mathematical interest in the variational problems described in the previous section lies in the fact that existence of minimizers cannot in general be obtained by a straightforward application of the direct methods in the calculus of variations. This approach is based on the idea to (1) choose a minimizing sequence for the functional $I$, (2) show that this sequence is bounded and precompact, and (3) prove that the functional is lower semicontinuous with respect to the notion of convergence,

$$I(u) \le \liminf_{j\to\infty} I(u_j) \quad \text{if } u_j \to u$$

The typical choice is to seek $u_j$ in a suitable Sobolev space $W^{1,p}(\Omega;\mathbb{R}^m)$ with $1 < p \le \infty$ which is related to growth and coercivity conditions for the energy density $W$,

$$c_1|F|^p - c_2 \le W(F) \le c_3\left(|F|^p + 1\right) \quad \text{for all } F \in \mathbb{M}^{m\times n} \qquad [4]$$

This leads to weak compactness in $W^{1,p}(\Omega;\mathbb{R}^m)$ (weak-$*$ compactness in $W^{1,\infty}(\Omega;\mathbb{R}^m)$) and to the requirement of sequential weak lower semicontinuity of the functional,

$$I(u) \le \liminf_{j\to\infty} I(u_j) \quad \text{if } u_j \rightharpoonup u \text{ in } W^{1,p}(\Omega;\mathbb{R}^m)$$

(sequential weak-$*$ lower semicontinuity for $p=\infty$). Morrey's fundamental work establishes a link between convexity conditions for the energy density and lower semicontinuity of the variational integral: under suitable growth and coercivity conditions, sequential weak-$*$ lower semicontinuity is equivalent to quasiconvexity of the integrand.

**Definition 1** A function $W : \mathbb{M}^{m\times n} \to \mathbb{R}$ is said to be quasiconvex at $F$ if

$$\int_\Omega W(F)\mathrm{d}x \le \int_\Omega W(F + D\phi)\mathrm{d}x \quad \text{for all } \phi \in W_0^{1,\infty}(\Omega;\mathbb{R}^m)$$

and for all open and bounded domains $\Omega \subset \mathbb{R}^n$ with $\mathcal{L}^n(\partial\Omega) = 0$. It is said to be quasiconvex if it is quasiconvex at all $F$.

In the language of nonlinear elasticity, $W$ is quasiconvex if affine functions are minimizers of the energy functional subject to their own boundary conditions. The direct method implies the following classical existence theorem.

**Theorem 1** *Suppose that* $W : \mathbb{M}^{m\times n} \to \mathbb{R}$ *is quasiconvex and satisfies the growth and coercivity condition* [4]. *Let* $u_0 \in W^{1,p}(\Omega;\mathbb{R}^m)$. *Then the variational problem: minimize* $I(u)$ *in*

$$\mathcal{A} = \left\{u \in W^{1,p}(\Omega;\mathbb{R}^m) : \ u - u_0 \in W_0^{1,p}(\Omega;\mathbb{R}^m)\right\}$$

*has a minimizer.*

The remarkable fact is that the structure of the zero set of a typical energy $W$ modeling a phase-transforming material in its low-temperature phase prevents $W$ from being quasiconvex. In order to see this, let $Q \subset \mathbb{R}^3$ be a cube with two of its sides perpendicular to $b = (1,1,0)/\sqrt{(2)}$ and let $h$ be the 1-periodic function with $h' = 0$ on $(0,\lambda)$ and $h' = 1$ on $(\lambda, 1)$ with $\lambda \in (0,1)$. Define $v_j(x) = U_1x + ah(jx\cdot b)/j$ and

$$\begin{aligned} u_j(x) &= \min\{v_j(x), \operatorname{dist}(x,\partial Q)\} \\ &= \min\{U_1x + ah(jx\cdot b)/j, \operatorname{dist}(x,\partial Q)\} \end{aligned}$$

where $\operatorname{dist}(x,\partial Q) = \inf\{\|x-y\|_\infty, y \in \partial Q\}$. Then $u_j \to u$, $u(x) = Cx$ strongly in $L^\infty(Q;\mathbb{R}^3)$ and weakly-$*$ in $W^{1,\infty}(Q;\mathbb{R}^3)$ with $C = \lambda U_1 + (1-\lambda)Q_1U_2 \notin K$ where $K$ is the zero set of $W$, see the previous section.

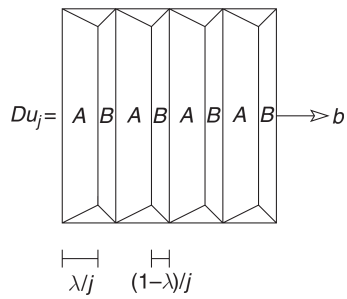

**Figure 3** Construction of a minimizing sequence $u_j$ with $Du_j \to \{A, B\}$ in measure and affine boundary conditions $u(x) = \lambda A + (1-\lambda)B$ Hadamard's compatibility condition requires that $A - B = a \otimes b$ is a rank-1 matrix and that the planar interfaces are perpendicular to $b$.

Moreover, $Du_j \in \{U_1, Q_1 U_2\}$ except in a small transition layer of volume $\mathcal{O}(1/j)$ close to $\partial Q$ and

$$I(u) = \int_\Omega W(C)\mathrm{d}x > \liminf_{j\to\infty} I(u_j) = 0$$

This inequality shows that the functional is not weakly-$*$ lower semicontinuous and therefore $W$ fails to be quasiconvex. The oscillations of $u_j$ on a scale $1/j$ are part of the mathematical model for the microstructures frequently observed in shape memory alloys. More generally, whenever $u$ is a Sobolev function on a domain $\Omega$ such that $Du$ takes only two values, say $Du \in \{A, B\}$, on open sets which are not empty and whose union is $\Omega$ (up to a set of measure zero), then the tangential continuity of the derivatives implies that the difference $A - B$ is a matrix of rank 1, $A - B = a \otimes b$, and that the interfaces between the regions with $Du = A$ and $Du = B$ are hyperplanes with normal parallel to $b$. This statement is usually referred to as "Hadamard's compatibility condition." Moreover, the pattern in Figure 3 is known as a "simple laminate" and the matrices $A$ and $B$ are said to be rank-1 connected.

## Relaxation

The discussion in the previous section shows that the variational problems related to models in materials science typically fail to be weakly lower semicontinuous. One approach which allows us to recover the macroscopic energy of the system and the macroscopic stress–strain relation is to pass to the relaxed variational problem which involves the quasiconvex envelope of the energy density $W$.

**Definition 2** Let $W : \mathbb{M}^{m\times n} \to \mathbb{R}$ be given. The function

$$W^{\mathrm{qc}} = \sup\{f : f \le W, f \text{ quasiconvex}\}$$

is called the quasiconvex envelope of $W$. Equivalently,

$$W^{\mathrm{qc}}(F) = \inf_{\phi \in W_0^{1,\infty}(\Omega;\mathbb{R}^m)} \frac{1}{|\Omega|}\int_\Omega W(F + D\phi)\mathrm{d}x$$

This formula implies that $W^{\mathrm{qc}}$ is the macroscopic energy of the system in the sense that it characterizes the smallest energy per unit volume that is required to subject a volume element to a deformation with affine boundary conditions. Here the system is allowed to minimize its energy with microstructures at any scale, a mechanism which was already explored in the previous section. The arguments in this section prove that $W^{\mathrm{qc}}(C) = 0$ and this shows that the zero set of $W^{\mathrm{qc}}$ can be strictly larger than the zero set of $K$, see Definition 4. The relaxed functional is given by

$$I^{\mathrm{qc}}(u) = \int_\Omega W^{\mathrm{qc}}(Du)\mathrm{d}x$$

Since $W^{\mathrm{qc}}$ satisfies the growth and coercivity conditions [4] if they are satisfied by $W$, the functional $I^{\mathrm{qc}}$ attains its minimum subject to given boundary conditions. The functional $I^{\mathrm{qc}}$ is the weakly lower semicontinuous envelope of $I$ in the sense that minimizing sequences for $I$ contain subsequences that converge to minimizers of $I^{\mathrm{qc}}$ and for all $u$ there exists a sequence $u_j$ which converges in $W^{1,p}(\Omega;\mathbb{R}^m)$ to $u$ such that the energies converge, $I(u_j) \to I(u)$. However, a lot of information in particular about oscillation patterns might be lost in the passage from $I$ to $I^{\mathrm{qc}}$ since the knowledge of a minimizer $u$ for $I^{\mathrm{qc}}$ does not provide any immediate information about the behavior of any minimizing sequence for $I$ that converges to $u$. Moreover, the minimization problem required in the definition of the relaxed energy has been solved explicitly only for very special energy densities.

In this context, one often relies on two related notions of convexity, one sufficient and the other necessary for quasiconvexity. For $F \in \mathbb{M}^{m\times n}$ let $M(F) \in \mathbb{R}^{d(m,n)}$ be the vector of all minors (subdeterminants) of $F$. In the special case $m = n = 2$ we have $M(F) = (F, \det F) \in \mathbb{R}^5$ and for $m = n = 3$ we find $M(F) = (F, \operatorname{cof} F, \det F) \in \mathbb{R}^{19}$ where cof $F$ is the $3 \times 3$ matrix of all $2 \times 2$ subdeterminants of $F$.

**Definition 3** Let $W : \mathbb{M}^{m\times n} \to \mathbb{R}$ be given. The function $W$ is said to be polyconvex if there exists a convex function $g : \mathbb{R}^{d(m,n)} \to \mathbb{R}$ such that $W(F) = g(M(F))$. The function $W$ is rank-1 convex if it is convex along all rank-1 lines in $\mathbb{M}^{m\times n}$, that is, the function $t \mapsto W(F + tR)$ is convex for all $F \in \mathbb{M}^{m\times n}$ and all $R \in \mathbb{M}^{m\times n}$ with $\mathrm{rank}(R) = 1$.

All notions of convexity reduce to classical convexity if $m=1$ or $n=1$. In the vector-valued case $m,n>1$ the following implications are true:

$$f \text{ convex} \Rightarrow f \text{ polyconvex} \Rightarrow f \text{ quasiconvex} \Rightarrow f \text{ rank-1 convex}$$

The reverse statements for the first two implications are not true. Rank-1 convexity does not imply quasiconvexity for $m \geq 3$ and it is a fundamental open problem with deep connections to harmonic analysis to decide whether rank-1 convexity and quasiconvexity are equivalent for $m=n=2$.

The polyconvex and the rank-1 convex envelope of an energy density $W$ are defined analogously to Definition 2. In view of the implications between the different notions of convexity, one has $W^{\mathrm{pc}} \leq W^{\mathrm{qc}} \leq W^{\mathrm{rc}}$ and essentially all explicitly known relaxation formulas are based on the approach to construct a candidate $W^*$ for $W^{\mathrm{rc}}$ and to verify that $W^*$ is polyconvex. Then the inequalities become equalities and one obtains a characterization for the relaxed energy. This approach does not work for extended-valued functions which are used in models for incompressible materials since quasiconvexity does not imply rank-1 convexity in this case. However, for a model system of particular interest, nematic elastomers, a complete characterization of the relaxed energy, the macroscopic stress–strain relation, and the macroscopic phase diagram have been obtained.

## Classical and Generalized Minimizers

The discussion of observed configurations as elements of minimizing sequences $\{u_j\}$ in the section "The direct method in the calculus of variations" leaves the question of the existence of minimizers open. The answer cannot be obtained via the direct methods since minimizing sequences do not need to converge strongly to minimizers. One approach to obtain the existence of solutions $u$ with $I(u)=0$ is to solve the differential relation $Du \in K, u(x)=Fx$ on $\partial\Omega$ by constructing special minimizing sequences that converge strongly so that one can pass to the limit in the energy integral. This idea has led to surprising solutions $u$ with affine boundary conditions for the two-well problem where $K=\mathrm{SO}(2)\mathrm{diag}(\eta,1/\eta) \cup \mathrm{SO}(2)\mathrm{diag}(1/\eta,\eta)$. However, the structure of the solutions is intrinsically complicated in the sense that the phase boundary has infinite length unless the boundary conditions are given by $u(x)=Fx$ with $F \in K$.

More generally, the right tool to pass to the limit in nonlinear functions of $z_j=Du_j$ like the energy is the "Young measure" generated by a subsequence. It is given by a family of probability measures $\nu_x$ that provide statistical information about the distribution of the values of $z_j$ close to a given point $x$. The existence and the fundamental properties of Young measures are described in the following theorem. For simplicity we assume that the sequence $z_j$ is uniformly bounded.

**Theorem 2** (Fundamental theorem on Young measures). *Let $E \subset \mathbb{R}^n$ be measurable, $\mathcal{L}^n(E) < \infty$, and let $z_j : E \to \mathbb{R}^d$ be a measurable and bounded sequence. Then there exists a subsequence $z_k$ and a weakly-$*$ measurable map $\nu : E \to \mathcal{M}(\mathbb{R}^d)$ such that the following assertions are true:*

(i) *The measures $\nu_x$ are non-negative probability measures.*
(ii) *If there exists a compact set $K$ such that $u_k \to K$ in measure, then $\operatorname{supp}\nu_x \subset K$ for a.e. $x \in E$.*
(iii) *If $f \in C(\mathbb{R}^d)$ and if $f(z_k)$ is relatively weakly compact in $L^1(E)$, then $f(z_k) \rightharpoonup \overline{f}$ in $L^1(E)$ where $\overline{f}(x) = \langle \nu_x, f \rangle$.*

Here $\langle \nu_x, f \rangle$ denotes the integration of the function $f$ with respect to the measure $\nu_x$. For example, the Young measure generated by the sequence $Du_j$ constructed in the section "The direct method in the calculus of variations" generates the Young measure $\nu_x = (1/2)\delta_A + (1/2)\delta_B$ (see Figure 3) and

$$I(u_j) = \int_\Omega W(Du_j)\,\mathrm{d}x \to \int_\Omega \int_{\mathbb{M}^{m\times n}} W(Y)\,\mathrm{d}\nu_x(Y)\,\mathrm{d}x = 0$$

A Young measure generated by a sequence of gradients is called a gradient Young measure (GYM). It is said to be homogeneous if $\nu_x = \nu$ is independent of $x$. We restrict our attention in the following to homogeneous GYMs generated by sequences that are bounded in $L^\infty$. The importance of quasiconvexity is also reflected in the following characterization of homogeneous GYMs.

**Theorem 3** *A non-negative probability measure $\nu$ is a GYM if and only if there exists a compact set $K \subset \mathbb{M}^{m\times n}$ with $\operatorname{supp}\nu \subset K$ and Jensen's inequality $\langle \nu, f \rangle \geq f(\langle \nu, \mathrm{id} \rangle)$ holds for all quasiconvex functions $f : \mathbb{M}^{m\times n} \to \mathbb{R}$.*

This motivates to characterize the generalized limits of minimizing sequences as

$$\mathcal{M}^{\mathrm{qc}}(K) = \{\nu \in \mathcal{M}(K) :\ f(\langle \nu, \mathrm{id}\rangle) \leq \langle \nu, f \rangle \text{ for all } f : \mathbb{M}^{m\times n} \to \mathbb{R} \text{ quasiconvex}\}$$

where $\mathcal{M}(K)$ is the set of all probability measures supported on $K$. If $\nu$ is generated by a sequence of

functions with affine boundary conditions $u_j(x) = Fx$, then $\langle \nu, \mathrm{id} \rangle = F$. The set of all affine deformations of the material that can be recovered by heating (shape memory effect) is therefore given as the set of all centers of mass of homogeneous GYMs supported on $K$, the so-called "quasiconvex hull" $K^{\mathrm{qc}}$ of $K$.

**Definition 4** Suppose that $K \subset \mathbb{M}^{m\times n}$ is compact. We define the quasiconvex hull of $K$ by

$$K^{\mathrm{qc}} = \{F = \langle \nu, \mathrm{id} \rangle : \ \nu \in \mathcal{M}^{\mathrm{qc}}(K)\}$$

There are several equivalent definitions of $K^{\mathrm{qc}}$. The foregoing definition corresponds to the definition of the convex hull of a set as the set of all centers of mass of probability measures supported on $K$ (which satisfy Jensen's inequality for all convex $f$). The set $K^{\mathrm{qc}}$ can also be defined as the set of all points that cannot be separated by quasiconvex functions from $K$ or as the zero set of the quasiconvex envelope of the distance function to $K$. The "polyconvex hull" $K^{\mathrm{pc}}$ and the "rank-1 convex hull" $K^{\mathrm{rc}}$ are defined analogously by replacing quasiconvexity with polyconvexity and rank-1 convexity in the foregoing definitions. It follows that $K^{\mathrm{rc}} \subset K^{\mathrm{qc}} \subset K^{\mathrm{pc}}$ and all of these inclusions can be strict.

A particularly useful set of conditions are the minors conditions

$$\langle \nu, M \rangle = M(\langle \nu, \mathrm{id} \rangle)$$

for all minors $M$ which follow from the weak continuity of the minors. For example, if $K = \{A, B\} \subset \mathbb{M}^{2\times 2}$, then any probability measure supported on $K$ is given by $\nu = \lambda\delta_A + (1-\lambda)\delta_B$. The minors condition with $M = \det$ implies that

$$\begin{aligned}\det(\lambda A + (1-\lambda)B) &= \det\langle \nu, \mathrm{id} \rangle = \langle \nu, \det \rangle \\ &= \lambda \det A + (1-\lambda)\det B\end{aligned}$$

This identity is equivalent to

$$\lambda(1-\lambda)\det(A-B) = 0$$

and therefore the quasiconvex hull is equal to $K$ if and only if $\det(A-B) \neq 0$. A very instructive example is the set $K = \{(1,3), (-1,-3), (-3,1), (3,-1)\}$ viewed as a subset of the space of all diagonal matrices in $\mathbb{M}^{2\times 2}$. It is frequently referred to as a $T_4$ configuration. The rank-1 convex hull is equal to the quasiconvex hull and given by the four points, the line segments, and the square in the center, the polyconvex hull is bounded by four hyperbolic arcs, and the convex hull is the square with the points as corners, see Figure 4. It is remarkable that the rank-1 convex hull is strictly larger than the set $K$ itself despite the fact that the set $K$ does not contain any rank-1 connections.

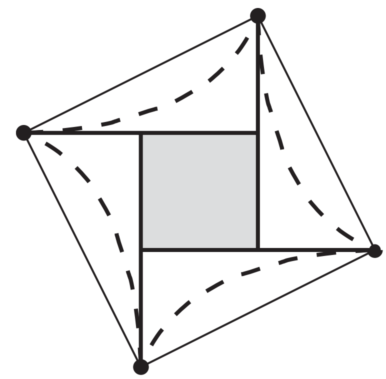

**Figure 4** The four-point subset $K$ in the space of all diagonal matrices and its convex hulls: $K^{\mathrm{rc}} = K^{\mathrm{qc}}$ are given by $K$, the line segments and the shade square, $K^{\mathrm{pc}}$ is bounded by the dashed hyperbolic arcs, and the convex hull is the outer square.

There are only a few examples in which explicit characterizations of the convex hulls for sets invariant under $SO(n)$ have been obtained. For $K = SO(3)U_1 \cup SO(3)U_2$ (see [2]), one finds

$$K^{\mathrm{qc}} = \left\{ F \in \mathbb{M}^{3\times 3} : F^T F = \begin{pmatrix} a & c & 0 \\ c & b & 0 \\ 0 & 0 & 1/\eta^2 \end{pmatrix}, \right.$$

$$\left. ab - c^2 = \eta^2, \ a + b + 2|c| \leq \eta^4 + \frac{1}{\eta^2} \right\}$$

The quasiconvex hull of the three-well problem [1] is not known. In two dimensions one finds for

$$\begin{aligned}&K = SO(2)U_1 \cup \cdots \cup SO(2)U_n, \\ &\det U_i = 1, \ i = 1, \ldots, n\end{aligned}$$

that

$$K^{\mathrm{qc}} = \left\{ F \in \mathbb{M}^{2\times 2} : \ \det F = 1, |Fe|^2 \leq \max_{i=1,\ldots,n} |U_i e|^2 \right\}$$

All examples in which envelopes of functions or hulls of sets have been obtained explicitly are based on the exceptional property that the polyconvex envelope coincides with the rank-1 convex envelope. The $T_4$ configuration in Figure 4 is one of the few cases where the quasiconvex hull is known to be different from the polyconvex hull. The construction of quasiconvex functions and the understanding of their properties is one of the challenges left for the future.

## Bibliographical Remarks

This article can only review some of the highlights of mathematical developments related to models in

nonlinear elasticity for solid–solid phase transformations based on a huge body of work in the original literature. The precise references can be found in the extensive bibliographies of the books and review articles that are cited in the subsequent section, in particular in Ball (2004), Bhattacharya (2003), Dolzmann (2003), James and Hane (2000), and Müller (1999). This article focuses on models for single crystals; the behavior of polycrystals (which strongly depends on the amount of symmetry breaking in the transformation) was studied by Bhattacharya and Kohn.

The formulation of solid–solid phase transformations via nonlinear continuum theory goes back to Ericksen and the analysis via tools in the calculus of variations was initiated by Ball and James, Chipot and Kinderlehrer, and Fonseca. The Russian school developed the theory in linear elasticity in the 1960s, see Khachaturyan (1983) for a review. A detailed discussion of the crystallographic and group-theoretical aspects is contained in Pitteri and Zanzotto (2002).

Quasiconvexity was introduced by Morrey (1966) and his results were extended to Carathéodory integrands by Acerbi and Fusco and Marcellini. A modern treatment including Dacorogna's relaxation theorem and a summary of the various notions of convexity and their properties can be found in Dacorogna (1989). Šverák proved that rank-1 convexity does not imply quasiconvexity for $m \geq 3$ and Milton modified his example to show that the rank-1 convex hull of a set can be strictly smaller than its quasiconvex hull. The explicit characterizations for nematic elastomers were obtained by DeSimone and Dolzmann.

Lipschitz solutions to differential inclusions were constructed by Müller and Šverák based on Gromov's concept of convex integration, by Dacorogna and Marcellini using Baire's category argument, and by Kirchheim in the framework of Banach Mazur games. The structure of solutions of the two-well problem with finite surface energy was analyzed by Dolzmann and Müller. Young measures (also called parametrized measures or chattering controls) were originally introduced as generalized solutions for optimal control problems which do not admit classical solutions (Young 1969). Tartar (1979) introduced Young measures as a fundamental tool for the analysis of oscillation effects in partial differential equations and for the passage from microscopic to macroscopic models. Gradient Young measures were characterized by Kinderlehrer and Pedregal. The four-point configuration was discovered independently in various contexts by several authors including Scheffer, Aumann and Hart, Casadio Tarabusi, Tartar, and Milton and Nesi. The characterization of the quasiconvex hull uses a quasiconvex function constructed by Šverák. The quasiconvex hull of the two-well problem in 3D was found by Ball and James, and the generalization to $n$ wells in 2D by Bhattacharya and Dolzmann.

## Introduction

The Navier–Stokes equations

$$\rho(u_t + u \cdot \nabla u) = -\nabla p + \mu \Delta u + f \qquad [1]$$

$$\nabla \cdot u = 0 \qquad [2]$$

provide the simplest model for the motion of a viscous incompressible fluid that is consistent with the principles of mass and momentum conservation, and with Stokes' hypothesis that the internal forces due to viscosity must be invariant with respect to any superimposed rigid motion of the reference frame. Despite their simplicity, they seem to govern the motion of air, water, and many other fluids very accurately over a wide range of conditions. Thus, their mathematical theory is central to the rigorous analysis of many experimental observations, from the asymptotics of steady wakes and jets, to the dynamics of convection cells, vortex shedding, and turbulence. During the last 80 years, a great deal of progress has been made on both the basic mathematical theory of the equations and on its application to the understanding of such phenomena. But one of the most important matters, that of estimating the regularity of solutions over long periods of time, remains a vexing and fascinating challenge. Such an estimate will almost certainly be needed to prove the "global" existence of smooth solutions. By that we mean the existence of smooth solutions of the initial-value problem over indefinitely long periods of time without any restriction on the "size" of the data. To date we can prove the "local" existence of smooth solutions, but there remains a concern that if the data are large, solutions may develop singularities within a finite period of time. In fact, there is a great deal more at issue than this question of existence. A regularity estimate is required to prove the reliability of the equations as a predictive model. That is because any estimate for the continuous dependence of solutions on the prescribed data for a problem depends upon a regularity estimate, as do error estimates for numerical approximations. A global estimate for the regularity of solutions is also required for a mathematically rigorous theory of turbulence. In fact, it may be hoped that the insight which ultimately yields a global regularity estimate will also be pivotal to our understanding of turbulence, perhaps justifying Kolmogorff theory; see Heywood (2003). In this article we aim to present a relatively simple approach to the local existence, uniqueness, and regularity theory for the initial boundary value problem for the Navier–Stokes equations, and to discuss some observations that bear on the question of global regularity. A wider-ranging review of open problems is given in Heywood (1990), and further observations concerning the problem of global regularity are given in Heywood (1994).

## Setting the Problem

To focus on core issues, we shall make some simplifying assumptions. The fluid under consideration will be assumed to completely fill (without free boundaries or vacuums) a bounded, connected, time-independent domain $\Omega \subset R^n, n = 2$ or 3, with smooth boundary $\partial\Omega$. We are mainly interested in the three-dimensional case, but comparisons with the two-dimensional case are illuminating. The $R^n$-valued velocity $u(x,t) = (u_1(x,t), \ldots, u_n(x,t))$ and $R$-valued pressure $p(x,t)$ are functions of the position $x = (x_1, \ldots, x_n) \in \Omega$ and time $t \geq 0$. Equation [1] is an expression of Newton's second law of motion, equating mass density times acceleration on the left with several force densities on the right, due to pressure and viscosity, and sometimes a prescribed external force $f$. Written in full, using the summation convention over repeated indices, its $i$th component is

$$\rho\left(\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j}\right) = -\frac{\partial p}{\partial x_i} + \mu \frac{\partial^2 u_i}{\partial x_j^2} + f_i$$

We will assume the density $\rho$ and the coefficient of viscosity $\mu$ are positive constants.

In this article, we consider the initial boundary value problem consisting of the equations [1], [2] together with the initial and boundary conditions

$$u|_{t=0} = u_0, \qquad u|_{\partial\Omega} = 0 \qquad [3]$$

The initial velocity $u_0(x)$ is prescribed. It will be assumed to possess whatever smoothness is convenient, and to satisfy $\nabla \cdot u_0 = 0$ and $u_0|_{\partial\Omega} = 0$. The boundary condition is a reasonable one, since fluids adhere to rigid surfaces.

Notice that a further condition would be needed to uniquely determine the pressure, since only its derivatives appear in the problem as posed. We prefer to do without auxiliary conditions for the pressure, and to refer to $u$ by itself as a solution of

the problem provided there exists a scalar function $p$ which together with $u$ satisfies [1]–[3]. The problem is said to be uniquely solvable if there is a unique solution $u$, in which case the gradient of the pressure is also uniquely determined, along with the pressure up to a constant. Notice also that under our assumptions a potential force like gravity has no effect on $u$. If $u$ solves the problem in the absence of such a force, then the inclusion of the force affects only the pressure, from which the potential must be subtracted. It turns out that the inclusion of a prescribed nonpotential force, while complicating many of the estimates below, does not affect in any essential way those parts of the theory to be presented here. Thus, for simplicity, we shall henceforth assume that $f \equiv 0$.

## Reynolds Number

We can make a slight further simplification of eqn [1] by rescaling, with the objective of setting $\rho = 1$, or even $\rho = 1$ and $\mu = 1$. This scaling is not required for the existence theory we are presenting, but provides an important insight for the study of stability, bifurcation, and turbulence. The Reynolds number

$$R = \frac{\max|u| \cdot |\Omega| \cdot \rho}{\mu}$$

plays an important role in rescaling. It expresses the ratio of the inertial to viscous effects. The notation $|\Omega|$ represents a characteristic length, such as the minimum diameter of a bounded domain. Generally speaking, a high Reynolds number corresponds to what is meant by "large" data, and the higher the Reynolds number the more inclined a flow is to instability and turbulence, and perhaps to the development of singularities. However, the size of the Reynolds number has precise implications only in comparing "dynamically similar" flows. We say that two vector fields $v(x,t)$ and $u(x,t)$ are dynamically similar if and only if $v(x,t) = \alpha u(x/\beta, t/\gamma)$ for some $\alpha, \beta, \gamma > 0$. In such a case, if $u$ is defined in $\Omega \times [0, T)$, then $v$ will be defined in $\beta\Omega \times [0, \gamma T)$, where $\beta\Omega = \{\beta x \colon x \in \Omega\}$. Furthermore, if $u$ satisfies the Navier–Stokes equations, then $v$ will satisfy

$$\begin{aligned} &\rho\alpha^{-1}\gamma v_t + \rho\alpha^{-2}\beta v \cdot \nabla v \\ &\quad = -\beta\nabla p(x/\beta, t/\gamma) + \alpha^{-1}\beta^2\mu\Delta v \end{aligned} \quad [4]$$

which has the form of the Navier–Stokes equations if and only if the coefficients of the two inertial terms on the left-hand side are equal. That is, if and only if

$$\alpha\gamma = \beta \quad [5]$$

in which case

$$v_t + v \cdot \nabla v = -\nabla q + \eta\Delta v \quad [6]$$

with

$$\eta = \alpha\beta\mu/\rho \quad [7]$$

and $q(x,t) = \alpha^2\rho^{-1}p(x/\beta, t/\gamma)$. We refer to such $u$ and $v$ as dynamically similar flows. The relation [7], that follows from [5], is equivalent to the equality of the Reynolds numbers for the two flows,

$$\begin{aligned} R(u) &= \frac{\max|u| \cdot |\Omega| \cdot \rho}{\mu} \\ &= \frac{\max|\alpha u| \cdot |\beta\Omega| \cdot 1}{\eta} = R(v) \end{aligned}$$

The condition [5] can be satisfied simultaneously with the condition $\eta = 1$. For example, one may choose $\beta = 1, \alpha = \rho/\mu$, and $\gamma = \mu/\rho$. This achieves a rescaling of the equation to

$$v_t + v \cdot \nabla v = -\nabla q + \Delta v \quad [8]$$

without changing the domain. Different Reynolds numbers result from varying the magnitude of the velocity. In what follows, we will work with the Navier–Stokes equation in this simplest possible form.

## Continuous Dependence on the Data

We begin our investigation of the initial boundary value problem

$$\begin{aligned} &u_t + u \cdot \nabla u = -\nabla p + \Delta u, \quad \nabla \cdot u = 0 \\ &\text{for } (x,t) \in \Omega \times (0, \infty), \\ &u|_{t=0} = u_0, \quad u|_{\partial\Omega} = 0 \end{aligned} \quad [9]$$

by considering two smooth solutions, say $u$ and $v$, taking possibly different initial values $u_0$ and $v_0$. Let their difference be $w = v - u$, with initial value $w_0$, and let $q$ be the difference of the corresponding pressures. Then, subtracting one equation from the other, one obtains

$$w_t + w \cdot \nabla w + u \cdot \nabla w + w \cdot \nabla u = -\nabla q + \Delta w \quad [10]$$

Multiplying this by $w$, integrating over $\Omega$, and integrating by parts, one then obtains

$$\frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\|w\|^2 + \|\nabla w\|^2 = -(w \cdot \nabla u, w) \quad [11]$$

where

$$\|w\|^2 = \int_\Omega w^2\,\mathrm{d}x$$
$$\|\nabla w\|^2 = \int_\Omega \frac{\partial w_i}{\partial x_j}\frac{\partial w_i}{\partial x_j}\,\mathrm{d}x$$
$$(w\cdot\nabla u, w) = \int_\Omega w_j \frac{\partial u_i}{\partial x_j} w_i\,\mathrm{d}x$$

since (and this should further explain our notation)

$$\begin{aligned}(w_t, w) &= \int_\Omega w_t\cdot w\,\mathrm{d}x\\ &= \frac{1}{2}\frac{d}{dt}\int_\Omega w^2\,\mathrm{d}x = \frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\|w\|^2\\ (\Delta w, w) &= \int_\Omega \frac{\partial^2 w_i}{\partial x_j^2} w_i\,\mathrm{d}x\\ &= -\int_\Omega \frac{\partial w_i}{\partial x_j}\frac{\partial w_i}{\partial x_j}\,\mathrm{d}x = -\|\nabla w\|^2\\ (\nabla q, w) &= \int_\Omega \frac{\partial q}{\partial x_i} w_i\,\mathrm{d}x = -\int_\Omega q\frac{\partial w_i}{\partial x_i}\,\mathrm{d}x = 0\\ (u\cdot\nabla w, w) &= \int_\Omega u_j\frac{\partial w_i}{\partial x_j} w_i\,\mathrm{d}x\\ &= -\frac{1}{2}\int_\Omega \frac{\partial u_j}{\partial x_j} w_i w_i\,\mathrm{d}x = 0\end{aligned}$$

and similarly $(w\cdot\nabla w, w)=0$. In deriving these we have used the fact that the vector fields are divergence free and vanish on the boundary. In the following, we will use such identities without further mention.

We can estimate the nonlinear term on the right-hand side of [11] by using the "Sobolev inequalities"

$$\begin{aligned}\|\phi\|_4^2 &\le \|\phi\|\|\nabla\phi\|, &&\text{if } n=2\\ \|\phi\|_4^2 &\le \|\phi\|^{1/2}\|\nabla\phi\|^{3/2}, &&\text{if } n=3\end{aligned} \qquad [12]$$

proved by Ladyzhenskaya (1969), though with larger constants. These are valid for any smooth function $\phi$ which vanishes on the boundary of $\Omega$. It may be either scalar or vector valued. The norms on the left are $L^4$-norms; we use the notation $\|\phi\|_p = (\int_\Omega|\phi|^p\,\mathrm{d}x)^{1/p}$ for any $p>1$, but usually drop the subscript when $p=2$. Using first Hölder's inequality and then [12], one obtains

$$|(w\cdot\nabla u, w)| \le \|w\|_4^2\|\nabla u\| \le \begin{cases}\|w\|\|\nabla w\|\|\nabla u\| & \text{if } n=2\\ \|w\|^{1/2}\|\nabla w\|^{3/2}\|\nabla u\| & \text{if } n=3\end{cases}$$

Young's inequality

$$ab \le \frac{1}{p}a^p + \frac{1}{q}b^q$$

holds if $a,b>0, p,q>1$ and $1/p+1/q=1$. Taking $a=\sqrt{2}\|\nabla w\|$, along with $p=q=2$ in the two-dimensional case, and $a=(4/3)^{3/4}\|\nabla w\|$, along with $p=4/3$, $q=4$ in the three-dimensional case, one obtains

$$|(w\cdot\nabla u, w)| \le \begin{cases}\|\nabla w\|^2+\frac{1}{4}\|\nabla u\|^2\|w\|^2, & \text{if } n=2\\ \|\nabla w\|^2+\frac{27}{256}\|\nabla u\|^4\|w\|^2, & \text{if } n=3\end{cases} \qquad [13]$$

Using these estimates for the right-hand side of [11], we obtain linear differential inequalities for $\|w\|^2$ that are easily integrated to give

$$\|w(t)\|^2 \le \begin{cases}\|w_0\|^2\exp\int_0^t \frac{1}{2}\|\nabla u\|^2\,\mathrm{d}\tau, & \text{if } n=2\\ \|w_0\|^2\exp\int_0^t \frac{27}{128}\|\nabla u\|^4\,\mathrm{d}\tau, & \text{if } n=3\end{cases} \qquad [14]$$

It follows that if we can estimate the integrals on the right, which concern only the solution $u$, and if $v$ is a second solution, perhaps differing only slightly from $u$ when $t=0$, then we can estimate the difference $\|v(t)-u(t)\|$ at later times. Moreover, at any particular time this difference will be bounded proportionally to $\|v(0)-u(0)\|$. The integral on the right-hand side of the two-dimensional version of [14] is easily estimated using the energy estimate [16] below. The estimation of the corresponding integral in the three-dimensional case, without a restriction on the size of the data, remains an open problem. It can be regarded as the most important open problem in the Navier–Stokes theory. It would never be enough to somehow prove that solutions are smooth without estimating this integral, or something equivalent to it. Of course, if solutions were known to be smooth one could infer their uniqueness from [14], since smoothness would imply that the integrals are finite, which is enough to conclude that $\|w(t)\|$ is zero if $\|w_0\|$ is zero.

## Energy Estimate

If one multiplies the Navier–Stokes equation for $u$ by $u$, and proceeds as in deriving [11], one obtains

$$\frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\|u\|^2+\|\nabla u\|^2=0 \qquad [15]$$

and hence

$$\frac{1}{2}\|u(t)\|^2+\int_0^t\|\nabla u\|^2\,\mathrm{d}\tau = \frac{1}{2}\|u_0\|^2 \qquad [16]$$

This settles the matter of continuous dependence in the two-dimensional case. Together with [16], the two-dimensional version of [14] implies

$$\|w(t)\|^2 \leq \|w_0\|^2 \exp\tfrac{1}{4}\|u_0\|^2, \quad \text{if } n = 2 \qquad [17]$$

We remark that the local rate of energy dissipation is $2|Du|^2$ rather than $|\nabla u|^2$, where $Du$ is the stress tensor $Du = (1/2)(\nabla u + (\nabla u)^{\mathrm{T}})$. However, integrating over the domain, and integrating by parts using the boundary condition $u|_{\partial\Omega} = 0$, one may verify that the rate of total energy dissipation $2\|Du\|^2$ equals $\|\nabla u\|^2$. For the purpose of this article, it is convenient to write the energy identity as [15].

## Estimates for $\|\nabla u(t)\|$ Pointwise in Time

Of course, an estimate for $\|\nabla u(t)\|$ pointwise in time would imply an estimate for the integral of $\|\nabla u(t)\|^4$ on the right-hand side of [14]. We can prove such an estimate for at least a finite interval of time by an argument due to Prodi (1962). It requires, in preparation, some deep results concerning the regularity of solutions of the steady Stokes equations. These cannot be proved here, but we can briefly summarize what will be needed. Let

$\boldsymbol{L}^2(\Omega)$ = space of vector fields $\phi$, with finite $\boldsymbol{L}^2$-norms $\|\phi\|$,
$\boldsymbol{C}_0^\infty(\Omega)$ = space of smooth vector fields with compact support in $\Omega$,
$\boldsymbol{D}(\Omega) = \{\phi \in \boldsymbol{C}_0^\infty(\Omega): \nabla\cdot\phi = 0\}$,
$\boldsymbol{J}(\Omega)$ = completion of $\boldsymbol{D}(\Omega)$ in the $\boldsymbol{L}^2$-norm $\|\phi\|$,
$\boldsymbol{J}_1(\Omega)$ = completion of $\boldsymbol{D}(\Omega)$ in the norm $\|\nabla\phi\|$,
$\boldsymbol{G}(\Omega) = \{\nabla p: p \in L^2(\Omega) \text{ with } \nabla p \in \boldsymbol{L}^2(\Omega)\}$, and
$P: \boldsymbol{L}^2(\Omega) \to \boldsymbol{J}(\Omega)$ be the $\boldsymbol{L}^2$-projection of $\boldsymbol{L}^2(\Omega)$ onto $\boldsymbol{J}(\Omega)$,

and define the Sobolev $W_2^2(\Omega)$ norm by

$$\|u\|^2_{W_2^2(\Omega)} = \|u\|^2 + \|\nabla u\|^2 + \int_\Omega \left|\partial^2 u_i/\partial x_j \partial x_k\right|^2 \mathrm{d}x$$

Furthermore, observe that $(\nabla p, \phi) = 0$ for $\nabla p \in \boldsymbol{G}(\Omega)$ and $\phi \in \boldsymbol{J}(\Omega)$, since it holds if $p$ is smooth and $\phi \in \boldsymbol{D}(\Omega)$. Therefore, $P\nabla p = 0$, since $(P\nabla p, \phi) = (\nabla p, \phi) = 0$, for all $\phi \in \boldsymbol{J}(\Omega)$. Later, when we need it, we will also argue that $\boldsymbol{L}^2(\Omega) = \boldsymbol{J}(\Omega) \oplus \boldsymbol{G}(\Omega)$.

With these preparations, it is evident that every smooth vector field $u$ satisfying $\nabla\cdot u = 0$ and $u|_{\partial\Omega} = 0$ can be regarded as a solution of the steady Stokes problem

$$-\Delta u + \nabla p = f \text{ and } \nabla\cdot u = 0 \text{ in } \Omega \;\; u|_{\partial\Omega} = 0 \qquad [18]$$

with $f = -P\Delta u$. For such solutions, and hence for all such $u$, we have the estimates

$$\|u\|_{W_2^2(\Omega)} \leq c\|P\Delta u\| \qquad [19]$$

and

$$\sup_\Omega |u|^2 \leq \begin{cases} c\|u\|\|P\Delta u\|, & \text{if } n = 2 \\ c\|\nabla u\|\|P\Delta u\|, & \text{if } n = 3 \end{cases} \qquad [20]$$

with constants independent of $u$. It can also be shown that every such vector field $u$ belongs to $\boldsymbol{J}_1(\Omega)$ and hence to $\boldsymbol{J}(\Omega)$; see Heywood (1973).

Some history and remarks are in order. The inequality [19] was proved independently by Solonnikov (1964, 1966), and by Prodi's student Cattabriga (1961). In fact, they gave $L^p$ versions of it for all orders of the derivatives. Several proofs specific to the $L^2$ case needed here have been given by Solonnikov and Sčadilov (1973) and by Beirão da Veiga (1997). The inequalities [20] can be proved by combining [19] with appropriate Sobolev inequalities, or better, by combining [19] with recent inequalities of Xie (1991) which are of precisely the form [20], but with $\triangle u$ instead of $P\triangle u$ on the right-hand side, and without the requirement that $\nabla\cdot u = 0$. The constant $c$ in [19] depends upon the regularity of the boundary, and tends to infinity along with a bound for the boundary curvature. Through the work of Xie (1992, 1997), there is reason to believe that the inequalities [20] are probably valid for arbitrary domains, with the constant $c = (2\pi)^{-1}$ if $n = 2$, and $c = (3\pi)^{-1}$ if $n = 3$. Xie's efforts to prove this have been continued by the author (Heywood 2001). If the inequalities [20] can be proved for arbitrary domains (i.e., arbitrary open sets), with these fixed constants, then the approach to Navier–Stokes theory presented in this article will extend immediately to arbitrary domains, as explained in Heywood and Xie (1997), with estimates independent of the domain.

We go on now with an estimation of $\|\nabla u(t)\|$ based on [20]. Multiplying the Navier–Stokes equation for $u$ by $-P\triangle u$, and integrating over $\Omega$, one obtains

$$\frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\|\nabla u\|^2 + \|P\Delta u\|^2 = (u\cdot\nabla u, P\Delta u) \leq \sup_\Omega |u|\|\nabla u\|\|P\Delta u\| \qquad [21]$$

since $(u_t, -P\Delta u) = (Pu_t, -\Delta u) = (u_t, -\Delta u) = (\nabla u_t, \nabla u)$ and $(\nabla p, P\Delta u) = 0$.

The right-hand side of [21] can be estimated using [20] and Young's inequality:

$$\sup_{\Omega} |u|\|\nabla u\|\|P\Delta u\|$$
$$\leq \begin{cases} c\|u\|^{1/2}\|\nabla u\|\|P\Delta u\|^{3/2}, & \text{if } n=2 \\ c\|\nabla u\|^{3/2}\|P\Delta u\|^{3/2}, & \text{if } n=3 \end{cases}$$
$$\leq \begin{cases} \frac{1}{2}\|P\Delta u\|^2 + c\|u\|^2\|\nabla u\|^4, & \text{if } n=2 \\ \frac{1}{2}\|P\Delta u\|^2 + c\|\nabla u\|^6, & \text{if } n=3 \end{cases}$$

Thus,

$$\frac{\mathrm{d}}{\mathrm{d}t}\|\nabla u\|^2 + \|P\Delta u\|^2 \leq \begin{cases} c\|u\|^2\|\nabla u\|^4, & \text{if } n=2 \\ c\|\nabla u\|^6, & \text{if } n=3 \end{cases} \qquad [22]$$

These differential inequalities are at the core of present theory. Consider first the two-dimensional case. It can be viewed as a linear differential inequality

$$\frac{\mathrm{d}}{\mathrm{d}t}\|\nabla u\|^2 \leq \left(c\|u\|^2\|\nabla u\|^2\right)\|\nabla u\|^2 \qquad [23]$$

with a coefficient $c\|u\|^2\|\nabla u\|^2$ that is integrable, in view of the energy estimate [16]. Integrating it yields a "global" estimate; for all $t \geq 0$,

$$\|\nabla u(t)\|^2 \leq \|\nabla u_0\|^2 \exp\int_0^t \|u\|^2\|\nabla u\|^2\,\mathrm{d}\tau$$
$$\leq \|\nabla u_0\|^2 \exp\frac{1}{2}\|u_0\|^4 \qquad [24]$$

However, if the three-dimensional version of [22] is viewed as a linear differential inequality, the coefficient to be integrated is $\|\nabla u(t)\|^4$. Thus, the same integral which is crucial to proving continuous dependence on the data is also crucial to proving regularity. What we can do in the three-dimensional case, is view [22] as a nonlinear differential inequality of the form

$$\varphi' \leq c\varphi^3 \quad \text{or} \quad \varphi' \leq c\|\nabla u\|^2\varphi^2 \qquad [25]$$

for $\varphi(t) = \|\nabla u(t)\|^2$. Integrating the first of these, one obtains a local estimate

$$\|\nabla u(t)\|^2 \leq \frac{\|\nabla u_0\|^2}{\sqrt{1-2c\|\nabla u_0\|^4 t}} \qquad [26]$$

for

$$0 \leq t < \frac{1}{2c\|\nabla u_0\|^4}$$

without any restriction on the size of the data. Integrating the second, one obtains a global estimate

$$\|\nabla u(t)\|^2 \leq \frac{\|\nabla u_0\|^2}{1 - c\|\nabla u_0\|^2 \int_0^t \|\nabla u\|^2\,\mathrm{d}\tau}$$
$$\leq \frac{\|\nabla u_0\|^2}{1-(c/2)\|u_0\|^2\|\nabla u_0\|^2} \qquad [27]$$

valid for all $t \geq 0$, provided

$$\|u_0\|^2\|\nabla u_0\|^2 < \frac{2}{c} \qquad [28]$$

This is a good interpretation of what we mean by "small data." If Xie's conjecture is correct, that the constant in the three-dimensional version of [20] is $c=(3\pi)^{-1}$, then we obtain [25]–[28] with the constant $c = 3/(128\pi^2)$. Thus, $2/c \simeq 842$.

## Further Regularity, Smoothing Estimates

Once one has an estimate of the form

$$\|\nabla u(t)\| \leq M(t), \quad \text{for } 0 \leq t < T \qquad [29]$$

as provided by [24], [26], or [27], one can estimate the solution's derivatives of all orders over the open time interval $(0, T)$. The initial time $t=0$ must be excluded from the interval, because the "imperfection" of prescribed data generally causes an impulsive acceleration along the boundary at time zero, resulting in a thin boundary layer in which the derivatives are so large that $\|\nabla u_t(t)\|$ and $\|u(t)\|_{W_2^3(\Omega)}$ tend to infinity as $t \to 0^+$. But the solution quickly smooths and remains smooth as long as [29] remains in force. Thus, our working assumption up to this point, that solutions are $C^\infty$ smooth in $\overline{\Omega} \times [0,\infty)$ is not valid at $t=0$. However, we will see that they are smooth in $\overline{\Omega} \times (0, T)$ and continuous in $\overline{\Omega} \times [0, T)$. They are also continuous on $[0, T)$ in the $W_2^2(\Omega)$ norm. This is sufficient regularity to justify everything that we have done to this point.

In this section, we give estimates for the derivatives of all orders with respect to time, of $u$ and its first- and second-order derivatives with respect to space. In the next section, we will prove an existence theorem by Galerkin approximation. It will be easily seen that all of the estimates proved in this and previous sections, for solutions that are assumed to be smooth, also hold for the approximations, without any unproven assumptions. Therefore, they will be inherited by the solution that is obtained upon passing to the limit of the approximations. At first, this solution will be something of a generalized solution, not fully classical, but one which is $C^\infty$ with respect to time over the interval $0 < t < T$, in the $W_2^2(\Omega)$ norm. In a final step,

viewing $u$ at any fixed time as a solution of the steady Stokes equations, we can apply regularity estimates for the Stokes equations to infer that it is $C^\infty$ in all variables throughout $\overline{\Omega} \times (0, T)$, with specific estimates for each derivative.

The estimates of this section are obtained by integrating an infinite sequence of differential inequalities, for $\|u\|, \|\nabla u\|, \|u_t\|, \|\nabla u_t\|, \|u_{tt}\|, \|\nabla u_{tt}\|, \ldots$. The first two are [15] and [21], which have already been dealt with. It turns out that after these first two, each succeeding differential inequality is linearized by the estimates obtained from its predecessor, which explains why the time intervals for these additional estimates do not become successively shorter. In fact, in the two-dimensional case, the energy estimate resulting from [15], which is valid for all time, already gives the linearization [23] of [21], which then provides an estimate valid for all time. Except for noting such differences between the two- and three-dimensional cases, we will henceforth deal with only the three-dimensional case.

The differential inequalities just mentioned are obtained by estimating the right-hand sides of two sequences of differential identities, and ordering them by an iteration between the two sequences. The first sequence begins with and is patterned after the energy identity,

$$\begin{aligned}
&\frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\|u\|^2 + \|\nabla u\|^2 = 0\\
&\frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\|u_t\|^2 + \|\nabla u_t\|^2 = -(u_t\cdot\nabla u, u_t)\\
&\frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\|u_{tt}\|^2 + \|\nabla u_{tt}\|^2 = -(u_{tt}\cdot\nabla u, u_{tt})\\
&\qquad\qquad - 2(u_t\cdot\nabla u_t, u_{tt})
\end{aligned} \qquad [30]$$

etc.

while the second begins with and is patterned after Prodi's identity,

$$\begin{aligned}
&\frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\|\nabla u\|^2 + \|P\Delta u\|^2 = (u\cdot\nabla u, P\Delta u)\\
&\frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\|\nabla u_t\|^2 + \|P\Delta u_t\|^2 = (u_t\cdot\nabla u, P\Delta u_t)\\
&\qquad\qquad + (u\cdot\nabla u_t, P\Delta u_t)\\
&\frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\|\nabla u_{tt}\|^2 + \|P\Delta u_{tt}\|^2 = (u_{tt}\cdot\nabla u, P\Delta u_{tt}) + \cdots
\end{aligned} \qquad [31]$$

etc.

Before going on, notice that we can return to [22] and use [29] to infer a more complete estimate of the form

$$\|\nabla u(t)\|^2 + \int_0^t \|P\Delta u\|^2\,\mathrm{d}\tau \le B(M,t), \quad \text{for } 0 \le t < T \qquad [32]$$

containing an integral of $\|P\Delta u\|^2$ on the left-hand side. We will use the notation $B(M,t)$ generically, for any bound that depends only on the function $M(t)$ and $t$. We remark, that a term $\|u_t\|^2$ can also be included under the integral sign on the left-hand side of [32], because $\|u_t\|$ and $\|P\Delta u\|$ are of essentially the same order, being the leading terms in the projection $u_t + P(u\cdot\nabla u) = P\Delta u$ of the Navier–Stokes equation. Finally, one can also include $\|u\|_{W_2^2(\Omega)}$ under the integral sign, in view of [19].

Going on, we obtain a third differential inequality from the second identity of the sequence [30]. Its right-hand side admits the estimate

$$\begin{aligned}
-(u_t\cdot\nabla u, u_t) &\le \|u_t\|_4^2\|\nabla u\|\\
&\le c\|u_t\|^{1/2}\|\nabla u_t\|^{3/2}\|\nabla u\|\\
&\le \frac{1}{2}\|\nabla u_t\|^2 + c\|\nabla u\|^4\|u_t\|^2
\end{aligned} \qquad [33]$$

which, in view of [29] or [32], produces a linear differential inequality with integrable coefficients. Its integration yields an estimate of the form

$$\|u_t(t)\|^2 + \int_0^t \|\nabla u_t\|^2\,\mathrm{d}\tau \le B(M, t, \|u_t(0)\|), \quad \text{for } 0 \le t < T \qquad [34]$$

provided $\|u_t(0)\|$ is bounded. Since $u_t = P(\Delta u - u\cdot\nabla u)$, we have the estimate

$$\|u_t(0)\| = \|P(\Delta u_0 - u_0\cdot\nabla u_0)\| \le \|\Delta u_0 - u_0\cdot\nabla u_0\| \le B\Big(\|u_0\|_{W_2^2(\Omega)}\Big) \qquad [35]$$

provided that $u$ is smooth in $\overline{\Omega}\times[0,T)$. This is a delicate point, having been forewarned of a regularity breakdown at $t=0$. But, we will be able to replicate the estimate [35] for the Galerkin approximations, ultimately validating [34] for the approximations and the solution.

The integration of the next differential inequality, which arises from the second of the identities [31], requires that $\|\nabla u_t(0)\| < \infty$. Similarly to [35], we have

$$\|\nabla u_t(0)\| = \|\nabla P(\Delta u_0 - u_0\cdot\nabla u_0)\| \le B\Big(\|u_0\|_{W_2^3(\Omega)}\Big) \qquad [36]$$

provided that $u$ is smooth in $\overline{\Omega}\times[0,T)$. However, there is a big difference between [35] and [36]. In the next section, we will not be able to obtain an analog of [36] for the Galerkin approximations. Consequently, the solution that is obtained will not be fully regular at time $t=0$. It will satisfy $u \in C(\overline{\Omega}\times[0,T)) \cap C^\infty(\overline{\Omega}\times(0,T))$, but not $u \in C^\infty(\overline{\Omega}\times[0,T))$. It will satisfy

$\|u(t) - u_0\|_{W_2^2(\Omega)} \to 0$ but not $\|u(t) - u_0\|_{W_2^3(\Omega)} \to 0$, as $t \to 0^+$.

One may wonder whether this is a fault or deficiency in the Galerkin method. It is not, remembering what was said at the beginning of this section. For most prescribed values of $u_0$, no matter how smooth, there is a breakdown in the regularity of the solution as $t \to 0^+$. In fact, it was proved in Heywood and Rannacher (1982) that if $\|\nabla u_t(t)\|$ or any one of several other quantities, including $\|u(t)\|_{W_2^3(\Omega)}$, remains bounded as $t \to 0^+$, then there exists a solution $p_0$ of the overdetermined Neumann problem

$$\begin{aligned} -\Delta p_0 &= \nabla \cdot (u_0 \cdot \nabla u_0) \quad \text{in } \Omega \\ \nabla p_0|_{\partial\Omega} &= \Delta u_0|_{\partial\Omega} \end{aligned} \qquad [37]$$

Generically speaking, this problem is not solvable, and therefore

$$\limsup_{t\to 0^+} \|\nabla u_t(t)\| = \infty$$

We mention that under our assumption that $u_0$ is smooth, the correctly posed Neumann problem, with boundary condition $\partial p_0/\partial n|_{\partial\Omega} = \Delta u_0 \cdot n|_{\partial\Omega}$, is uniquely solvable for a solution $p_0 \in W_2^1(\Omega)/R$, and $\|\nabla p(t) - \nabla p_0\| \to 0$, as $t \to 0^+$; see Heywood and Rannacher (1982).

Since solutions are smooth for $0 < t < T$, the pressure in the Navier–Stokes equations satisfies the overdetermined Neumann problem for all $t \in (0, T)$. So it may seem appropriate to require that the prescribed initial value $u_0$ be a function for which problem [37] is solvable. We do not agree with that. It is too difficult, if not impossible, to find such functions, except by solving the Navier–Stokes equations. For example, one might think that the condition that [37] should be solvable might be satisfied if $u_0 \in \boldsymbol{D}(\Omega)$, since such functions are zero in a neighborhood of the boundary. In fact, K Masuda has shown that if $\Omega$ is a three-dimensional sphere, then the overdetermined Neumann problem [37] is never solvable for nonzero $u_0 \in \boldsymbol{D}(\Omega)$. Hence, the gradient of the initial pressure will have a nonzero tangential component, causing an impulsive tangential acceleration along the boundary.

If we are to use the Navier–Stokes equations to make predictions of the future, we must solve the initial boundary value problem for "man-made" initial values, and accept the fact that there is a momentary breakdown in regularity along the boundary, immediately following the initial time. Thereafter, the solution smooths as "nature" takes over. To prove the reliability of our predictions, we need continuous dependence estimates and error estimates for numerical methods that take into account this initial breakdown in the regularity. The continuous dependence estimate [14] meets this requirement. So also do the error estimates given in a series of four papers by Rannacher and the author, beginning with Heywood and Rannacher (1982). They were based on the "smoothing" regularity estimates for solutions that are being presented here. We go on with these now, as models for similar estimates for the Galerkin approximations.

Estimating the right-hand side of the second of the identities [31] using [20] and Young's inequality, and then multiplying through by $t$, we get the linear differential inequality

$$\begin{aligned} &\frac{\mathrm{d}}{\mathrm{d}t}\left(t\|\nabla u_t\|^2\right) + t\|P\Delta u_t\|^2 \\ &\quad \le \|\nabla u_t\|^2 + c\left(\|\nabla u\|^4 + \|\nabla u\|^2 \right. \\ &\qquad \left. + \|P\Delta u\|^2\right)\left(t\|\nabla u_t\|^2\right) \end{aligned} \qquad [38]$$

for $t\|\nabla u_t\|^2$, with coefficients that are integrable in view of the previous estimates [32], [34], and [35]. Therefore, its integration yields an estimate analogous to [32] of the form

$$\begin{aligned} &t\|\nabla u_t(t)\|^2 + \int_0^t t\|P\Delta u_t\|^2 \,\mathrm{d}\tau \\ &\quad \le B\left(M, t, \|u_0\|_{W_2^2(\Omega)}\right), \quad \text{for } 0 < t < T \end{aligned} \qquad [39]$$

provided its "initial value" is finite. It is, due to the time weight, in the sense that

$$\limsup_{t\to 0^+} \left(t\|\nabla u_t(t)\|^2\right) = 0 \qquad [40]$$

This is proved by noting that if the lim sup were positive, then the integral on the left-hand side of [34] would be infinite. Finally, a term $t\|u_{tt}\|^2$ can be included under the integral sign on the left-hand side of [39], because $\|u_{tt}\|$ and $\|P\Delta u_t\|$ are of essentially the same order, being the leading terms in the projection $u_{tt} + P(u_t \cdot \nabla u + u \cdot \nabla u_t) = P\Delta u_t$ of the time differentiated Navier–Stokes equation.

We continue inductively. Estimating the right-hand side of the third of the identities [30] using [12], [20], and Young's inequality, and then multiplying through by $t^2$, we get the linear differential inequality

$$\begin{aligned} &\frac{\mathrm{d}}{\mathrm{d}t}\left(t^2\|u_{tt}\|^2\right) + t^2\|\nabla u_{tt}\|^2 \\ &\quad \le 2t\|u_{tt}\|^2 + t^2\|\nabla u_t\|^2 + t^2\|P\Delta u_t\|^2 \\ &\qquad + c\left(\|\nabla u\|^4 + \|\nabla u_t\|^4\right)\left(t^2\|u_{tt}\|^2\right) \end{aligned} \qquad [41]$$

with coefficients that are integrable in view of preceding estimates. In particular, the integrability

of the first term on the right-hand side follows from the boundedness of the integral

$$\int_0^t t\|u_{tt}\|^2 \, d\tau \qquad [42]$$

which, we have pointed out, can be included on the left-hand side of [39]. Finally, notice that the boundedness of the integral [42] implies

$$\limsup_{t\to 0^+}\left(t^2\|u_{tt}(t)\|^2\right) = 0 \qquad [43]$$

Therefore, we can integrate [41] to get the estimate

$$t^2\|u_{tt}(t)\|^2 + \int_0^t t^2\|\nabla u_{tt}\|^2 \, d\tau \le B\left(M, t, \|u_0\|_{W_2^2(\Omega)}\right), \quad \text{for } 0 \le t < T \qquad [44]$$

analogous to [34].

At this point, we have introduced every device needed to proceed by induction to an infinite sequence of time-weighted estimates, similar to [39] and [44], but with successively higher orders of time derivatives and weights. The dependence of these estimates on $\|u_0\|_{W_2^2(\Omega)}$ was introduced through [34] and [35]. It can be eliminated by beginning the introduction of powers of $t$ as weight functions one step earlier, with the added advantage that the initial velocity $u_0$ needs only belong to $\boldsymbol{J}_1(\Omega)$. In the two-dimensional case, the weight functions can be introduced even another step earlier, with the advantage that the initial velocity $u_0$ needs only belong to $\boldsymbol{J}(\Omega)$. Each of these cases leads to an existence theorem for solutions $u \in C^\infty(\overline{\Omega} \times (0, T))$, with the initial values assumed in the norms of $\boldsymbol{J}_1(\Omega)$ and $\boldsymbol{J}(\Omega)$, respectively.

## Existence by Galerkin Approximation

Let $\{a^1, a^2, \ldots\}$ and $\{\lambda_1, \lambda_2, \ldots\}$ denote the eigenfunctions and eigenvalues of the Stokes equations,

$$-\Delta a^k + \nabla p = \lambda_k a^k, \quad \nabla \cdot a^k = 0 \quad \text{in } \Omega$$
$$a^k\big|_{\partial\Omega} = 0 \qquad [45]$$

chosen to be orthonormal in $L^2(\Omega)$. Clearly, $-P\Delta a_k = \lambda_k a^k$, so they are also the eigenfunctions and eigenvalues of the Stokes operator, $-P\Delta$. Using regularity estimates for the Stokes equations, each eigenfunction is known to be $C^\infty$ smooth in $\overline{\Omega}$.

The $n$th Galerkin approximation for problem [9] is the solution

$$u^n(x,t) = \sum_{k=1}^n c_{kn}(t) a^k(x)$$

of the system of ordinary differential equations

$$\left(u_t^n, a^l\right) + \left(u^n \cdot \nabla u^n, a^l\right) = \left(\Delta u^n, a^l\right)$$
$$\text{for } l = 1, 2, \ldots, n \qquad [46]$$

satisfying the initial conditions $(u^n(0), a^l) = (u_0, a^l)$, for $l = 1, 2, \ldots, n$. Of course, since $(u_t^n, a^l) = \partial c_{ln}/\partial t$ and $(\Delta u^n, a^l) = (P\Delta u^n, a^l) = -\lambda_l c_{ln}$, the differential equations can be written as

$$\frac{d}{dt} c_{ln} = -\sum_{i,j=1}^n c_{in} c_{jn}\left(a^i \cdot \nabla a^j, a^l\right) - \lambda_l c_{ln}$$

and the initial conditions as $c_{ln}(0) = (u^n(0), a^l)$, for $l = 1, 2, \ldots, n$.

The system [46] is at least locally solvable, on some interval $[0, T_n)$, with each coefficient satisfying $c_{ln} \in C^\infty[0, T_n)$. Therefore, since the eigenfunctions are also smooth, $u^n$ is $C^\infty$ smooth in $\overline{\Omega} \times [0, T_n)$. It also satisfies all of the identities [30] and [31] on the interval $[0, T_n)$. Indeed, multiplying [46] by $c_{ln}$ and summing over $l$ from 1 to $n$ has the effect of converting $a^l$ into $u^n$. The resulting identity for $u^n$ leads immediately to the energy identity

$$\frac{1}{2}\frac{d}{dt}\|u^n\|^2 + \|\nabla u^n\|^2 = 0 \qquad [47]$$

The remaining identities in the sequence [30] are obtained similarly. For example, the second is obtained by taking the time derivative of [46], multiplying through by $dc_{ln}/dt$ and summing over $l$.

Prodi's identity is obtained by multiplying [46] by $\lambda_l c_{ln}$ and summing, which has the effect of converting $a^l$ into $-P\Delta u^n$. To obtain the second of the identities [31] for $u^n$, one differentiates [46], multiplies by $\lambda_l dc_{ln}/dt$ and sums. The remaining identities in the sequence [31] are obtained similarly.

The initial conditions easily imply that $\|u^n(0)\| \le \|u_0\|$, because $u_0 \in \boldsymbol{J}(\Omega)$ and the eigenfunctions are orthogonal and complete in $\boldsymbol{J}(\Omega)$. Therefore, integration of [47] yields the energy estimate

$$\frac{1}{2}\|u^n(t)\|^2 + \int_0^t \|\nabla u^n\|^2 \, d\tau \le \frac{1}{2}\|u_0\|^2 \qquad [48]$$

which is uniform in $n$. Since $\|u^n(t)\|$ remains bounded, the solution $u^n(t)$ can be continued for all time. Thus, $T_n = \infty$, for all $n$. Hence, our early working assumption about solutions, that they are smooth in $\overline{\Omega} \times [0, \infty)$, is actually valid for the Galerkin approximations. The issue becomes one of obtaining estimates for their derivatives that are uniform in $n$. All of the estimates we have proved for solutions are proved in exactly the same way for the approximations. The only possible source of nonuniformity would arise from the initial values of $\|\nabla u^n\|$ and $\|u_t^n\|$.

The estimates [24], [26], and [27] are uniform in $n$, since $u_0 \in \boldsymbol{J}_1(\Omega)$ and hence $\|\nabla u^n(0)\| \le \|\nabla u_0\|$, due to the orthogonality of the eigenfunctions in the inner-product $(\nabla u, \nabla v)$, and their completeness with respect to functions in $\boldsymbol{J}_1(\Omega)$. We also obtain a uniform bound for $\|u_t^n(0)\|$ of the form [35], by multiplying [46] by $\partial c_{ln}/\partial t$ and summing over $l$. In the last step, we also need the inequality $\|u^n(0)\|_{W_2^2(\Omega)} \le \|u_0^n\|_{W_2^2(\Omega)}$, which follows from the orthogonality of the eigenfunctions in the inner product $(P\Delta u, P\Delta v)$, and their completeness with respect to functions in $\boldsymbol{J}_1(\Omega) \cap W_2^2(\Omega)$; see Ladyzhenskaya (1969, p. 46). Any attempt to find a bound for $\|\nabla u_t^n(0)\|$ analogous to [36] is certain to fail, as it would lead to a contradiction with aforementioned results from Heywood and Rannacher (1982).

### Passage to the Limit

We now have $L^2$-bounds for $u^n, \nabla u^n, u_t^n, \partial^2 u^n/\partial x_i \partial x_j$, and $\nabla u_t^n$ over any space-time region $\Omega \times (0, T')$, with $0 < T' < T$. We also have $L^2$-bounds for all orders of the time derivatives of these quantities over any subregion $\Omega \times (\varepsilon, T')$, with $0 < \varepsilon < T' < T$. From these $L^2$-bounds, we may infer the existence of a subsequence of the Galerkin approximations, again denoted by $\{u^n\}$, which converges, along with those of its derivatives for which we have bounds, to a limit $u$ and its derivatives. The convergence $u^n \to u$ and $\nabla u^n \to \nabla u$ is strong in $\boldsymbol{L}^2(\Omega \times (0, T'))$; the convergence of $u_t^n$ is strong in $\boldsymbol{L}^2(\Omega \times (\varepsilon, T'))$ and weak in $\boldsymbol{L}^2(\Omega \times (0, T'))$; the convergence of $P\Delta u^n$ is weak in $\boldsymbol{L}^2(\Omega \times (0, T'))$; all time derivatives of $u^n, \nabla u^n$ converge strongly in $\boldsymbol{L}^2(\Omega \times (\varepsilon, T'))$.

Because of estimates for the time derivatives, trace arguments give the strong convergence $u^n \to u$, $\nabla u^n \to \nabla u, u_t^n \to u_t$, and the weak convergence $P\Delta u^n \to P\Delta u$, in $\boldsymbol{L}^2(\Omega)$, for every $t > 0$.

For any fixed time, $u \in W_2^2(\Omega)$, and therefore $u$ is continuous in $\overline{\Omega}$ by a well known Sobolev inequality. Since $u \in \boldsymbol{J}_1(\Omega)$, it must equal zero along the boundary. The estimates for the time derivatives of $u^n, \nabla u^n, \partial^2 u^n/\partial x_i \partial x_j$ imply that $u$ and its time derivatives are time continuous in $W_2^2(\Omega)$. Therefore, $u, u_t, u_{tt}, \ldots$ are classically continuous in $\overline{\Omega} \times (0, T)$.

### Introduction of the Pressure

Because of the strong convergence $u^n \to u$, $\nabla u^n \to \nabla u, u_t^n \to u_t$ and the weak convergence $P\Delta u^n \to P\Delta u$, in $\boldsymbol{L}^2(\Omega)$, for any $t > 0$, it is an easy matter to let $n \to \infty$ in [46], obtaining, for all $t > 0$,

$$\left(u_t, a^l\right) + (u \cdot \nabla u, a^l) = \left(\Delta u, a^l\right) \quad \text{for } l = 1, 2, \ldots \qquad [49]$$

Since the eigenfunctions are complete in $\boldsymbol{J}(\Omega)$, and $\boldsymbol{D}(\Omega) \subset \boldsymbol{J}(\Omega)$, this implies

$$(u_t + u \cdot \nabla u - \Delta u, \phi) = 0, \quad \text{for all } \phi \in \boldsymbol{D}(\Omega) \qquad [50]$$

Therefore, there exists a vector field $\nabla p \in \boldsymbol{G}(\Omega)$ such that

$$u_t + u \cdot \nabla u - \Delta u = -\nabla p \qquad [51]$$

Indeed, the usual test to determine whether a smooth vector field $w$ is conservative in some domain $\Omega$, and therefore representable as a gradient, is to check whether the curve integrals

$$\oint_C w \cdot \tau \, \mathrm{d}s \qquad [52]$$

vanish for every smooth closed curve $C \subset \Omega$. Here, $\tau$ is the unit tangent to the curve and $\mathrm{d}s$ is its arc length. With a little reflection, one will realize that these curve integrals can be approximated by volume integrals of the form $(w, \phi)$ with $\phi \in \boldsymbol{D}(\Omega)$. For this, one should choose $\phi$ to have its support in a small tubular neighborhood of the curve, and its streamlines parallel to the curve, with unit net flux through any section of the tube. If $w$ is not smooth, but only known to belong to $\boldsymbol{L}^2(\Omega)$, one can approximate it with its smooth mollifications. This argument can be made rigorous. We previously showed that $\boldsymbol{J}(\Omega)$ and $\boldsymbol{G}(\Omega)$ are orthogonal subspaces of $\boldsymbol{L}^2(\Omega)$. Now we have argued that $\boldsymbol{L}^2(\Omega) = \boldsymbol{J}(\Omega) \oplus \boldsymbol{G}(\Omega)$.

### Classical $C^\infty$ Regularity

At any fixed time, we may regard $u$ as a solution of the steady Stokes problem [18] with $f = -u_t - u \cdot \nabla u$. Included in Cattabriga (1961) and Solonnikov (1964, 1966) are regularity estimates for all orders of derivatives of the form

$$\|u\|_{W_2^{k+2}(\Omega)} \le c\|f\|_{W_2^k(\Omega)}$$

From our estimates above, we easily conclude that $f \equiv -u_t - u \cdot \nabla u \in W_2^1(\Omega)$. Hence, $u \in W_2^3(\Omega)$. In fact, in view of the regularity we have proven with respect to time, $f \in C^\infty(0, T; W_2^1(\Omega))$ and $u \in C^\infty(0, T; W_2^3(\Omega))$. Thus begins a bootstrapping argument. In the next step, we observe that $f \in C^\infty(0, T; W_2^2(\Omega))$ and conclude that $u \in C^\infty(0, T; W_2^4(\Omega))$. By induction, one obtains $u \in C^\infty(0, T; W_2^k(\Omega))$ for every positive integer $k$. Then well-known Sobolev inequalities imply that $u \in C^\infty(\overline{\Omega} \times (0, T))$.

### Assumption of the Initial Values

We begin by showing that $u(t) \to u_0$, weakly in $L^2(\Omega)$, as $t \to 0^+$. Of course, $\|u(t)\|$ remains bounded as $t \to 0^+$, in virtue of [48], and the eigenfunctions $\{a^l\}$ are complete in $J(\Omega)$. Writing

$$\left(u(t) - u_0, a^l\right) = \left(u(t) - u^n(t), a^l\right) + \left(u^n(t) - u^n(0), a^l\right) + \left(u^n(0) - u_0, a^l\right)$$

note that the first and third terms on the right-hand side can be made small by choosing $n$ large. The second can be written as

$$\left(u^n(t) - u^n(0), a^l\right) = \int_0^t \left(u^n_t, a^l\right) \mathrm{d}\tau$$

which will be small if $t$ is small, in view of [34]. Thus, $(u(t) - u_0, a^l) \to 0$, as $t \to 0^+$, which implies the desired weak convergence.

The strong convergence $u(t) \to u_0$ in $L^2(\Omega)$ follows from the weak convergence if $\limsup_{t\to 0^+} \|u(t)\| \leq \|u_0\|$. The energy estimate [48] for the approximations implies this also.

To conclude that $u(t) \to u_0$ strongly in $J_1(\Omega)$, it only remains to be shown that $\limsup_{t\to 0^+} \|\nabla u(t)\| \leq \|\nabla u_0\|$. This readily follows from [29], provided the bounding function $M(t)$ satisfies $M(t) \to \|\nabla u_0\|$, as $t \to 0^+$. The bounding functions provided by our basic estimates [24], [26], and [27] all have this property.

We may conclude that $u(t) \to u_0$ weakly in $W_2^2(\Omega)$, provided $\|u(t)\|_{W_2^2(\Omega)}$ remains bounded as $t \to 0^+$. To see this, remember that $\|P\Delta u\|$ and $\|u_t\|$ are of essentially the same order. Thus the term $\|u_t(t)\|^2$ on the left-hand side of [34] can be accompanied by a term $\|u(t)\|^2_{W_2^2(\Omega)}$.

Finally, to prove that $u(t) \to u_0$ strongly in $W_2^2(\Omega)$, we need only show that $\limsup_{t\to 0^+} \|P\Delta u(t)\| \leq \|P\Delta u_0\|$, since $\|P\Delta\cdot\|$ and $\|\cdot\|_{W_2^2(\Omega)}$ are equivalent norms on $J_1(\Omega) \cap W_2^2(\Omega)$. To this end, multiply [46] by $\lambda_l \mathrm{d}c_{ln}/\mathrm{d}t$ and sum to get

$$\frac{1}{2}\frac{\mathrm{d}}{\mathrm{d}t}\|P\Delta u^n\|^2 + \left\|\nabla u^n_t\right\|^2 = \left(u^n \cdot \nabla u^n, P\Delta u^n_t\right) = \frac{\mathrm{d}}{\mathrm{d}t}\left(u^n \cdot \nabla u^n, P\Delta u^n\right) - \left(u^n_t \cdot \nabla u^n + u^n \cdot \nabla u^n_t, P\Delta u^n\right)$$

Integrating this gives

$$\begin{aligned}\|P\Delta u^n(t)\|^2 - \|P\Delta u^n(0)\|^2 &= \int_0^t \frac{\mathrm{d}}{\mathrm{d}t}\|P\Delta u^n\|^2 \mathrm{d}s \\ &= 2(u^n \cdot \nabla u^n, P\Delta u^n)|_t - 2(u^n \cdot \nabla u^n, P\Delta u^n)|_0 \\ &\quad - 2\int_0^t \left\|\nabla u^n_t\right\|^2 \mathrm{d}s - 2\int_0^t \left(u^n_t \cdot \nabla u^n + u^n \cdot \nabla u^n_t, P\Delta u^n\right) \mathrm{d}s\end{aligned} \quad [53]$$

For the terms under the last integral we have

$$\left|\left(u^n_t \cdot \nabla u^n, P\Delta u^n\right) + \left(u^n \cdot \nabla u^n_t, P\Delta u^n\right)\right| \leq \left\|\nabla u^n_t\right\|^2 + c\|\nabla u^n\|^{1/2}\|P\Delta u^n\|^{3/2}$$

Therefore, [53] implies

$$\|P\Delta u^n(t)\|^2 \leq \|P\Delta u^n(0)\|^2 + 2(u^n \cdot \nabla u^n, P\Delta u^n)|_t - 2(u^n \cdot \nabla u^n, P\Delta u^n)|_0 + Kt$$

uniformly in $n$, as $t \to 0^+$, where $K$ is a constant depending on the estimates [32] and [34]. Letting $n \to \infty$, gives

$$\|P\Delta u(t)\|^2 \leq \|P\Delta u(0)\|^2 + 2(u \cdot \nabla u, P\Delta u)|_t - 2(u \cdot \nabla u, P\Delta u)|_0 + Kt$$

Since $u \cdot \nabla u \to u_0 \cdot \nabla u_0$ strongly in $L^2(\Omega)$, and $P\Delta u \to P\Delta u_0$ weakly in $L^2(\Omega)$, we get the desired result. The continuous assumption of the initial values in $W_2^2(\Omega)$ also implies their continuous assumption in the classical sense, and hence that $u \in C(\overline{\Omega} \times [0, T))$.

### Conclusion

Years ago, mathematical questions concerning the Navier–Stokes equations were usually considered in the context of generalized or weak solutions, which was a technical barrier to many in the scientific community. Nowadays, realizing that solutions are at least locally classical, fundamental questions such as that of global regularity can be studied within the classical context. If the estimate [29] is proved for classical solutions, with $T = \infty$, and without a restriction on the size of the data, this particular matter will be settled.

# von Neumann Algebras: Introduction, Modular Theory, and Classification Theory

**V S Sunder**, The Institute of Mathematical Sciences, Chennai, India

## Introduction

von Neumann algebras, as they are called now, first made their appearance under the name "rings of operators" in a series of seminal papers – see Murray and von Neumann (1936, 1937, 1943) and von Neumann (1936) – by F J Murray and J von Neumann starting in 1936. Murray and von Neumann (1936) specifically cite "attempts to generalize the theory of unitary group representations" and "demands by various aspects of the quantum-mechanical formalism" among the reasons for the elucidation of this subject.

In fact, the simplest definition of a von Neumann algebra is via unitary group representations: a collection $M$ of continuous linear operators on a Hilbert space $\mathcal{H}$ (in order to avoid some potential technical problems, we shall restrict ourselves to separable Hilbert spaces throughout this article) is a von Neumann algebra precisely when there is a representation $\rho$ of a group $G$ as unitary operators on $\mathcal{H}$ such that

$$M = \{x \in \mathcal{L}(\mathcal{H}) : x\rho(t) = \rho(t)x \ \forall t \in G\}$$

As above, we shall write $\mathcal{L}(\mathcal{H})$ for the collection of all continuous linear operators on the Hilbert space $\mathcal{H}$; recall that a linear mapping $x : \mathcal{H} \to \mathcal{H}$ is continuous precisely when there exists a positive constant $K$ such that $\|x\xi\| \leq K\|\xi\| \ \forall \xi \in \mathcal{H}$. If the norm $\|x\|$ of the operator $x$ is defined as the smallest constant $K$ with the above property, then the set $\mathcal{L}(\mathcal{H})$ acquires the structure of a Banach space. In fact $\mathcal{L}(\mathcal{H})$ is a Banach $^*$-algebra with respect to the composition product, and involution $x \mapsto x^*$ given by

$$\langle x\xi, \eta\rangle = \langle \xi, x^*\eta\rangle \ \forall \xi, \eta \in \mathcal{H}$$

The first major result in the subject is the remarkable "double commutant theorem," which establishes the equivalence of a purely algebraic requirement to purely topological ones. We need

two bits of terminology to be able to state the theorem.

First, define the commutant $S'$ of a subset $S \subset \mathcal{L}(\mathcal{H})$ by

$$S' = \{x' \in \mathcal{L}(\mathcal{H}) : x'x = xx' \ \forall x \in S\}$$

Second, the strong (resp., weak) operator topology is the topology on $\mathcal{L}(\mathcal{H})$ of "pointwise strong (resp., weak) convergence": that is, $x_n \to x$ precisely when $\|x_n\xi - x\xi\| \to 0 \ \forall \xi \in \mathcal{H}$ (resp., $\langle x_n\xi - x\xi, \eta\rangle \to 0 \ \forall \xi, \eta \in \mathcal{H}$).

**Theorem 1** *The following conditions on a unital* $^*$*-subalgebra M of* $\mathcal{L}(\mathcal{H})$ *are equivalent*:

(i) $M = M''(= (M')')$.
(ii) *M is closed in the strong operator topology.*
(iii) *M is closed in the weak operator topology.*

The conventional definition of a von Neumann algebra is that it is a unital $^*$-subalgebra of $\mathcal{L}(\mathcal{H})$ which satisfies the equivalent conditions above. The equivalence with our earlier "simplest definition" is a consequence of the double commutant theorem and the fact that any element of a von Neumann algebra is a linear combination of four unitary elements of the algebra: simply take $G$ to be the group of unitary operators in $M'$.

Another consequence of the double commutant theorem is that von Neumann algebras are closed under any "canonical construction." For instance, the uniqueness of the spectral measure $E \mapsto P_x(E)$ associated to a normal operator $x$ shows that if $u$ is unitary, then $P_{uxu^*}(E) = uP_x(E)u^*$ for all Borel sets $E$. In particular, if $x \in M$ and $u' \in \mathcal{U}(M')$, then $u'P_x(E)u'^* = P_{u'xu'^*}(E) = P_x(E)$, and hence, we may conclude that $P_x(E) \in \mathcal{U}(M')' = (M')' = M$ (we will write $\mathcal{U}(N)$ (resp., $\mathcal{P}(N)$) to denote the collection of unitary (resp., projection) operators in any von Neumann algebra $N$); that is, if a von Neumann algebra contains a normal operator, it also contains all the associated spectral projections. This fact, together with the spectral theorem, has the consequence that any von Neumann algebra $M$ is the closed linear span of $\mathcal{P}(M)$.

The analogy with unitary group representations is fruitful. Suppose then that $M = \rho(G)'$, for a unitary representation of $G$. Then the last sentence of the previous paragraph implies that $\rho(G)' = \mathbb{C}$ precisely when there exist no nontrivial $\rho$-stable subspaces (here and in the sequel, we identify $\mathbb{C}$ with its image under the unique unital homomorphism of $\mathbb{C}$ into $\mathcal{L}(\mathcal{H})$; and we reserve the symbol $Z(M)$ to denote the center of $M$), that is, when $\rho$ is irreducible. In general, the $\rho$-stable subspaces are precisely the ranges of projection operators in $M$. The notion of unitary equivalence of subrepresentations of $\rho$ is seen to translate to the equivalence defined on the set $\mathcal{P}(M)$ of projections in $M$, whereby $p \sim q$ if and only if there exists an operator $u \in M$ such that $u^*u = p$ and $uu^* = q$. (Such a $u$ is called a partial isometry, with "initial space" = range $p$, and "final space" = range $q$.) This is the definition of what is known as the "Murray–von Neumann equivalence rel $M$" and is denoted by $\sim_M$ . The following accompanying definition is natural: if $p, q \in \mathcal{P}(M)$, say $p \preceq_M q$ if there exists $p_0 \in \mathcal{P}(M)$ such that $p \sim_M p_0 \leq q$ – where of course $e \leq f \Leftrightarrow \text{range}(e) \subset \text{range}(f)$.

## The Murray–von Neumann Classification of Factors

We start with a fact (whose proof is quite easy) and a consequent fundamental definition.

**Proposition 2** *The following conditions on a von Neumann algebra M are equivalent*:

(i) *for any* $p, q \in \mathcal{P}(M)$, *it is true that either* $p \preceq_M q$ *or* $q \preceq_M p$.
(ii) $Z(M) = M \cap M' = \mathbb{C}$.

*The von Neumann algebra M is called a* "factor" *if it satisfies the equivalent conditions above.*

The alert reader would have noticed that if $G$ is a finite group, then $\rho(G)'$ is a factor precisely when the representation $\rho$ is "isotypical." Thus, the "representation-theoretic fact," that any unitary representation is expressible as a direct sum of isotypical subrepresentations, translates into the "von Neumann algebraic fact" that any $*$-subalgebra of $\mathcal{L}(\mathcal{H})$ is isomorphic, when $\mathcal{H}$ is finite dimensional, to a direct sum of factors. In complete generality, von Neumann (1949) showed that any von Neumann algebra is expressible as a "direct integral of factors." We shall interpret this fact from "reduction theory" as the statement that all the magic/mystery of von Neumann algebras is contained in factors and hence restrict ourselves, for a while, to the consideration of factors.

Murray and von Neumann initiated the study of a general factor $M$ via a qualitative as well as a quantitative analysis of the relation $\preceq_M$ on $\mathcal{P}(M)$. First, call a $p \in \mathcal{P}(M)$ infinite if there exists a $p_0 \leq p$ such that $p \sim_M p_0$ and $p_0 \neq p$; otherwise, say $p$ is finite. They obtained an analog, called the "dimension function," of the Haar measure, as follows.

**Theorem 3**

(i) *With M as above, there exists a function* $D_M : \mathcal{P}(M) \to [0, \infty]$ *which satisfies the following*

*properties, and is determined up to a multiplicative constant, by them*:

- $p \preceq_M q \Leftrightarrow D_M(p) \leq D_M(q)$
- *p is finite if and only if* $D_M(p) < \infty$
- *If* $\{p_n : n = 1, 2, \ldots\}$ *is any sequence of pairwise orthogonal projections in* $\mathcal{P}(M)$ *and* $p = \sum_n p_n$, *then* $D_M(p) = \sum_n D_M(p_n)$

(ii) *M falls into exactly one of five possible cases, depending on which of the following sets is the range of some scaling of* $D_M$:

- $(I_n)$ $\{0, 1, 2, \ldots, n\}$
- $(I_\infty)$ $\{0, 1, 2, \ldots, \infty\}$
- $(II_1)$ $[0, 1]$
- $(II_\infty)$ $[0, \infty]$
- $(III)$ $\{0, \infty\}$

In words, we may say that a factor $M$ is of:

1. type $I$ (i.e., of type $I_n$ for some $1 \leq n \leq \infty$) precisely when $M$ contains a minimal projection,
2. type $II$ (i.e., of type $II_1$ or $II_\infty$) precisely when $M$ contains nonzero finite projections but no minimal projections, and
3. type $III$ precisely when $M$ contains no nonzero finite projections.

**Examples** $L^\infty(\Omega, \mu)$ may be regarded as a von Neumann algebra acting on $L^2(\Omega, \mu)$ as multiplication operators; thus, if we set $m_f(\xi) = f\xi$, then $m : f \mapsto m_f$ defines an isomorphism of $L^\infty(\Omega, \mu)$ onto a commutative von Neumann subalgebra of $\mathcal{L}(L^2(\Omega, \mu))$. In fact, "up to multiplicity," this is how any commutative von Neumann algebra looks.

It is a simple exercise to prove that $M \subset \mathcal{L}(\mathcal{H})$ is a factor of type $I_n, 1 \leq n \leq \infty$, if and only if there exist Hilbert spaces $\mathcal{H}_n$ and $\mathcal{K}$ and identifications $\mathcal{H} = \mathcal{H}_n \otimes \mathcal{K}, M = \{x \otimes \mathrm{id}_\mathcal{K} : x \in \mathcal{L}(\mathcal{H}_n)\}$ where $\dim \mathcal{H}_n = n$; and so $M \cong \mathcal{L}(\mathcal{H}_n)$.

To discuss examples of the other types, it will be convenient to use "crossed products" of von Neumann algebras by ergodically acting groups of automorphisms. We shall now digress with a discussion of this generalization of the notion of a semidirect product of groups.

If $\alpha : G \to \mathrm{Aut}(M)$ is an action of a countable group $G$ on $M$, where $M \subset \mathcal{L}(\mathcal{H})$ is a von Neumann algebra, and $\widetilde{\mathcal{H}} = \ell^2(G, \mathcal{H})$, there are representations $\pi : M \to \mathcal{L}(\widetilde{\mathcal{H}})$ and $\lambda : G \to \mathcal{U}(\mathcal{L}(\widetilde{\mathcal{H}}))$ defined by

$$(\pi(x)\xi)(s) = \alpha_{s^{-1}}(x)\xi(s), \quad (\lambda(t)\xi)(s) = \xi(t^{-1}s)$$

These representations satisfy the commutation relation $\lambda(t)\pi(x)\lambda(t^{-1}) = \pi(\alpha_t(x))$, and the crossed product $M \rtimes_\alpha G$ is the von Neumann subalgebra of $\mathcal{L}(\widetilde{\mathcal{H}})$ defined by $\widetilde{M} = (\pi(M) \cup \lambda(G))''$.

Let us restrict ourselves to the case of $M = L^\infty(\Omega, \mu)$ acting on $L^2(\Omega, \mu)$. In this case, it is true that any automorphism of $M$ is of the form $f \mapsto f \circ T^{-1}$, where $T$ is a "nonsingular transformation of the measure space $(\Omega, \mu)$" (= a bijection which preserves the class of sets of $\mu$-measure 0). So, an action of $G$ on $M$ is of the form $\alpha_t(f) = f \circ T_t^{-1}$, for some homomorphism $t \mapsto T_t$ from $G$ to the group of nonsingular transformations of $(\Omega, \mu)$. We have the following elegantly complete result from Murray and von Neumann (1936).

**Theorem 4** *Let* $M, G, \alpha$ *be as in the last section, and let* $\widetilde{M} = M \rtimes_\alpha G$. *Assume the G-action is "free," meaning that if* $t \neq 1 \in G$, *then* $\mu(\{\omega \in \Omega : T_t(\omega) = \omega\}) = 0$. *Then*:

(i) $\widetilde{M}$ *is a factor if and only if G acts ergodically on* $(\Omega, \mu)$ *– meaning that the only G-fixed functions in M are the constants.*

(ii) *Assume that G acts ergodically. Then the type of the factor* $\widetilde{M}$ *is determined as follows*:

- $\widetilde{M}$ *is of type I or II if and only if there exists a G-invariant measure* $\nu$ *which is mutually absolutely continuous with respect to* $\mu$, *meaning* $\nu(E) = 0 \Leftrightarrow \mu(E) = 0$; (*the ergodicity assumption implies that such a* $\nu$ *is necessarily unique up to scaling by a positive constant*;)
- $\widetilde{M}$ *is of type* $I_n$ *precisely when the* $\nu$ *as above is totally atomic, and* $\Omega$ *is the disjoint union of n atoms for* $\nu$;
- $\widetilde{M}$ *is of type II precisely when the* $\nu$ *as above is nonatomic*;
- $\widetilde{M}$ *is of finite type – meaning that* 1 *is a finite projection in* $\widetilde{M}$ *– precisely when the* $\nu$ *as above is a finite measure*;
- $\widetilde{M}$ *is of type III if and only if there exists no* $\nu$ *as above.*

Thus, we get all the types of factors by this construction; for instance, we may take:

$(I_n)$ $G = \mathbb{Z}_n$ acting on $\Omega = \mathbb{Z}_n$ by translation, and $\mu = \nu =$ counting measure
$(I_\infty)$ $G = \mathbb{Z}$ acting on $\Omega = \mathbb{Z}$ by translation, and $\mu = \nu =$ counting measure
$(II_1)$ $G = \mathbb{Z}$ acting on $\Omega = \mathbb{T} = \{z \in \mathbb{C} : |z| = 1\}$ by powers of an aperiodic rotation, and $\mu = \nu =$ arclength measure
$(II_\infty)$ $G = \mathbb{Q}$ acting on $\Omega = \mathbb{R}$ by translations, and $\mu = \nu =$ Lebesgue measure
$(III)$ $G = ax + b$ group acting in the obvious manner on $\Omega = \mathbb{R}, \mu = \nu =$ Lebesgue measure.

Such crossed products of a commutative von Neumann algebra by an ergodically acting countable

group were intensively studied by Krieger (1970, 1976). We shall simply refer to such factors as "Krieger factors." The term "Krieger factor" is actually used for factors obtained from a slightly more general construction, with ergodic group actions replaced by more general ergodic equivalence relations. Since there is no difference in the two notions at least in good (amenable) cases, we will say no more about this.

## Abstract von Neumann Algebras

So far, we have described matters as they were in von Neumann's time. To come to the modern era, it is desirable to "free a von Neumann algebra from the ambient Hilbert space" and to regard it as an abstract object in its own right which can act on different Hilbert spaces – for example, $L^\infty(\Omega,\mu)$ is an object worthy of study in its own right, without reference to $L^2(\Omega,\mu)$.

The abstract viewpoint is furnished by a theorem of Sakai (1983); let us define an abstract von Neumann algebra to be an abstract $C^*$-algebra (this is a Banach algebra with an involution related to the norm by the so-called $C^*$-identity $\|x\|^2 = \|x^*x\|$) $M$ which admits a pre-dual $M_*$ – i.e., $M$ is isometrically isomorphic to the Banach dual space $(M_*)^*$. It turns out that a predual of such an abstract von Neumann algebra is unique up to isometric isomorphism. Consequently, an abstract von Neumann algebra comes equipped with a canonical "weak$^*$-topology," usually called the "$\sigma$-weak topology" on $M$. The natural morphisms in the category of abstract von Neumann algebras are $*$-homomorphisms which are continuous with respect to $\sigma$-weak topologies on domain and range. It is customary to call a linear map between abstract von Neumann algebras "normal" if it is continuous with respect to $\sigma$-weak topologies on domain and range.

The equivalence of the "abstract" definition of this section, with the "concrete" one given earlier (which depends on an ambient Hilbert space), relies on the following four facts:

1. $\mathcal{L}(\mathcal{H})$ is an abstract von Neumann algebra, with the predual $\mathcal{L}(\mathcal{H})_*$ being the so-called "trace class" of operators, equipped with the "trace norm."
2. A self-adjoint subalgebra of $\mathcal{L}(\mathcal{H})$ is closed in the strong operator topology, and is hence a "concrete von Neumann algebra" precisely when it is closed in the $\sigma$-weak topology on $\mathcal{L}(\mathcal{H})$.
3. If $M$ is an abstract von Neumann algebra, and $N$ is a $^*$-subalgebra of $M$ which is closed in the $\sigma$-weak topology of $M$, then $N$ is also an abstract von Neumann algebra, with one candidate for $N_*$ being $M_*/N_\perp$ (where $N_\perp = \{\rho \in M_* : n(\rho) = 0\ \forall n \in N\}$).
4. Any abstract von Neumann algebra (with separable predual) is isomorphic (in the category of abstract von Neumann algebras) to a (concrete) von Neumann subalgebra of $\mathcal{L}(\mathcal{H})$ (for a separable $\mathcal{H}$).

With the abstract viewpoint available, we shall look for modules over a von Neumann algebra $M$, meaning pairs $(\mathcal{H},\pi)$ where $\pi : M \to \mathcal{L}(\mathcal{H})$ is a normal $^*$-homomorphism.

A brief digression into the proof of fact (4) above – which asserts the existence of faithful $M$-modules – will be instructive and useful. Suppose $M$ is an abstract von Neumann algebra. A linear functional $\phi$ on $M$ is called a normal state if:

- (positivity) $\phi(x^*x) \geq 0 \forall x \in M$;
- (normality) $\phi : M \to \mathbb{C}$ is normal; and
- (normalization) $\phi(1) = 1$.

(Normal states on $L^\infty(\Omega,\mu)$ correspond to non-negative probability measures on $\Omega$ which are absolutely continuous with respect to $\mu$.) It is true that there exist plenty of normal states on $M$. In fact, they linearly span $M_*$. This implies that if $M_*$ is separable, then there exist normal states on $M$ which are even "faithful" – meaning $\phi(x^*x) = 0 \Leftrightarrow x = 0$.

Fix a faithful normal state $\phi$ on $M$. (Consistent with our convention about separable $\mathcal{H}$'s, we shall only consider $M$'s with separable preduals.) The well-known "Gelfand–Naimark–Segal" construction then yields a faithful $M$-module which is usually denoted by $L^2(M,\phi)$ – motivated by the fact that if $M = L^\infty(\Omega,\mu)$, and $\phi(f) = \int f \,\mathrm{d}\nu$, with $\nu$ a probability measure mutually absolutely continuous with respect to $\mu$, then $L^2(M,\phi) = L^2(\Omega,\nu)$ with $L^\infty(\Omega,\mu)$ acting as multiplication operators. The construction mimics this case: the assumptions on $\phi$ ensure that the equation

$$\langle x, y \rangle = \phi(y^*x)$$

defines a positive-definite inner product on $M$; let $L^2(M,\phi)$ be the Hilbert space completion of $M$. It turns out that the operator of left-multiplication by an element of $M$ extends as a bounded operator to $L^2(M,\phi)$, and it then follows easily that $L^2(M,\phi)$ is indeed a faithful $M$-module, thereby establishing fact (4) above.

Since we wish to distinguish between elements of the dense subspace $M$ of $L^2(M,\phi)$ and the operators of left-multiplication by members of $M$, let us write $\hat{x}$ for an element of $M$ when thought of as an

element of $L^2(M,\phi)$, and $x$ for the operator of left-multiplication by $x$; thus, for instance, $\hat{x} = x\hat{1}$, and $x\hat{y} = \widehat{xy}$, $\langle x\hat{1}, \hat{1}\rangle = \phi(x)$, etc.

## Modular Theory

While type *III* factors were more or less an enigma at the time of von Neumann, all that changed with the advent of Connes. The first major result of this "type *III* era" is the celebrated "Tomita–Takesaki theorem" (cf. Takesaki (1970)), which views the adjoint mapping on $M$ as an appropriate operator on $L^2(M,\phi)$, and analyzes its polar decomposition. Specifically, we have:

**Theorem 5** *If $\phi$ is any faithful normal state on $M$, consider the densely defined conjugate-linear operator given, with domain $\{\hat{x}: x \in M\}$, by $S_\phi^{(0)}(\hat{x}) = \widehat{x^*}$. Then,*

(i) *there is a unique conjugate-linear operator $S_\phi$ (the "closure of $S_\phi^{(0)}$") whose graph is the closure of the graph of $S_\phi^{(0)}$; if we write $S_\phi = J_\phi \Delta_\phi^{1/2}$ for the polar decomposition of the conjugate-linear closed operator $S_\phi$, then*
(ii) *$J_\phi$ is an antiunitary involution on $L^2(M,\phi)$ (i.e., it is a conjugate-linear norm-preserving bijection of $L^2(M,\phi)$ onto itself which is its own inverse);*
(iii) *$\Delta_\phi$ is an injective positive self-adjoint operator on $L^2(M,\phi)$ such that $J_\phi f(\Delta_\phi) J_\phi = \bar{f}(\Delta_\phi^{-1})$ for all Borel functions $f: \mathbb{R} \to \mathbb{R}$, and most crucially*
(iv)

$$J_\phi M J_\phi = M' \quad \text{and} \quad \Delta_\phi^{it} M \Delta_\phi^{-it} = M \ \forall t \in \mathbb{R}$$

*(Here and elsewhere, we shall identify $x \in M$ with the operator of "left-multiplication by $x$" on $L^2(M,\phi)$.)*

Thus, each faithful normal state $\phi$ on $M$ yields a one-parameter group $\{\sigma_t^\phi : t \in \mathbb{R}\}$ of automorphisms of $M$ – referred to as the group of "modular automorphisms" – given by

$$\sigma_t^\phi(x) = \Delta_\phi^{it} x \Delta_\phi^{-it}$$

The extent of dependence of the modular group on the state is captured precisely by Connes' Radon Nikodym theorem (Connes 1973), which shows that the modular groups associated to two different faithful normal states are related by a "unitary cocycle in $M$." This has the consequence that if $\epsilon : \mathrm{Aut}(M) \to \mathrm{Out}(M) = \mathrm{Aut}(M)/\mathrm{Int}(M)$ is the quotient mapping – where $\mathrm{Int}(M)$ denotes the normal subgroup of inner automorphisms given by unitary elements of $M$ – then the one-parameter subgroup $\{\epsilon(\sigma_t^\phi) : t \in \mathbb{R}\}$ of $\mathrm{Out}(M)$ is independent of $\phi$.

## Connes' Classification and Injective Factors

Given a factor $M$, Connes defined

$$S(M) = \bigcap \{\mathrm{spec}(\Delta_\phi) : \phi \text{ a faithful normal state on } M\}$$

which is obviously an isomorphism invariant. He then classified (Connes 1973) type *III* factors into a continuum of factors:

**Theorem 6** *Let $M$ be a factor. Then,*

(i) *$0 \in S(M) \Leftrightarrow M$ is of type III; and*
(ii) *if $M$ is a type III factor, there are three mutually exclusive and exhaustive possibilities:*

- *$(III_0) S(M) = \{0, 1\}$*
- *$(III_\lambda) S(M) = \{0\} \cup \lambda^{\mathbb{Z}}$, for some $0 < \lambda < 1$*
- *$(III_1) S(M) = [0, \infty)$*

**Example 7** Consider the compact group $\Omega = \prod_{n=1}^\infty G_n$ where $G_n$ is a finite cyclic group of order $\nu_n$ for each $n$. Let $\mu = \prod_{n=1}^\infty \mu_n$, where $\mu_n$ is a probability measure defined on the subsets of $G_n$ which assigns positive mass to each singleton. Let $G = \oplus_{n=1}^\infty G_n$ be the dense subgroup of $\Omega$ consisting of finitely nonzero sequences. It is not hard to see that each translation $T_g, g \in G$ (given by $T_g(\omega) = g + \omega$) is a nonsingular transformation of the measure space $(\Omega, \mu)$. The density of $G$ in $\Omega$ shows that this action of $G$ on $L^\infty(\Omega,\mu)$ is fixed-point-free and ergodic, with the result that the crossed product $L^\infty(\Omega,\mu) \rtimes G$ is a factor.

Krieger showed that in the case of a Krieger factor $M = L^\infty(\Omega,\mu) \rtimes G$, the invariant $S(M)$ agrees with the so-called "asymptotic ratio set" of the group $G$ of nonsingular transformations, which is computable purely in terms of the Radon–Nikodym derivatives $\mathrm{d}(\mu \circ T_t)/\mathrm{d}\mu$. Using this ratio set description, it is not hard to see that the Krieger factor $M$ given by the infinite product $\Omega$

- is a factor of type $III_\lambda$ if $\nu_n = 2$ and $\mu_n\{0\} = \lambda/(1+\lambda)$ for all $n$;
- is a factor of type $III_1$ if $\nu_n = 2$ and $\mu_{2n}\{0\} = \lambda/(1+\lambda)$, $\mu_{2n+1}\{0\} = \kappa/(1+\kappa)$, for all $n$, provided that $\{\lambda, \kappa\}$ generates a dense multiplicative subgroup of $\mathbb{R}_+^\times$;
- can be of type $III_0$.

Among all factors, Connes identified one tractable class – the so-called injective factors – which are ubiquitous and amenable to classification. To start

with, he established the equivalence of several (seemingly quite disparate) requirements on a von Neumann algebra $M \subset \mathcal{L}(\mathcal{H})$ – ranging from injectivity (meaning the existence of a projection of norm 1 from $\mathcal{L}(\mathcal{H})$ onto $M$) to "approximate finite dimensionality" (meaning $M = (\cup_n A_n)''$ for some increasing sequence $A_1 \subset A_2 \subset \cdots \subset A_n \subset \cdots$ of finite-dimensional $*$-subalgebras). In the same paper, Connes (1976) essentially finished the complete classification of injective factors. Only the injective $III_1$ factor withstood his onslaught; but eventually even it had to surrender to the technical virtuosity of Haagerup (1987) a few years later!

In the language we have developed thus far, the classification of injective factors may be summarized as follows:

- Every injective factor is isomorphic to a Krieger factor.
- Up to isomorphism, there is a unique injective factor of each type with the solitary exception of $III_0$.
- Injective factors of type $III_0$ are classified (up to isomorphism) by an invariant of an ergodic-theoretic nature called the "flow of weights"; unfortunately, coming up with a crisp description of this invariant, which is simultaneously accessible to the nonexpert and is consistent with the stipulated size of this survey, is beyond the scope of this author.

The interested reader is invited to browse through one of the books (Connes 1994, Sunder 1986, Dixmier 1981) for further details; the third book is the oldest (a classic but the language has changed a bit since it was written), the second is more recent (but quite sketchy in many places), and the first is clearly the best choice (if one has the time to read it carefully and digest it). Alternatively, the interested reader might want to browse through the encyclopediac treatments (Kadison and Ringrose) or (Takesaki).

# von Neumann Algebras: Subfactor Theory

**Y Kawahigashi**, University of Tokyo, Tokyo, Japan

## Introduction

Subfactor theory was initiated by Jones (1983) and has experienced rapid progress beyond the framework of operator algebras. Here we start with a basic introduction in this section.

A factor is a von Neumann algebra with a trivial center. A von Neumann algebra $M$ is an algebra of bounded linear operators on a Hilbert space $H$, which contains the identitiy operator and is closed under the $*$-operation and weak operator topology, and its center is the intersection of $M$ and its commutant

$$M' = \{x \in B(H) | xy = yx \text{ for all } y \in M\}$$

where $B(H)$ denotes the set of all the bounded linear operators on $H$. (We are mostly interested in separable, infinite-dimensional Hilbert spaces. A von Neumann algebra is automatically closed also in the norm topology and thus it is also a $C^*$-algebra.) By definition, a factor $M$ acts on a certain Hilbert space $H$, but we also consider its action on another Hilbert space $K$, that is, a $\sigma$-weakly continuous homomorphism preserving the $*$-operation from $M$ into $B(K)$. A subfactor is a factor $N$ which is contained in another factor $M$ and has the same identity. A factor is classified into types $\mathrm{I}_n$ $(n = 1, 2, 3, \ldots)$, $\mathrm{I}_\infty$, $\mathrm{II}_1$, $\mathrm{II}_\infty$, and III. In most of the interesting studies of subfactors, the two factors are of both type $\mathrm{II}_1$ or both type III. A factor $M$ is said to be of type $\mathrm{II}_1$ if it is infinite dimensional and has a finite trace $\mathrm{tr}: M \to \mathbf{C}$. By definition, a finite trace tr is a linear functional on $M$ satisfying $\mathrm{tr}(1) = 1$, $\mathrm{tr}(xy) = \mathrm{tr}(yx)$ for all $x, y \in M$, and $\mathrm{tr}(x^*x) \geq 0$ for all $x \in M$. When a factor $M$, not isomorphic to $\mathbf{C}$, acts on a separable Hilbert space, it is of type III if and only if for any two nonzero projections $p, q \in M$, we have an operator $v \in M$ with $vv^* = p$ and $v^*v = q$. One obviously cannot have a trace on such a factor. (See Takesaki (2002, 2003) for a general theory on factors.)

Let $M$ be a type $\mathrm{II}_1$ factor acting on a Hilbert space $H$. We then have the coupling constant of Murray and von Neumann, which is denoted by $\dim_M H$ and belongs to $(0, \infty]$. This measures the relative dimension of $H$ with respect to $M$. Note that the factor $M$ acts on $M$ itself by the left multiplication. We introduce an inner product on $M$ by $(x, y) = \mathrm{tr}(y^*x)$ and denote the completion by $L^2(M)$. Then $M$ acts on this Hilbert space and we have $\dim_M L^2(M) = 1$.

Let $N \subset M$ be a subfactor and suppose that both $N$ and $M$ are of type $\mathrm{II}_1$. (We then simply say that $N \subset M$ is a type $\mathrm{II}_1$ subfactor.) Suppose that $M$ acts on a Hilbert space $H$ with $\dim_M H < \infty$. Then we define the Jones index of $N$ in $M$ by

$$[M : N] = \frac{\dim_N H}{\dim_M H} \in [1, \infty]$$

This number is independent of the choice of $H$, as long as $\dim_M H < \infty$, so we can take $H = L^2(M)$, then we have $[M : N] = \dim_N L^2(M)$. The equality $[M : N] = 1$ means $M = N$. The first major discovery of Jones (1983) is that the value of the Jones index is in the set

$$\{4\cos^2(\pi/m) | m = 3, 4, 5, \ldots\} \cup [4, \infty] \qquad [1]$$

and all the values in this set are indeed realized.

Suppose we have a $\mathrm{II}_1$ factor $M$ and an action of an at most countable, discrete group $G$ on $M$, that is, a homomorphism $\alpha: G \to \mathrm{Aut}(M)$, where $\mathrm{Aut}(M)$ is the automorphism group of $M$. Then we have a construction $M \rtimes_\alpha G$, called the crossed product. If $\alpha_g$ is not an inner automorphism of $M$ for any $g \in G$ other than the identity element of $G$, then $M \rtimes_\alpha G$ is also a type $\mathrm{II}_1$ factor. (An automorphism $\pi$ of $M$ is said to be inner if it is of the form $\pi(x) = uxu^*$ for some unitary operator $u \in M$.) The index of a subfactor $M \subset M \rtimes_\alpha G$ is the order of $G$, which can be infinite. If we have a subgroup $H$ of $G$, then we obtain a subfactor $M \rtimes_\alpha H \subset M \rtimes_\alpha G$ and its index is given by the index $[G : H]$ of the subgroup $H$. This analogy to the index of a subgroup is the origin of the terminology of the Jones index for a subfactor. The Jones index is also analogous to the degree of an extension of a field. From the viewpoint of this analogy, subfactor theory can be regarded as a certain generalized analogue (or the "quantum" version) of the classical Galois theory for field extensions. (The direct analog of the classical Galois correspondence for subfactors was studied by Nakamura–Takeda in the early days, and Izumi–Longo–Popa gave the most general form.)

The tools Jones (1983) has introduced to study subfactors are as follows. Let $N \subset M$ be a subfactor of type $\mathrm{II}_1$ with finite Jones index. We consider the actions of $N$, $M$ on $L^2(M)$. The completion of $N$ with respect to the inner product given by the trace gives $L^2(N)$, which is naturally regarded as a closed subspace of $L^2(M)$. Let $e_N$ be the projection on $L^2(M)$ onto $L^2(N)$, which is called the Jones

projection. We define $M_1$ to be the von Neumann algebra generated by $M$ and $e_N$ on $L^2(M)$. This is again a type $\mathrm{II}_1$ factor and denoted by $M_1$. This construction is called the basic construction. We obtain $[M_1 : M] = [M : N]$. Repeat the same procedure for $M \subset M_1$ acting on $L^2(M_1)$ this time. In this way, we have an increasing sequence of type $\mathrm{II}_1$ factors,

$$N \subset M \subset M_1 \subset M_2 \subset M_3 \subset \cdots$$

which is called the Jones tower. We label the corresponding Jones projections as $e_1 = e_N$, $e_2 = e_M$, $e_3 = e_{M_1}, \ldots$. We then have the following celebrated Jones relations:

$$e_j e_k = e_k e_j, \quad \text{if } |j-k| > 1$$
$$e_j e_{j\pm 1} e_j = \frac{1}{[M:N]} e_j \qquad [2]$$

Jones proved the above-mentioned restriction on the possible values of the Jones index using these relations. The realization of the index values below 4 in the set [1] by Jones also relies on these relations of the Jones projection. The basic construction is also possible for the other direction. That is, we can construct a subfactor $N_1 \subset N$ so that $N \subset M$ is the basic construction of $N_1 \subset N$. This is called the downward basic construction. This $N_1$ is not unique, but is unique up to an inner automorphism of $N$.

A subfactor $N \subset M$ is said to be irreducible if the relative commutant $N' \cap M$ is equal to $\mathbf{C}$. If a subfactor has Jones index less than 4, then it is automatically irreducible. The original realization of the Jones index values above 4 by Jones was through reducible subfactors. Popa proved that all the values above 4 are realized with irreducible subfactors. A factor is said to be hyperfinite if it has a dense subalgebra given as the union of increasing sequence of finite-dimensional $*$-algebras. If $M$ is a hyperfinite type $\mathrm{II}_1$ factor, then its subfactor is automatically also hyperfinite by a deep theorem of Connes. For hyperfinite, irreducible type $\mathrm{II}_1$ subfactors, it is still an open problem to determine all the possible values of the Jones index.

For type $\mathrm{II}_1$ factors $N \subset M \subset P$, the Jones index $[P:N]$ is equal to the product $[P:M][M:N]$. Thus for the Jones tower, we have $[M_k:N] = [M:N]^{k+1}$. In general, if a subfactor $N \subset M$ has a finite Jones index, then the relative commutant $N' \cap M$ is automatically finite dimensional. So, if we start with a type $\mathrm{II}_1$ subfactor $N \subset M$ with finite Jones index, we have an increasing sequence of finite-dimensional algebras as follows:

$$N' \cap M \subset N' \cap M_1 \subset N' \cap M_2 \subset N' \cap M_3 \subset \cdots \qquad [3]$$

These finite-dimensional algebras are called higher relative commutants of $N \subset M$. We draw the Bratteli diagram for the higher relative commutants as follows. Consider $N' \cap M_k$ (with convention $M_{-1} = N$, $M_0 = M$), then it is a finite-dimensional $*$-algebra; thus, it is of the form $\bigoplus_j M_{n_j}(\mathbf{C})$, where we have only finitely many direct summands. We draw a dot for each summand. We similarly draw a dot for each summand in $\bigoplus_l M_{m_l}(\mathbf{C})$ for $N' \cap M_{k+1}$. Let $\iota$ be the inclusion map from $N' \cap M_k = \bigoplus_j M_{n_j}(\mathbf{C})$ to $N' \cap M_{k+1} \bigoplus_l M_{m_l}(\mathbf{C})$ and $p_l$ the identity of $M_{m_l}(\mathbf{C})$, which is a projection in $N' \cap M_{k+1}$. We denote by $\mu_{jl}$ the multiplicity of the embedding map $x \mapsto \iota(x)p_l$ from $M_{n_j}(\mathbf{C})$ to $M_{m_l}(\mathbf{C})$. Then we draw $\mu_{jl}$ edges from the $j$th dot for $M_{n_j}(\mathbf{C})$ to the $l$th dot for $M_{m_l}(\mathbf{C})$. We repeat this procedure for all $k$, and get a picture as in Figure 1, which is called the Bratteli diagram of the higher relative commutants of $N \subset M$.

It turns out that the edges connecting the $k$th and $(k+1)$th steps of the Bratteli diagram consist of the reflection of those connecting the $(k-1)$th and $k$th steps, and a (possibly empty) new part. The "new" parts taken altogether in the above Bratteli diagram constitute the principal graph of a subfactor $N \subset M$. In the example of Figure 1, the principal graph is the Dynkin diagram $A_5$. In general, a principal graph can be finite or infinite. If it is finite, we say that a subfactor is of finite depth. If a subfactor has the Jones index less than 4, it is automatically of finite depth and the principal graph must be one of the $A$–$D$–$E$ Dynkin diagrams.

Pimsner and Popa (1986) obtained the characterization of the Jones index value in terms of the Pimsner–Popa inequality for a conditional expectation. This can be used as a definition of the index for a subfactor of arbitrary type (and even for $C^*$-subalgebras). Kosaki obtained a definition of the index for type III subfactors based on works of Connes and Haagerup.

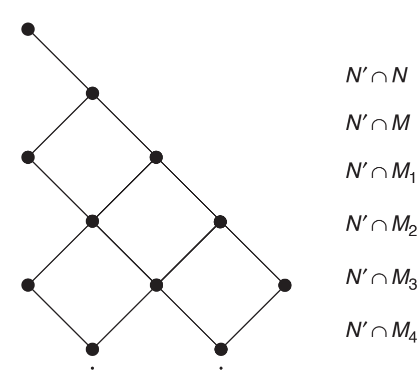

**Figure 1** The Bratteli diagram of the higher relative commutants.

## Analytic Classification Theory

If $M$ is a hyperfinite type $II_1$ factor, then it is unique up to isomorphism. So any subfactor of such $M$ is isomorphic to $M$ itself. We next consider the classification problem of hyperfinite type $II_1$ subfactors. We say that a subfactor $N \subset M$ is isomorphic to $P \subset Q$ if we have an isomorphism of $M$ onto $Q$ which maps $N$ onto $P$. The following tower of finite-dimensional algebras is a natural invariant for a type $II_1$ subfactor $N \subset M$ with finite Jones index and it is called the standard invariant for $N \subset M$:

$$\begin{array}{ccccccc} M' \cap M & \subset & M' \cap M_1 & \subset & M' \cap M_2 & \subset & \cdots \\ \cap & & \cap & & \cap & & \\ N' \cap M & \subset & N' \cap M_1 & \subset & N' \cap M_2 & \subset & \cdots \end{array} \qquad [4]$$

Each square

$$\begin{array}{ccc} M' \cap M_k & \subset & M' \cap M_{k+1} \\ \cap & & \cap \\ N' \cap M_k & \subset & N' \cap M_{k+1} \end{array}$$

is a special combination of inclusions called a commuting square. Under a fairly general condition (called extremality of a subfactor, which automatically holds for an irreducible subfactor), the above sequence [4] is anti-isomorphic to the following sequence of finite-dimensional algebras, including the trace values:

$$\begin{array}{ccccccc} M' \cap M & \subset & N' \cap M & \subset & N_1' \cap M & \subset & \cdots \\ \cap & & \cap & & \cap & & \\ M' \cap M_1 & \subset & N' \cap M_1 & \subset & N_1' \cap M_1 & \subset & \cdots \end{array} \qquad [5]$$

where $\cdots \subset N_3 \subset N_2 \subset N_1 \subset N \subset M$ is given by repeated downward basic constructions. So, if the closure of $\bigcup_j (N_j' \cap M_1)$ in the weak operator topology is equal to $M_1$ for an appropriate choice of $N_j$'s, then the closure of $\bigcup_j (N_j' \cap M)$ is also $M$, and the isomorphism class of the subfactor $N \subset M$ is recovered from the standard invariant. In such a case, we say that a subfactor has a generating property, and then we have a complete classification of subfactors in terms of the standard invariant. Popa (1994) introduced a notion called strong amenability and proved that a subfactor of type $II_1$ is strongly amenable if and only if it has the generating property. This is the fundamental result in the classification of subfactors. A hyperfinite type $II_1$ subfactor with finite Jones index and finite depth is automatically strongly amenable, so such a subfactor is covered by this classification theorem of Popa. Popa also has a similar result for subfactors of type III.

## Constructions and Combinatorial Classification

As mentioned in the above section, Jones constructed hyperfinite type $II_1$ subfactors for all possible index values below 4. They have the Dynkin diagrams $A_n$ as the principal graphs. It has been an important problem to construct new subfactors since then. Using the Hecke algebras, Wenzl constructed a series of subfactors with index values $\sin^2(N\pi/k)/\sin^2(\pi/k)$ with $N = 2, 3, 4, \ldots$, where the series for $N = 2$ coincide with the ones constructed by Jones. Wenzl's dimension estimate in this work for the relative commutant has been an important tool to study subfactors. It was soon noticed that the subfactors of Jones and Wenzl are related to the quantum groups $U_q(\mathrm{sl}_N)$ of Drinfel'd–Jimbo, at the value of the deformation parameter $q$ at $\exp(\pi i/k)$. Constructions of subfactors from other quantum groups have been given by Wenzl.

Ocneanu (1988) has introduced a notion of a paragroup and characterized the higher relative commutants arising from a type $II_1$ subfactor with finite Jones index and finite depth as a paragroup. If we start with a subfactor $N \subset N \rtimes_\alpha G$ for a finite group $G$, the corresponding paragroup contains complete information on the group $G$ and its representations. In this sense, a paragroup is a generalization of a (finite) group. The basic idea is to regard the bimodule ${}_N L^2(M)_M$ as an analog of the fundamental representation of a compact Lie group and make finite relative tensor products

$$\cdots \otimes_N L^2(M) \otimes_M L^2(M) \otimes_N L^2(M) \otimes_M \cdots$$

Then one makes an irreducible decomposition and studies various intertwiners arising from these irreducible bimodules. In this way, we obtain a certain combinatorial object and it is called a paragroup. The vertices of the principal graphs correspond to irreducible bimodules and the edges correspond to basis vectors in the intertwiner spaces. Note that by Popa's theorem explained in the previous section, a classification of subfactors of a hyperfinite type $II_1$ factor with finite Jones index and finite depth is reduced to one of paragroups.

Using this theory of paragroups, Ocneanu has found that the Dynkin diagrams $A_n$, $D_{2n}$, $E_6$, and $E_8$ are realized as principal graphs of subfactors, but $D_{2n+1}$ and $E_7$ are not. Furthermore, each of the graphs $A_n$ and $D_{2n}$ has unique realization and each of $E_6, E_8$ has two realizations. At the index value 4, the principal graph must be one of the extended Dynkin diagrams, $A_{2n-1}^{(1)}$, $D_n^{(1)}$, $E_6^{(1)}$, $E_7^{(1)}$, $E_8^{(1)}$, $A_\infty$, $A_{\infty,\infty}$, and $D_\infty$, and all are realized. (The last three correspond to subfactors of infinite depth.)

See Evans and Kawahigashi (1998) and Goodman *et al.* (1989) for these constructions and classifications. Evans-Kawahigashi and Xu studied the orbifold construction of subfactors applied to the Hecke algebra subfactors of Wenzl.

In a theory of integrable lattice models, we have squares with labeled edges, and we assign complex numbers to them. A paragroup has much formal similarity to such a lattice model, and the paragroups of subfactors of Jones and Wenzl correspond to the lattice models of Andrews–Baxter–Forrester.

Goodman–de la Harpe–Jones have another construction of subfactors from the Dynkin diagrams, and for $E_6$ this gives a hyperfinite type $\mathrm{II}_1$ subfactor with Jones index $3+\sqrt{3}$ and finite depth. Haagerup has made a combinatorial study on type $\mathrm{II}_1$ subfactors with Jones index values between 4 and $3+\sqrt{3}$ and obtained a list of candidates of possible higher relative commutants. Haagerup himself showed one in the list with Jones index $(5+\sqrt{13})/2$ is indeed realized. Asaeda–Haagerup showed that another in the list having the Jones index $(5+\sqrt{17})/2$ is also realized. These two examples are still among the most mysterious examples of subfactors today and do not seem to arise from other constructions using quantum groups or conformal field theory. Izumi has another construction of a subfactor with the Jones index $(7+\sqrt{29})/2$ using an endomorphism of the Cuntz algebra.

Popa has obtained a complete characterization of higher relative commutants including the case of infinite depth, and axiomatized the higher relative commutant as the standard $\lambda$-lattices. Xu has constructed standard $\lambda$-lattices, hence subfactors, from quantum groups. This realization of Popa of a given standard $\lambda$-lattice produces a nonhyperfinite type $\mathrm{II}_1$ subfactor. Popa–Shlyakhtenko later showed that any standard $\lambda$-lattice is realized for a subfactor of a single type $\mathrm{II}_1$ factor, a group $\mathrm{II}_1$ factor arising from the free group $F_\infty$ having countably many generators, which is not hyperfinite.

Jones (1999) has introduced a combinatorial characterization of standard $\lambda$-lattices as planar algebras. This approach uses planar operads based on tangles and provides a new viewpoint on the structure of higher relative commutants. More studies on planar algebras have been done by Bisch–Jones.

## Topological Invariants in Three Dimensions and Tensor Categories

Through the relations of the Jones projections, Jones (1985) discovered the Jones polynomial as an invariant for links. This was the beginning of series of entirely new theories in three-dimensional topology. The Jones polynomial was quickly generalized to the two-variable HOMFLY polynomial by Hoste, Ocneanu, Millet, Freyd, Lickorish, and Yetter.

A three-dimensional topological quantum field theory ($\mathrm{TQFT}_3$) assigns a complex number to each closed oriented 3-manifold and a finite dimensional vector space to each closed oriented surface. Furthermore, to each compact oriented 3-manifold with boundary, it assigns a vector in the vector space corresponding to its boundary. Turaev–Viro have constructed $\mathrm{TQFT}_3$ from combinatorial data called quantum $6j$-symbols arising from quantum groups. Ocneanu has found that a subfactor of finite index and finite depth also produces quantum $6j$-symbols, which give rise to a $\mathrm{TQFT}_3$ generalizing the Turaev–Viro construction. See Evans and Kawahigashi (1998) for this construction. Reshetikhin–Turaev have another construction of $\mathrm{TQFT}_3$ from a modular tensor category, which is a braided tensor category with nondegenerate braiding. Ocneanu has found a subfactor version of the quantum double construction which produces a modular tensor category from a type $\mathrm{II}_1$ subfactor of finite index and finite depth. From a type $\mathrm{II}_1$ subfactor of finite index and finite depth, we can apply Ocneanu's generalization of the Turaev–Viro construction on one hand, and also the Reshetikhin–Turaev construction to the modular tensor category arising from the quantum double construction of Ocneanu. The resulting two $\mathrm{TQFT}_3$s are shown to be equal by Kawahigashi–Sato–Wakui. Concrete computations of these topological invariants have been made by Sato–Wakui based on Izumi's work. Turaev and Wenzl have other constructions of $\mathrm{TQFT}_3$ and modular tensor categories.

## Algebraic Quantum Field Theory

An operator algebraic approach to quantum field theory is called algebraic quantum field theory and the standard reference is Haag (1996). In this approach, instead of quantum fields which are operator-valued distributions, we consider a family $\{A(O)\}$ of von Neumann algebras parametrized by spacetime regions $O$ in a Minkowski space. Each $A(O)$ is meant to be generated by self-adjoint operators which are observables in $O$. We axiomatize such a family of von Neumann algebras and call one a local net of von Neumann algebras. It is enough to take $O$ of a special form, called a double cone. The name "local" comes from the locality axiom which is a mathematical expression of the Einstein causality on a Minkowski space. The

Poincaré group is used as the spacetime symmetry of the Minkowski space. Doplicher *et al.* (1971, 1974) have introduced a representation theory of a local net $A$ of von Neumann algebras and found that a "physically nice" representation is realized as an endomorphism of a one von Neumann algebra $A(O)$ for some fixed $O$. They have a notion of a statistical dimension for such a representation and it is an integer (or infinite) if the spacetime dimension is larger than 2. Longo (1989, 1990) has shown that this statistical dimension of a representation is equal to the square root of the index $[A(O) : \lambda(A(O))]$, where $\lambda$ is the corresponding endomorphism of $A(O)$ to the representation. The relation between algebraic quantum field theory and subfactor theory has been found in this way. Longo (1989, 1990) has also started a theory of canonical endomorphisms for a subfactor and Izumi has further studied it. Longo has later obtained a characterization when an endomorphism of a factor becomes a canonical endomorphism by introducing a $Q$-system.

Recently, conformal field theory has attracted much attention. An approach based on algebraic quantum field theory describes a conformal field theory with a local net of von Neumann algebras on a two-dimensional Minkowski space with diffeomorphism group as the spacetime symmetry. We can restrict such a theory into a tensor product of two theories on the circle, the compactified one-dimensional Euclidean space. Each theory on the circle is called a chiral conformal field theory and described by a local conformal net of von Neumann algebras, which is a family of von Neumann algebras parametrized by intervals on the circle. The name "conformal" comes from the fact that we use the orientation preserving diffeomorphism group on the circle as the symmetry group of the space. For a local conformal net $A$ of von Neumann algebras on the circle with natural irreducibility assumption, each von Neumann algebra $A(I)$ is automatically a type III factor. The Doplicher–Haag–Roberts theory works in this setting after an appropriate adaptation as in Fredenhagen *et al.* (1989) and each representation of a local conformal net of von Neumann algebras is realized by an endomorphism of $A(I)$, where $I$ is an arbitrarily fixed interval on the circle. (Here we do not need an assumption that a representation is "physically nice" since it now automatically holds.) Now the representations give a braided tensor category.

Buchholz–Mack–Todorov constructed examples of local conformal nets of von Neumann algebras on the circle using the U(1)-current algebra. Wassermann (1998) has constructed more examples using positive energy representations of the loop groups LSU($N$) and computed their representation theory, and his construction has been extended to other Lie groups by Toledano Laredo and others. For the local conformal net $A$ of von Neumann algebras on the circle arising from LSU($N$), we take an endomorphism $\lambda$ of $A(I)$ arising from a representation of the local conformal net, then we have a subfactor $\lambda(A(I)) \subset A(I)$. This is isomorphic to the type $\mathrm{II}_1$ subfactor constructed by Jones and Wenzl tensored with a common type III factor.

Longo–Rehren (1995) started the study of a local net of subfactors, $A(I) \subset B(I)$. They have defined a certain induction procedure which gives a representation of the larger local conformal net $B$ from that of $A$. This procedure is today called $\alpha$-induction. Xu has studied this procedure and found several basic properties. In the cases of local conformal nets of subfactors arising from conformal embeddings, he has found a simple construction of subfactors with principal graphs $E_6$ and $E_8$ using $\alpha$-induction. In the context of subfactor theory, $\alpha$-induction has been further studied by Böckenhauer–Evans–Kawahigashi, together with graphical methods of Ocneanu on the Dynkin diagrams. More detailed studies on local conformal nets of factors on the circle have been pursued partly using various techniques of subfactor theory, including classification of local conformal nets of von Neumann algebras on the circle with central charge less than 1 by Kawahigashi–Longo.

# Vortex Dynamics

**M Nitsche**, University of New Mexico, Albuquerque, NM, USA

## Introduction

A vortex is commonly associated with the rotating motion of fluid around a common centerline. It is defined by the vorticity in the fluid, which measures the rate of local fluid rotation. Typically, the fluid circulates around the vortex, the speed increases as the vortex is approached and the pressure decreases. Vortices arise in nature and technology applications in a large range of sizes, as illustrated by the examples given in Table 1. The next section presents some of the mathematical background necessary to understand vortex formation and evolution. Next, some sample flows are described, including important instabilities and reconnection processes. Finally, some of the numerical methods used to simulate these flows are presented.

## Background

Let $D$ be a region in three-dimensional (3D) space containing a fluid, and let $\boldsymbol{x}=(x,y,z)^{\mathrm{T}}$ be a point in $D$. The fluid motion is described by its velocity $\boldsymbol{u}(\boldsymbol{x},t)=u(\boldsymbol{x},t)\boldsymbol{i}+v(\boldsymbol{x},t)\boldsymbol{j}+w(\boldsymbol{x},t)\boldsymbol{k}$, and depends on the fluid density $\rho(\boldsymbol{x},t)$, temperature $T(\boldsymbol{x},t)$, gravitational field $\boldsymbol{g}$, and other external forces possibly acting on it. The fluid vorticity is defined by $\boldsymbol{\omega}=\nabla\times\boldsymbol{u}$. The vorticity measures the local fluid rotation about an axis, as can be seen by expanding the velocity near $\boldsymbol{x}=\boldsymbol{x}_0$,

$$\boldsymbol{u}(\boldsymbol{x}) = \boldsymbol{u}(\boldsymbol{x}_0)+D(\boldsymbol{x}_0)(\boldsymbol{x}-\boldsymbol{x}_0)+\tfrac{1}{2}\boldsymbol{\omega}(\boldsymbol{x}_0)\times(\boldsymbol{x}-\boldsymbol{x}_0) + O(|\boldsymbol{x}-\boldsymbol{x}_0|^2) \quad [1]$$

where

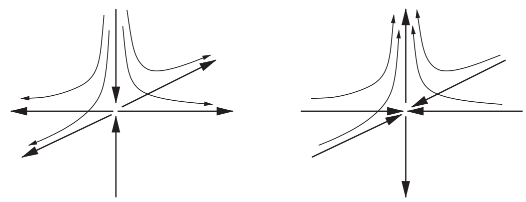
$$D(\boldsymbol{x}_0)=\tfrac{1}{2}(\nabla\boldsymbol{u}+\nabla\boldsymbol{u}^{\mathrm{T}}),\quad \nabla\boldsymbol{u}=\begin{bmatrix} u_x & u_y & u_z\\ v_x & v_y & v_z\\ w_x & w_y & w_z\end{bmatrix} \quad [2]$$

The first term $\boldsymbol{u}(\boldsymbol{x}_0)$ corresponds to translation: all fluid particles move with constant velocity $\boldsymbol{u}(\boldsymbol{x}_0)$. The second term $D(\boldsymbol{x}_0)(\boldsymbol{x}-\boldsymbol{x}_0)$ corresponds to a strain field in the three directions of the eigenvectors of the symmetric matrix $D$. If the eigenvalue corresponding to a given eigenvector is positive, the fluid is stretched in that direction, if it is negative, the fluid is compressed. Note that, in incompressible flow, $\nabla\cdot\boldsymbol{u}=0$, so the sum of the eigenvalues of $D$ equals zero. Thus, at least one eigenvalue is positive and one negative. If the third eigenvalue is positive, fluid particles move towards sheets (Figure 1a). If the third eigenvalue is negative, fluid particles move towards tubes (Figure 1b). The last term in eqn [1], $(1/2)\boldsymbol{\omega}(\boldsymbol{x}_0)\times(\boldsymbol{x}-\boldsymbol{x}_0)$, corresponds to a rotation: near a point with $\boldsymbol{\omega}(\boldsymbol{x}_0)\neq 0$, the fluid rotates with angular velocity $|\boldsymbol{\omega}|/2$ in a plane normal to the vorticity vector $\boldsymbol{\omega}$. Fluid for which $\boldsymbol{\omega}=0$ is said to be irrotational.

A vortex line is an integral curve of the vorticity. For incompressible flow, $\nabla\cdot\boldsymbol{\omega}=\nabla\cdot(\nabla\times\boldsymbol{u})=0$, which implies that vortex lines cannot end in the interior of the flow, but must either form a closed loop

**Table 1** Sample vortices and typical sizes

| *Vortex* | *Diameter* |
|---|---|
| Superfluid vortices | $10^{-8}$ cm (= 1 Å) |
| Trailing vortex of Boeing 727 | 1–2 m |
| Dust devils | 1–10 m |
| Tornadoes | 10–500 m |
| Hurricanes | 100–2000 km |
| Jupiter's Red Spot | 25 000 km |
| Spiral galaxies | Thousands of light years |



(a) (b)

**Figure 1** Strain field: (a) two positive eigenvalues, sheet formation and (b) one positive eigenvalue, tube formation.

interior of the flow, but must either form a closed loop or start and end at a bounding surface. In 2D flow, $\boldsymbol{u} = u\boldsymbol{i} + v\boldsymbol{j}$ and the vorticity is $\boldsymbol{\omega} = \omega\boldsymbol{k}$, where $\omega$ is the scalar vorticity. Thus, in 2D, the vorticity points in the $z$-direction and the vortex lines are straight lines normal to the $x$–$y$ plane. A vortex tube is a bundle of vortex lines. The strength of a vortex tube is defined as the circulation $\int_C \boldsymbol{u} \cdot \mathrm{d}\boldsymbol{s}$ about a curve $C$ enclosing the tube. By Stokes' theorem,

$$\int_C \boldsymbol{u} \cdot \mathrm{d}\boldsymbol{s} = \iint_A \boldsymbol{\omega} \cdot \boldsymbol{n}\, \mathrm{d}S \qquad [3]$$

and thus the circulation can also be interpreted as the flux of vorticity through a cross section of the tube. In inviscid incompressible flow of constant density, Helmholtz' theorem states that the tube strength is independent of the curve $C$, and is therefore a well-defined quantity, and Kelvin's theorem states that a tube's strength remains constant in time. A vortex filament is an idealization in which a tube is represented by a single vortex line of nonzero strength.

The evolution equation for the fluid vorticity, as derived from the Navier–Stokes equations, is

$$\frac{\mathrm{d}\boldsymbol{\omega}}{\mathrm{d}t} = \boldsymbol{\omega} \cdot \nabla \boldsymbol{u} + \nu \Delta \boldsymbol{\omega} \qquad [4]$$

where $\mathrm{d}/\mathrm{d}t = \partial/\partial t + \boldsymbol{u} \cdot \nabla$ is the total time derivative. Equation [4] states that the vorticity is transported by the fluid velocity (first term), stretched by the fluid velocity gradient (second term), and diffused by viscosity $\nu$ (last term). These equations are usually nondimensionalized and written in terms of the Reynolds number, a dimensionless quantity inversely proportional to viscosity.

To understand high Reynolds number flow it is of interest to study the inviscid Euler equations. The corresponding vorticity evolution equation in 2D is

$$\frac{\mathrm{d}\omega}{\mathrm{d}t} = 0 \qquad [5]$$

which states that 2D vortex filaments in inviscid flow move with the fluid velocity. Furthermore, in incompressible flow, the fluid velocity is determined by the vorticity, up to an irrotational far-field component $\boldsymbol{u}_\infty$, through the Biot–Savart law,

$$\boldsymbol{u}(\boldsymbol{x}) = -\frac{1}{4\pi} \int \frac{(\boldsymbol{x} - \boldsymbol{x}') \times \boldsymbol{\omega}(\boldsymbol{x}')}{|\boldsymbol{x} - \boldsymbol{x}'|^3} \mathrm{d}\boldsymbol{x}' + \boldsymbol{u}_\infty \qquad [6]$$

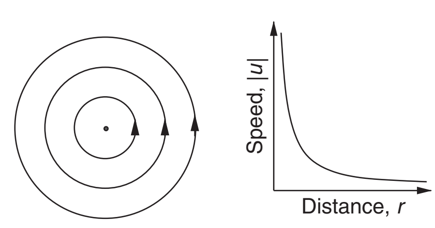
In planar 2D flow, eqn [6] reduces to

$$\boldsymbol{u}(\boldsymbol{x}) = K_{2\mathrm{D}}\omega, \quad K^*{}_{2\mathrm{D}}(\boldsymbol{x}) = \frac{1}{2\pi} \frac{-y\boldsymbol{i} + x\boldsymbol{j}}{|\boldsymbol{x}|^2} \qquad [7]$$

where $\omega(\boldsymbol{x})$ is the scalar vorticity. Equations [4], [5] and [6], [7] are the basis of the numerical methods discussed later in this article.

A vortex is typically defined by a region in the fluid of concentrated vorticity. A simple model is a point vortex in 2D flow, which corresponds to a straight vortex filament of unit circulation. The associated scalar vorticity is a $\delta$-function in the plane, and the induced velocity is obtained from the Biot–Savart law. For a point vortex at the origin, this reduces to the radial velocity field $\boldsymbol{u}(\boldsymbol{x}) = K^*{}_{2\mathrm{D}}\delta = K_{2\mathrm{D}}(\boldsymbol{x})$. Corresponding particle trajectories are shown in Figure 2a. The particle speed $|\boldsymbol{u}| = 1/(2\pi r)$ increases unboundedly as the vortex center is approached, and vanishes as $r \to \infty$ (Figure 2b). In general, the far-field velocity of a concentrated vortex behaves similarly to the one of a point vortex, with speeds decaying as $1/r$. Near the vortex center, the velocity typically increases in magnitude and, as a result, the fluid pressure decreases (Bernoulli's theorem). A vortex of arbitrary shape can be approximated by a sum of point vortices (in 2D) or vortex filaments (in 3D), as is often done for simulation purposes.

Vorticity can be generated by a variety of mechanisms. For example, vorticity can be generated by density gradients, which in turn are induced by spatial temperature variations. This mechanism explains the formation of warm-air vortices when a layer of hot air is trapped underneath cooler air. Vorticity is also generated near solid walls in the form of boundary layers caused by viscosity. To illustrate, imagine



(a) (b)

**Figure 2** Flow induced by a point vortex: (a) streamlines and (b) speed $|\boldsymbol{u}|$ vs. distance $r$.

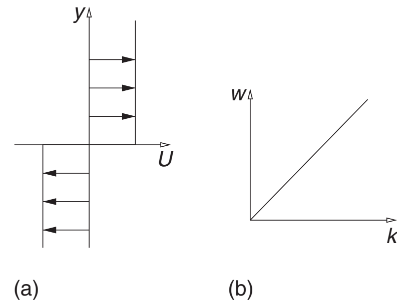

**Figure 5** Vortex sheet: (a) velocity profile and (b) dispersion relation.

horizontal flow with speed $U_o$ moving past a solid wall at rest (Figure 3a). Since in viscous flow the fluid sticks to the wall (the no-slip boundary condition), the fluid velocity at the wall is zero. As a result, there is a thin layer near the wall in which the horizontal velocity varies greatly while the vertical velocity gradients are small, yielding large negative vorticity values $\omega = v_x - u_y$ (Figure 3b). Similarity solutions to the approximating Prandtl boundary-layer equations show that the boundary-layer thickness $d$ grows proportional to $\sqrt{t}$, where $t$ measures the time from the beginning of the motion. Boundary layers can separate from the wall at corners or regions of high curvature and move into the fluid interior, as illustrated in several of the following examples.

## Sample Vortex Flows

### Shear Layers

A shear layer is a thin region of concentrated vorticity across which the tangential velocity component varies greatly. An example is the constant-vorticity layer given by parallel 2D flow $u(x, y) = U(y)$, $v(x, y) = 0$, where $U$ is as shown in Figure 4a. In this case, the velocity is constant outside the layer and linear inside. The vorticity $\omega = -U'(y)$ is zero outside the layer and constant inside. Shear layers occur naturally in the ocean or atmosphere when regions of distinct temperature or density meet. To illustrate this scenario, consider a tank containing two horizontal layers of fluids of different densities, one on top of the other. If the tank is tilted, the heavier bottom fluid moves downstream, and the lighter one moves upstream, creating a shear layer.

Flat shear layers are unstable to perturbations: they do not remain flat but roll up into a sequence of vortices. This is the Kelvin–Helmholtz instability, which can be deduced analytically using linear stability analysis. One shows that in a periodically perturbed flat shear layer, the amplitude of a perturbation with wave number $k$ will initially grow exponentially in time as $e^{wt}$, where $w = w(k)$ is the dispersion relation, leading to instability. The wave number of largest growth depends on the layer thickness. This is illustrated in Figure 4b, which plots $w(k)$ for a constant-vorticity layer of thickness $2d$. The wave number of maximal growth is proportional to $1/d$.

A vortex sheet is a model for a shear layer. The layer is approximated by a surface of zero thickness across which the tangential velocity is discontinuous, as illustrated in Figure 5a. In this case, the dispersion relation reduces to $w(k) = \pm k$. That is, for each wave number $k$ there is a growing and a decaying mode, and the growing mode grows faster the higher the wave number is, as shown in Figure 5b. The vortex sheet arises from a constant vorticity shear layer as the thickness $d \to 0$ and the vorticity $\omega \to \infty$ in such a way that the product $\omega d$ remains constant. Figure 6 shows the roll-up of a periodically perturbed vortex sheet due to the

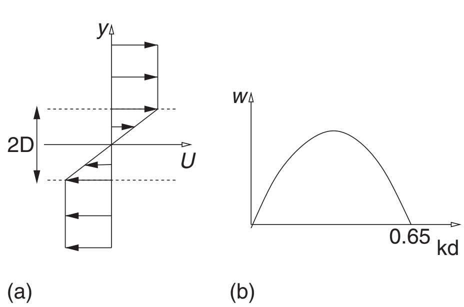

**Figure 4** Shear layer: (a) velocity profile and (b) dispersion relation.

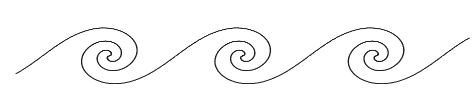

**Figure 6** Computation of vortex sheet roll-up.

Kelvin–Helmholtz instability, computed using one of the methods described in the next section.

### Aircraft Trailing Vortices

One can often observe trailing vortices that shed from the wings of a flying aircraft (also called contrails). These vortices are formed because the wing develops lift. The pressure on the top of the wing is lower than on bottom, causing air to move around the edge of the wing from the bottom surface to the top. The boundary layer on the wing separates as a shear layer that rolls up into a vortex attached to the tip of the wing (Figure 7). Since the velocity inside the vortex is high, the pressure is correspondingly low and causes water vapor in the air to condense, forming water droplets that visualize the vortices. The vortex strength increases with increasing lift, and is particularly strong in high-lift conditions such as take-off and landing. Since lift is proportional to weight, it also increases with the size of the airplane. Vortices of large planes are strong enough to flip a small one if it gets too close. Trailing vortices are the principal reason for the time delay between take-off and landing and are still a serious issue for crowded urban airports.

The trailing vortices can be modeled by a pair of counter-rotating vortex lines (Figure 8a). Two parallel vortex lines of opposite strength induce a downward motion on each other, similar to two point vortices, the zero-core limit. Two point vortices of strength $\pm\Gamma$ at a distance $2d$ from each other translate with self-induced velocity (Figure 9):

$$U = \frac{\Gamma}{4\pi d} \qquad [8]$$

As a result trailing vortices near takeoff hit the ground as a strong downwash air current.

Vortex decay results generally from the development of instabilities. Two parallel vortex tubes are subject to the long-wavelength Crow instability. Triggered by turbulence in the surrounding air, or by local variations in air temperature or density, the vortices develop symmetric sinusoidal perturbations with long wavelength, of the same order as the vortex separation (Figure 8b). As the perturbations grow to finite amplitude, the tubes reconnect and produce a sequence of vortex rings. Note that the two-dimensional schematic in Figure 8c does not convey the three-dimensional structure of the rings. The reconnection process destroys the initial wake structure more rapidly than viscous decay of the individual filaments.

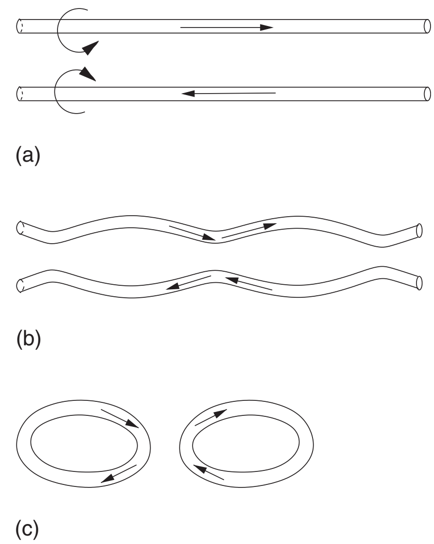

**Figure 8** Sketch. Onset of Crow instability in a pair of vortex lines and ensuing reconnection.

Of much interest is the study of how to accelerate the vortex decay. High-aspect-ratio vortices are subject to a shorter-wavelength elliptic instability, which leads to earlier destruction. However, such vortices are not realistic in current aircraft wakes. Wing designs have been proposed in which more than two trailing vortices form which interact strongly and lead to faster decay. Other interesting aspects are the effect of ambient turbulence and vortex breakdown. Breakdown refers to a disturbance in the vortex core in which it quickly, within an axial distance of few core diameters, develops a region of reversed flow and loses its laminar behavior.

Unlike the counter-rotating vortices discussed so far, two equally signed vortices rotate under their self-induced velocity about a common axis. If the separation distance between them is too small, two equally signed patches merge into one. Vortex merging occurs in two- or three-dimensional flows, as opposed to vortex reconnection, which is a strictly three-dimensional phenomenon.

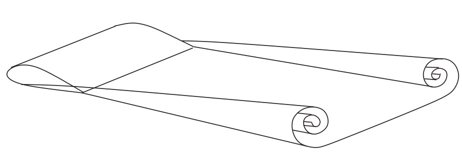

**Figure 7** Sketch. Shear layer separation and roll-up into trailing vortices behind an airfoil.

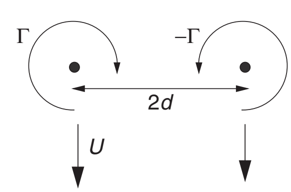

**Figure 9** Self-induced downward motion of a vortex pair.

### Vortex Rings

A vortex tube that forms a closed loop is called a vortex ring. Vortex rings can be formed by ejecting fluid from a circular opening, such as when a smoke ring is formed. The boundary layer wall vorticity separates at the opening as a cylindrical shear layer that rolls up at its edge into a ring (Figure 10). The vorticity is concentrated in a core, which may be thin or thick relative to the ring diameter. The limiting cases are an infinitely thin circular filament of nonzero circulation and the Hill's vortex, in which the vorticity occupies all the interior of a sphere.

Just as a counter-rotating vortex pair, a ring translates under its self-induced velocity $U$ in direction normal to the plane of the ring (Figure 11). However, unlike the vortex pair, the ring velocity depends significantly on its core thickness. For a ring with radius, circulation and core size, respectively, $R$, $\Gamma$, $a$, the self-induced velocity is

$$U \sim \frac{\Gamma}{4\pi R}\left(\log\frac{8R}{a} - \frac{1}{4}\right) \qquad [9]$$

asymptotically as $a \to 0$. Thus, the translation velocity becomes unbounded for rings with decreasing core size. In reality, at some point viscosity takes over and spreads the core vorticity, slowing the ring down.

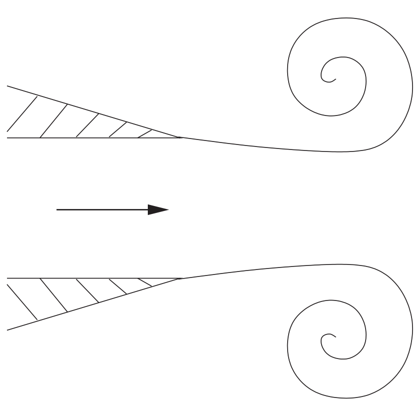

**Figure 10** Vortex ring, formed by ejecting fluid from a circular tube.

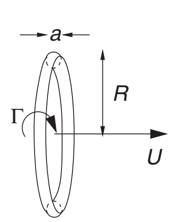

**Figure 11** Self-induced motion of a vortex ring.

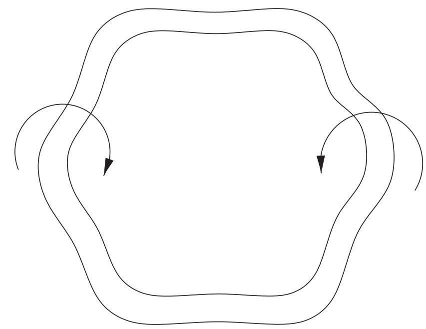

**Figure 12** Sketch. Onset of azimuthal vortex ring instability.

Vortex rings of small cross section are subject to an azimuthal instability. Theory, experiment, and simulations show that if a ring is perturbed in the azimuthal direction, there exists a dominant wave number which is unstable and grows (Figure 12). The unstable wave number increases as the core size decreases, while its spatial amplification rate is almost independent of the core size.

Interesting dynamics are obtained when two or more rings interact. Two coaxial vortex rings of equally signed circulation move in the same direction and exhibit leap-frogging: the rear ring causes the front ring to grow in radius and the front ring causes the rear one to decrease. From eqn [9] it can be seen that the ring velocity is inversely proportional to its radius. Consequently, the front ring slows down and the rear ring speeds up, until the rear ring travels through the front ring. This process repeats itself and is known as leap-frogging. On the other hand, two coaxial vortex rings of oppositely signed circulation approach each other and grow in radius. Their cores contract in order to preserve volume, and their vorticity increases in order to preserve circulation. Under certain experimental conditions, the azimuthal instability develops, the resulting waves on opposite rings reconnect and a sequence of smaller rings form.

### Vortices, Mixing, and Chaos

Mixing is important in many natural processes and technological applications. For example, mixing in shear flows and wakes is relevant to aeronautics and combustion, mixing and diffusion determine chemical reaction rates, and mixing of contaminants pollutes oceans and atmosphere. It is therefore important to understand and control mixing processes.

Efficient mixing of two fluids is obtained by efficient stretching and folding of material lines.

Stretching and folding in turn are the fingerprint of chaos; thus, mixing and chaos are intimately related. Mixing and associated chaotic fluid motion can be obtained by simple vortical motion. For example, two counter-rotating vortices subject to a periodic strain field oscillate in a regular fashion but induce chaos in a region of fluid moving with them. Similarly, two corotating vortices of equal strength that are turned on and off periodically so that one is on when the other is off, known as the blinking vortices, rotate around a common axis in a stepwise manner but induce chaos in nearby regions. On the other hand, if there are four or more vortices present, the vortex motion itself is generally chaotic. It should be noted that there are also nonchaotic equilibrium solutions of four or more vortices forming what is called a vortex crystal.

Information about chaotic particle motion is obtained by studying Poincaré sections, examining the associated stable and unstable manifolds, and investigating the existence of chaotic maps such as the horseshoe map.

### Atmospheric Vortices

Atmospheric vortices are driven by temperature gradients, Earth's rotation (Coriolis force), spatial landscape variations, and instabilities. For example, temperature differences between the equator and the poles and Earth's rotation lead to large-scale vortices such as the trade winds (Hadley cell), the jet streams, and the polar vortex (Figure 13). Semi-annual temperature oscillations are responsible for the Indian monsoons. Daily oscillations cause land- and sea-breezes. Landscape variations can cause urban–rural wind flows and mountain–valley circulations.

Instabilities are often responsible for large cyclonic vortices. Barotropic instability results from large horizontal velocity gradients, and has been deemed responsible for disturbances over the Sahara region that occasionally intensify into tropical cyclones. Baroclinic instability, which occurs when temperature advection is superposed on a velocity field, can lead to cyclonic vortices at the front between air of polar origin and that of tropical origin. The inertial or centrifugal instability occurs when air flows around high-pressure systems and the pressure gradient force is not large enough to balance the centripetal acceleration and the Coriolis effect.

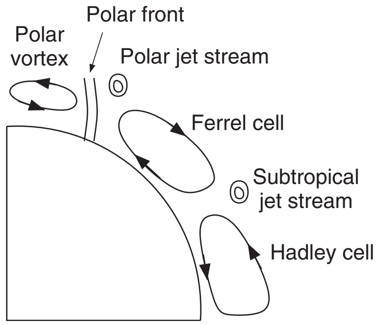

**Figure 13** Vortices in the atmosphere.

Vortices also form on other planets with an atmosphere. On Mars, dust devils are quite common. They are ~10–50 times larger than the ones on Earth and can carry high-voltage electric fields caused by the rubbing of dust grains against each other. Jupiter's characteristic spots are extremely large storm vortices. The Great Red Spot is a vortex spanning twice the diameter of the Earth. Unlike the low-pressure terrestrial storms and hurricanes, the Great Red Spot is a high-pressure system that has been stable for more than 300 years. Other vortices on Jupiter decay and vanish, such as the White Ovals, three large anticyclones which merged into one within two years. Recent computer simulations predict that many of Jupiter's vortices will merge and disappear in the next decade. As a result, mixing of heat across zones will decay and the planet's temperature is predicted to increase.

Numerical simulations of the atmosphere are expensive due to the large number of parameters and the relatively small scales that need to be resolved. For climate models and medium-range forecast models, the governing 3D compressible Euler equations are simplified using the hydrostatic approximation (in which only the pressure gradient and the gravitational forces are retained in the vertical-momentum equation) and the anelastic approximation (in which $d\rho/dt$ is neglected), to obtain the primitive equations. Additional vertical averaging yields the shallow-water equations. One big hurdle is to accurately incorporate the effect of clouds, which is significant and is usually treated using subgrid models.

### Vortices in Superfluids and Superconductors

At temperatures below 2.2 K, liquid helium is a superfluid, meaning that it acts essentially like a fluid with zero viscosity governed by the Euler equations. The fluid is irrotational, except for extremely thin vortex filaments, which are formed by quantum-mechanical processes. Since the vortices cannot end in the interior of the flow, they can be generated only at the surface or they nucleate as

vortex rings inside the fluid. As an example, if a cylindrical container with helium is rotated sufficiently fast, vortex lines attached to both ends of the container appear. These quantum vortices have discrete values of circulation ($= nh/m$, where $h =$ Planck's constant, $m =$ mass of helium atom, $n =$ integer), core sizes of about 1 Å (roughly the diameter of a single hydrogen atom) and move without viscosity.

Similarly, certain types of materials lose their electric resistance at low temperatures and become superconductors. One distinguishes type-I superconductors (most pure metals) from type-II superconductors (alloys). Using the Ginzburg–Landau theory it has been predicted that in type-II superconductors a lattice of vortex filaments forms, each carrying a quantized amount of magnetic flux. This was subsequently confirmed by experimental observation. More precisely, for temperatures $T$ below a critical value $T_c$, there are three regions corresponding to increasing values of the magnetic field (Figure 14). At low magnetic fields ($H < H_{c1}$), no vortices exist (superconducting phase). At intermediate values ($H_{c1} < H < H_{c2}$), the magnetic field penetrates the superconductor in the form of quantized vortices, also called flux lines (mixed phase). The values $H_{c1,c2}$ are determined by the London penetration depth $\lambda$, which measures the electromagnetic response of the superconductor. With increasing magnetic field, the density of flux lines increases until the vortex cores overlap when the upper critical field $H_{c2}$ is reached, beyond which one recovers the normal metallic state (normal conductor).

When an external current density $\boldsymbol{j}$ is applied to the vortex system, the flux lines start to move under the action of the Lorentz force. As a result, a dissipating electric field $\boldsymbol{E}$ appears that is parallel to $\boldsymbol{j}$, and the superconducting property of dissipation-free current flow is lost. In order to recover the desired property of dissipation-free flow, flux lines have to be pinned, for example, by introducing inhomogeneities and structural defects. For a given pinning force, flux lines remain pinned as long as the current density stays below a critical value. A major research objective is to optimize the pinning force in order to preserve superconductivity at larger current densities.

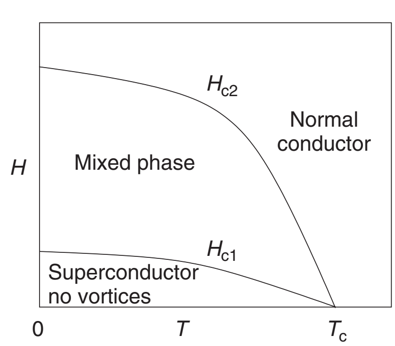

**Figure 14** Superconductor phase dependence on magnetic field $H$ and temperature $T$.

## Numerical Vortex Methods

Many numerical methods used to compute fluid flow are Eulerian schemes based on a fixed mesh, such as finite difference, finite element, and spectral methods, commonly used for example in atmosphere and ocean modeling. This section briefly describes alternative vorticity-tracking methods used to simulate incompressible inviscid vortex flows, and concludes with some extensions to viscous flows. The premise of these methods is that since the fluid velocity is determined by the vorticity through the Biot–Savart law (eqn [6]), it suffices to track only that portion of the fluid carrying nonzero vorticity. This region is often much smaller than the total fluid volume, and computational efficiency is gained. Numerical vortex methods are typically Lagrangian, that is, the computational elements move with the fluid velocity.

### Point-Vortex Approximation in 2D

To compute the evolution of a vorticity distribution $\omega(\boldsymbol{x}, t)$ in 2D, the simplest approach is to approximate the vorticity by a set of point vortices at $\boldsymbol{x}_j(t)$ with circulation $\Gamma_j$ and evolve them under their self-induced motion. The values $\Gamma_j$ are an estimate of the initial circulation around $\boldsymbol{x}_j(0)$. The vortex positions $\boldsymbol{x}_j(t)$ evolve in the induced velocity field

$$\frac{\mathrm{d}\boldsymbol{x}_j}{\mathrm{d}t} = \sum_{\substack{k=1\\k\neq j}}^{N} \Gamma_k \boldsymbol{K}_{2\mathrm{D}}(\boldsymbol{x}_j - \boldsymbol{x}_k) \qquad [10]$$

where the exclusion $k \neq j$ accounts for the fact that a point vortex induces zero velocity on itself. The solution to the system of ordinary differential equations [10] can be obtained using any method, such as Runge–Kutta or Adams–Bashforth.

The point-vortex approximation can be written in Hamiltonian form as

$$\frac{\mathrm{d}x_j}{\mathrm{d}t} = -\frac{1}{\Gamma_j}\frac{\partial H}{\partial y_j}, \qquad \frac{\mathrm{d}y_j}{\mathrm{d}t} = \frac{1}{\Gamma_j}\frac{\partial H}{\partial x_j} \qquad [11]$$

where the Hamiltonian

$$H(x,y) = \frac{1}{4\pi}\sum_{j=1}^{N}\sum_{\substack{k=1\\k>j}}^{N}\Gamma_j\Gamma_k \log\left[(x_j - x_k)^2 + (y_j - y_k)^2\right] \qquad [12]$$

is conserved along fluid particles, $\mathrm{d}H/\mathrm{d}t = 0$. The method also conserves the fluid circulation and the linear and angular momenta.

Ideally, the solution to [10] should converge as $N \to \infty$ to the solution of the Euler equations. This is true for smooth vorticity distributions, but for singular distributions such as a vortex sheet, the situation is more complicated. The vortex sheet, a curve in the plane, develops a singularity in finite time at which the curvature becomes unbounded at a point. The point-vortex approximation converges before the singularity formation time, provided the growth of spurious roundoff error due to Kelvin–Helmholtz instability is suppressed using a filter. However, past the singularity formation time, the point-vortex approximation no longer converges.

The general approach is to replace the singular kernel $\boldsymbol{K}_{2\mathrm{D}}$ by a regularization $\boldsymbol{K}_{2\mathrm{D}}^{\delta}$, such as

$$K_{2\mathrm{D}}^{\delta} = \frac{1}{2\pi}\frac{-y\boldsymbol{i} + x\boldsymbol{j}}{|\boldsymbol{x}|^2 + \delta^2} \qquad [13a]$$

$$K_{2\mathrm{D}}^{\delta} = \frac{1}{2\pi}\frac{-y\boldsymbol{i} + x\boldsymbol{j}}{|\boldsymbol{x}|^2}\left(1 - \mathrm{e}^{-|\boldsymbol{x}|^2/\delta^2}\right) \qquad [13b]$$

where $\delta$ is a numerical parameter. The regularization amounts to replacing the $\delta$-function vorticity of a point vortex by an approximate $\delta$-function. In order to recover the solution to the Euler equations, it is necessary to study the limit $N \to \infty, \delta \to 0$. For smooth vorticity distributions, this process converges. For vortex sheet initial data, there is evidence of convergence, but details of the limiting behavior remain under investigation. Regularized solutions with fixed value $\delta$ and vortex sheet initial data are shown in **Figures 6** and **15**. **Figure 6** shows the onset of the Kelvin–Helmholtz instability in a periodically perturbed flat vortex sheet. **Figure 15** shows the rollup of an elliptically loaded flat vortex sheet that models the evolution of an aircraft wake (see **Figure 7**). The correspondence between the two-dimensional simulation and the three-dimensional wake is made by replacing the spatial coordinate in the aircraft's line of flight by a time coordinate.

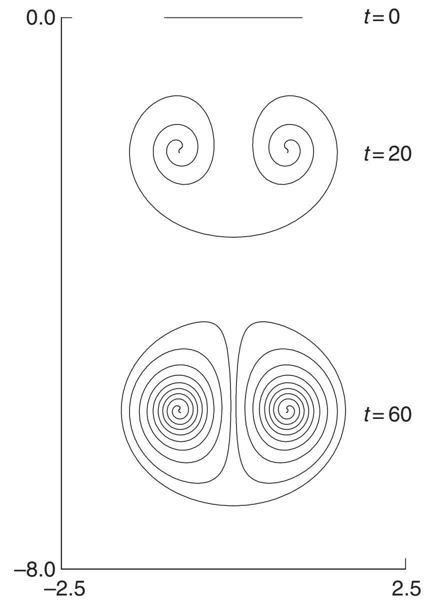

**Figure 15** Computed evolution of an elliptically loaded flat vortex sheet.

### Contour Dynamics in 2D

Consider a planar patch of constant vorticity $\omega_o$ bounded by a curve $\boldsymbol{x}(s,t), 0 \le s \le L$, moving in inviscid, incompressible flow. In view of Kelvin's theorem and eqn [5], the vorticity in the patch remains constant and equal to $\omega_o$ for all time, and the patch area remains constant. Only the patch boundary moves. The velocity at a point $\boldsymbol{x}(\alpha, t)$ on the boundary can be written as a line integral over the boundary:

$$\frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}t} = -\frac{\omega_o}{2\pi}\int_C \log|\boldsymbol{x} - \boldsymbol{x}(s,t)|\frac{\partial \boldsymbol{x}}{\partial s}\mathrm{d}s \qquad [14]$$

The contour dynamics method consists of approximating a given vorticity distribution by a superposition of vortex patches, and moving their boundaries according to eqn [14]. This method has been applied to compute the evolution of single-vortex patches and shear layers, and to geophysical flows. Typically, filamentation occurs: the patch develops thin filaments which increase the boundary length significantly and thereby the computational expense. The approach generally taken is to remove the thin filaments at several times throughout the computation, which is referred to as contour surgery. The contour dynamics approach as well as the point-vortex approximation have also been generalized to treat quasigeostrophic flows.

### Vortex Filament Methods in 3D

Vortex simulations in 3D differ from those in 2D in that the stretching term in eqn [4] needs to be incorporated. The vortex filament method approximates the fluid vorticity by a finite number of filaments whose circulation remains constant in time. Each filament is marked by computational mesh points which move with the regularized induced velocity. The regularization is necessary to prevent the infinite self-induced velocities of curved vortex filaments. As in 2D, this method automatically conserves circulation. Vorticity stretching is accounted for by the stretching between computational mesh points. As the filament length increases, more meshpoints are typically introduced to keep it resolved. Also, the number of filaments can be increased throughout the simulation to maintain resolution.

### Viscous Vortex Methods

While inviscid models are expected to approximate small viscosity fluids well far from boundaries, near boundaries, where vortex shedding is an inherently viscous mechanism, it is important to incorporate the effects of viscosity. The first methods to do so used operator splitting in which inviscid and viscous terms of the Navier–Stokes equations were solved in a sequential manner. In each time step, the computational elements would first be convected, and then they would be diffused by a random-walk scheme. The particle strength exchange method, introduced more recently, does not rely on operator splitting and has better accuracy. The particle position and vorticity evolve simultaneously, and viscous diffusion is accounted for in a consistent manner.

Vortex dynamics continues to be a source of interesting problems of theoretical and practical importance. In particular, much remains to be learned to better understand turbulence and the transition to turbulence, a process dominated by deterministic vortex dynamics.

## Further Remarks

Finally, some remarks on relevant literature on this subject are in order. Lugt (1983) and Tritton (1988) are recommended as elementary introduction to vortex flows. van Dyke (1982) presents beautiful and instructive flow visualizations. Comprehensive treatments of incompressible fluid dynamics are given in Batchelor (1967), Chorin and Marsden (1992), Lamb (1932), and Saffman (1992), and compressible flow is treated in Anderson (1990). Cottet and Koumoutsakos (2000) give an overview of numerical vortex methods.

Special topics have also been addressed; atmosphere (Andrews *et al.* 1987), point vortex motion and chaos (Aref 1983, Newton 2001, Ottino 1989), superfluids and superconductors (Blatter *et al.* 1994, Donnelly 1991), turbulence theory using statistical mechanics ( Chorin 1994), vortex reconnection (Kida and Takaoka 1994), theory for Euler and Navier–Stokes equations (Majda and Bertozzi 2002), contour dynamics (Pullin 1992), vortex rings (Shariff and Leonard 1992), and aircraft trailing vortices (Spalart 1998). Green (1995) includes survey articles on various topics.

## Nomenclature

| | |

## Wave Equations and Diffraction

**M E Taylor**, University of North Carolina, Chapel Hill, NC, USA

### Introduction

The most basic wave equation is

$$\frac{\partial^2 u}{\partial t^2} - \Delta u = 0 \qquad [1]$$

for $u = u(t, x)$, where $\Delta$ is the Laplace operator, given by $\Delta u = \partial^2 u/\partial x_1^2 + \cdots + \partial^2 u/\partial x_n^2$ on $n$-dimensional Euclidean space $\mathbb{R}^n$. More generally, $u$ might be defined on $\mathbb{R} \times M$, where $\mathbb{R}$ is the $t$-axis and $M$ is a Riemannian manifold, with a metric tensor given in local coordinates by $(g_{jk})$. Then the Laplace–Beltrami operator is given, in local coordinates, by

$$\Delta u = g^{-1/2} \sum_{j,k} \frac{\partial}{\partial x_j}\left(g^{1/2} g^{jk} \frac{\partial u}{\partial x_k}\right) \qquad [2]$$

where $(g^{jk})$ is the matrix inverse to $(g_{jk})$ and $g = \det(g_{jk})$. Even if one concentrates on wave propagation in Euclidean space, one frequently wants to use curvilinear coordinates, and [2] is useful. Equation [1] is supplemented by initial conditions of the form

$$u(0, x) = f(x), \qquad \partial_t u(0, x) = g(x) \qquad [3]$$

called Cauchy data. If the spatial domain $M$ has a boundary $\partial M$ (e.g., if $M$ is a bounded region in $\mathbb{R}^n$), then boundary conditions are imposed. The most common are the Dirichlet boundary condition

$$u(t, x) = 0 \quad \text{for } x \in \partial M \qquad [4]$$

and the Neumann boundary condition

$$\partial_\nu u(t, x) = 0 \quad \text{for } x \in \partial M \qquad [5]$$

where $\partial_\nu u$ denotes the normal derivative of $u$ at the boundary. More generally, one might have a driving force, and replace 0 on the right-hand side of [1] by a function $F(t, x)$. Similarly, one can consider nonzero boundary data in [4] and [5].

The wave equation [1] models a number of physical phenomena, at least in the linear approximation. The vibration of a drum head is modeled by [1], with $M$ a planar domain, and with the Dirichlet boundary condition [4]. The motion of sound waves in a room with hard walls is modeled by [1], with $M$ a region in $\mathbb{R}^3$, and with the Neumann boundary condition [5]. The propagation of electromagnetic waves is given by Maxwell's equations:

$$\begin{aligned} \frac{\partial E}{\partial t} - \operatorname{curl} B &= -J \\ \frac{\partial B}{\partial t} + \operatorname{curl} E &= 0 \\ \operatorname{div} E &= \rho \\ \operatorname{div} B &= 0 \end{aligned} \qquad [6]$$

where $\rho$ is the electric charge density and $J$ the current. These equations yield [1] (with the right-hand side replaced by some function $F(t, x)$ if $J$ and $\rho$ are not zero) for the components of the electric field $E$ and the magnetic field $B$. If the propagation is in a region $M$ in $\mathbb{R}^3$ bounded by a perfect conductor, then the boundary conditions are that $E$ is normal to $\partial M$ and $B$ is tangential to $\partial M$. If $\partial M$ is flat, these equations can be decomposed into Dirichlet problems for some components and Neumann problems for the rest, but if $\partial M$ is curved such a decomposition is not possible.

Other models of vibrating objects produce variants of [1]. Examples include vibrating elastic solids, yielding an equation like [1] with $\Delta u$ replaced by $\mu \Delta u + (\lambda + \mu) \operatorname{grad} \operatorname{div} u$, for linear elasticity. Here $\Delta$ acts componentwise on $u$, and $\mu$ and $\lambda$ are constants, called Lamé constants. Other examples model vibrations of crystals and propagation of electromagnetic waves in crystals. Further interesting phenomena arise in these various cases, such as Rayleigh waves in linear elasticity and conical refraction in crystal optics.

Here we discuss the propagation of waves and their reflection and diffraction at boundaries. In the interest of providing reasonable coverage in a brief space, we restrict attention to the wave equation [1].

## Basic Propagation Phenomena

The simplest examples of waves propagating according to [1] are plane waves, of the form

$$u(t,x) = \varphi(x \cdot \omega - t) \qquad [7]$$

with $(t,x) \in \mathbb{R} \times \mathbb{R}^n, \omega$ a unit vector in $\mathbb{R}^n$, and $\varphi$ a function on $\mathbb{R}$. If $\varphi$ has two continuous derivatives, [7] defines a classical solution of [1]. More generally, one can allow $\varphi$ to be less regular. For example, it could be piecewise smooth with a jump discontinuity at some point $a \in \mathbb{R}$. In such a case, $u$ will be piecewise smooth with a jump across the $n$-dimensional surface $x \cdot \omega - t = a$ in $\mathbb{R} \times \mathbb{R}^n$, which will solve [1] in a weak, or distributional, sense. For fixed $t, u(t,\cdot)$ has a jump across the $(n-1)$-dimensional surface $\Sigma_t = \{x \in \mathbb{R}^n : x \cdot \omega = t + a\}$. As $t$ varies, $\Sigma_t$ moves in the direction $\omega$ with unit speed.

There are also spherical wave solutions to [1] on $\mathbb{R} \times \mathbb{R}^n$, such as

$$u(t,x) = \frac{\operatorname{sgn} t}{2\pi}(t^2 - |x|^2)_+^{-1/2} \qquad [8]$$

for $n = 2$, and

$$u(t,x) = \frac{1}{4\pi t}\delta(|x| - |t|) \qquad [9]$$

for $n = 3$. Here $s_+ = s$ for $s > 0, s_+ = 0$ for $s \le 0$, and $\delta(s)$ is the Dirac delta function. In fact, [8] and [9] are "fundamental solutions" (more on which in the section on harmonic analysis) to the wave equation on $\mathbb{R} \times \mathbb{R}^n$, for $n = 2$ and 3, respectively. In such cases, the singularity in $u(t,\cdot)$ for each fixed $t$ lies in $\Sigma_t = \{x \in \mathbb{R}^n : |x| = |t|\}$, a family of surfaces in $\mathbb{R}^n$ that moves, in the direction of the normal to $\Sigma_t$, at unit speed.

The examples mentioned above illustrate two general phenomena about the behavior of solutions to [1]. The first is finite propagation speed. Its general formulation is that, given a closed set $K \subset M$,

$$\begin{aligned} \operatorname{supp} f, g \subset K \ \Rightarrow\ & \operatorname{supp} u(t,\cdot) \\ & \subset \{x \in M : \operatorname{dist}(x,K) \le |t|\} \end{aligned} \qquad [10]$$

In fact, given that [8]–[9] are fundamental solutions, [10] is a consequence of these formulas when $M = \mathbb{R}^2$ or $\mathbb{R}^3$. The result [10] is true in great generality, with well-known demonstrations involving energy estimates.

The second phenomenon involves propagation of singularities. Typically, if the Cauchy data $f$ and $g$ in [3] are smooth on the complement of an $(n-1)$-dimensional surface $\Sigma_0$, perhaps with a jump across $\Sigma_0$, or such a singularity as in [8] or [9], the solution $u(t,x)$ will be a sum of two terms, with singularities of a similar nature on the surfaces $\Sigma_t^{\pm}$, moving at unit speed in the direction of their normals, $\Sigma_t^+$ flowing from $\Sigma_0$ in one direction and $\Sigma_t^-$ in the other. This also holds for the manifold case [2]. That happens at least until such surfaces develop singularities, when matters become more elaborate.

An alternative way to describe how the set of singularities evolves is the following. Let $S_1M$ denote the space of unit vectors tangent to $M$; this is a submanifold of the tangent bundle of $M, TM$. There is a natural projection $\pi : S_1M \to M$. Associated to a smooth surface $\Sigma_0$ of dimension $n-1$ in $M$ (of dimension $n$) are two preimages $\Lambda_0^+$ and $\Lambda_0^-$ in $S_1M$, consisting of unit vectors lying over points of $\Sigma_0$ and normal to $\Sigma_0$. The geodesic flow is a flow on $S_1M$, and it takes $\Lambda_0^{\pm}$ to smooth $(n-1)$-dimensional surfaces $\Lambda_t^{\pm}$ in $S_1M$. The sets $\Sigma_t^{\pm}$ are the images of $\Lambda_t^{\pm}$ under $\pi$. The geodesics starting out at points in $\Lambda_0^{\pm}$ and sweeping out $\Lambda_t^{\pm}$ are the rays along which the singularities of the solution $u$ propagate.

This latter description works for all $t$ if $M$ has no boundary and is complete, that is, all geodesics are defined for all $t$, although singularities develop in the images $\pi(\Lambda_t^{\pm}) = \Sigma_t^{\pm}$, at points $p \in \Sigma_t^{\pm}$, where $\Lambda_t^{\pm}$ meets $T_pM$ nontransversally. The behavior of $u$ near such singular points of $\Sigma_t^{\pm}$, known as caustics, is more complicated than that near regular points, but it can be captured in terms of integrals. Methods of establishing this propagation of singularities are discussed in the section on geometrical optics.

Such a description needs further elaboration if $M$ has a boundary. One of the principal problems of diffraction theory is to explain how singularities of solutions to [1], with a boundary condition such as [4] or [5], propagate and reflect off the boundary.

Considering the case where $M$ is a half-space in $\mathbb{R}^n$,

$$M = \mathbb{R}_+^n = \{x \in \mathbb{R}^n : x_n \ge 0\} \qquad [11]$$

provides a guide to the simplest reflection phenomena. In such a case, one can solve the Dirichlet or Neumann boundary problem for the wave equation [1] by the method of images. One extends $f$ and $g$ from $\mathbb{R}_+^n$ to $\mathbb{R}^n$. For the Dirichlet problem [4], one takes odd extensions, $f(x', -x_n) = -f(x', x_n)$, and similarly for $g$. For the Neumann problem [5], one takes even extensions, $f(x', -x_n) = f(x', x_n)$, etc. One then solves the wave equation [1] on $\mathbb{R} \times \mathbb{R}^n$ with the extended Cauchy data, and the restriction to $\mathbb{R} \times \mathbb{R}_+^n$ solves the respective boundary problem. Suppose $\Sigma_0$ is a smooth $(n-1)$-dimensional surface that does not meet $\partial\mathbb{R}_+^n$, and that $f$ and $g$ have singularities on $\Sigma_0$, as above. (Suppose for simplicity that $f$ and $g$ vanish near $\partial\mathbb{R}_+^n$.) Those rays issuing

from normals to $\Sigma_0$ have mirror images, which are rays in $\mathbb{R}^n_-$. If such a ray hits $\partial\mathbb{R}^n_+$, its mirror image does so also, and continues into $\mathbb{R}^n_+$, as the reflected ray. The singularities of $u$ propagate along such reflected rays.

Such a description extends to a general complete Riemannian manifold with boundary $M$, in the case of rays that hit the boundary transversally. Such a ray is reflected by retaining the tangential component of its velocity vector at the point of intersection $\partial M$ and reversing the sign of the normal component. One says that the ray is reflected according to the laws of geometrical optics. Singularities of $u$ carried by such rays that hit $\partial M$ are correspondingly reflected. Methods to establish such transversal reflection of singularities are natural extensions of those developed to treat the propagation away from $\partial M$, mentioned above.

Matters become more delicate when there are rays that are tangent to $\partial M$. A model example is given by

$$M = \mathbb{R}^n \setminus B, \quad B = \{x \in \mathbb{R}^n : |x| < 1\} \qquad [12]$$

which one takes when studying the scattering of waves in $\mathbb{R}^n$ by the obstacle $B$. Consider a solution to [1] with boundary condition given by [4] or [5] that has a simple singularity on $\Sigma_t = \{x \in \mathbb{R}^n : x_n = t\}$ for $t < -1$. The associated rays are of the form $\gamma_{x'}(t) = (x', t)$, for $t < -1$, with $x' \in \mathbb{R}^{n-1}$. If $|x'| > 1$, these rays continue on in $\mathbb{R}^n \setminus B$, for all $t \geq -1$. If $|x'| < 1$, these rays hit $\partial M = \partial B$ transversally, and their reflection is as described above. If $|x'| = 1$, these rays hit $\partial B$ tangentially, at $t = 0$; they are sometimes called grazing rays. One also continues them past $t = 0$. One defines in this fashion $\Sigma_t$ for $t \geq -1$. The region

$$\mathcal{S} = \{x = (x', x_n) \in \mathbb{R}^n \setminus B : |x'| < 1, x_n > 0\} \qquad [13]$$

is called the "shadow region." It is disjoint from $\Sigma_t$ for all $t$. The solution $u$ is smooth in $\mathcal{S}$ for all $t$, although it is not identically zero. The set

$$\mathcal{S}^b = \{x = (x', x_n) \in \mathbb{R}^n \setminus B : |x'| = 1, \, x_n \geq 0\} \qquad [14]$$

is the "shadow boundary."

One can replace $B$ in [12] by a more general smooth, convex obstacle $K$, with positive Gauss curvature everywhere, and the same considerations of transversal and grazing rays and shadow regions apply. These notions also extend to a more general class of Riemannian manifolds with boundary, called manifolds with diffractive boundary. In the case $K = B$, one can use separation of variables to reduce the problem of analyzing solutions to [1] and showing that singularities propagate along such rays to a problem in harmonic analysis on the sphere $S^{n-1}$. For more general convex obstacles $K$ or manifolds with diffractive boundary, other techniques are required, to show that waves reflect off the boundary in a fashion similar to the case [12].

Another situation arises if instead of [12] one takes $M = B$, or more generally $M = K$, a convex region as described above. A ray starting off from a point in $\partial M$, almost tangent to $\partial M$ but with a small component in the direction of the normal pointing into $M$, will undergo many reflections in a short time. Upon shrinking the normal component of the initial velocity to zero, one obtains in the limit a geodesic in $\partial M$, known as a gliding ray. In such a case, singularities of solutions to [1], with such a boundary condition as [4] or [5], propagate along both transversally reflected and gliding rays.

For the generic smooth obstacle $K$ in $\mathbb{R}^n$, the second fundamental form can have a variety of signatures at various boundary points. Various types of "generalized rays" occur – generally speaking limits of sequences of transversally reflected rays. This situation also holds for general complete Riemannian manifolds with smooth boundary. The main result about propagation of singularities in such a case is that it is always along such generalized rays. This was established by Melrose and Sjöstrand (1978).

Further diffraction effects arise when $\partial M$ has singularities, such as edges and corners. The simplest example is

$$M = \{x \in \mathbb{R}^2 : a \leq \theta \leq b, r \geq 0\} \qquad [15]$$

where $(r, \theta)$ are the polar coordinates of $x \in \mathbb{R}^2$, and we assume $0 \leq a < b \leq 2\pi$. Here one is studying the diffraction of waves by a wedge. In the limiting case $a = 0$, $b = 2\pi$, the wedge becomes a half-line, that is,

$$M = \mathbb{R}^2 \setminus \{(x_1, 0) : x_1 > 0\} \qquad [16]$$

Singularities of solutions to [1] on $\mathbb{R} \times M$ with such a boundary condition as [4] or [5] propagate in the interior of $M$ and reflect off the regular points of $\partial M$ as before. If a family of continuous, piecewise smooth curves $\Sigma_t$ carrying the singularity of $u$ hit the corner $x = 0$ at $t = a$, this reflection creates a tear in $\Sigma_t$ for $t > a$. In addition, a diffracted wave spreads out from the corner at unit speed. This diffracted wave carries a singularity that is weaker than that of the incident wave. For example, if one has a solution like [8], but shifted to have support in a disk of radius $|t|$ about a point $p \neq 0$ in $\mathbb{R}^2$, for small $|t|$, then the diffracted wave will have a jump discontinuity.

The space $M$ in [15] is a special case of a cone. More generally, if $N$ is a complete Riemannian

manifold (possibly with boundary), then the cone $C(N)$ with base $N$ is the set

$$C(N) = [0, \infty) \times N \qquad [17]$$

with all points $(0, x)$, $x \in N$, identified, with the metric tensor

$$ds^2 = dr^2 + r^2 g \qquad [18]$$

where $g$ is the metric tensor on $N$, and points on $C(N)$ are denoted $(r, x), r \in [0, \infty), x \in N$. The space in [14] has the form $M = C(N)$ with $N = [a, b]$, an interval. A cone in Euclidean space $\mathbb{R}^n$ is of the form $C(N)$ with $N$ a domain in the unit sphere $S^{n-1}$.

The propagation of singularities for solutions to [1] on $C(N)$, when $N$ has smooth boundary, has a description similar to that above for the case [15]. Again, there is a diffracted wave set off from the conic point $\{r = 0\}$ when a singularity of a wave hits it. The diffracted wave is typically $(n - 1)/2$ units smoother than the singular wave producing it, where $n = \dim C(N)$. For example, the fundamental solution to the wave equation on $C(N)$ produces a diffracted wave which is the sum of a jump discontinuity and (in general) a logarithmic singularity.

In fact, precise understanding of the behavior of the fundamental solution to the wave equation on $C(N)$ is encoded in terms of the behavior of the solution operator to the wave equation on the base $N$. This is discussed in further detail in the section on harmonic analysis. In the case where $C(N)$ is given by [15], we are dealing with the wave equation on an interval $[a, b]$, whose behavior is elementary.

One can use analysis of [15] together with finite propagation speed to get a good qualitative picture of diffraction of waves in $\mathbb{R}^2$ by a polygonal obstacle. A variation of this argument allows one to understand the behavior of the wave equation on a "polygonal" domain $N$ in $S^2$, that is, one whose boundary consists of a finite number of geodesic segments in $S^2$. Going from there to $C(N)$, one can then analyze diffraction of waves in $\mathbb{R}^3$ by a polyhedron.

It is worth remarking how the "shadow region" for such an obstacle as a wedge in $\mathbb{R}^2$ differs from that in [12]–[14]. For example, if one considers $M$ given by [16] and $u(t, x) = \delta(x_2 - t)$, for $t < 0$, then the region

$$\mathcal{S} = \{x = (x_1, x_2) : x_1, x_2 > 0\} \qquad [19]$$

is the "shadow region," in the sense that rays either missing or reflecting off the obstacle $\{(x_1, 0) : x_1 > 0\}$ do not enter the region [19]. However, unlike the case [13], the solution $u(t, x)$ is not smooth in the region [19] for $t > 0$. There is a singularity there, although it is weaker than the singularity of the main wave.

Taking Cartesian products of spaces of the form [15] with $\mathbb{R}^k$ yields spaces with $k$-dimensional edges. There are also spaces with curvy edges. Rather than continuing with further general description, one more particular case is discussed next, which has had a historical significance. Namely, we consider the reflection of waves in $\mathbb{R}^3$ off a disk, that is, take

$$M = \mathbb{R}^3 \setminus D, \quad D = \left\{(x_1, x_2, 0) : x_1^2 + x_2^2 \le 1\right\} \qquad [20]$$

Consider a wave given for $t < 0$ by $u(t, x) = \delta(x_3 - t)$. This wave hits $D = \partial M$ at $t = 0$, giving off a diffracted wave, traveling away from $\sigma = \{(x_1, x_2, 0) : x_1^2 + x_2^2 = 1\}$ at speed 1 for $t > 0$. This diffracted wave carries a singularity that blows up like the $-1/2$ power of the distance to the torus of points of distance $t$ from $\sigma$, for $t \in (0, 1)$. For $t > 1$, there is a focusing effect along the $x_3$-axis, producing a stronger singularity for $u(t, x)$ there.

This sort of phenomenon was understood, at least from a heuristic point of view, in the nineteenth century, and it played a role in an important argument of Poisson. At the time, there was a debate about whether the propagation of light was a wave phenomenon. Poisson did not think it was, and he noted that if it were, the light waves propagated past such an obstacle should produce a bright spot along the axis normal to the disk and through its center. The experiment was performed and the bright spot was observed. This is now called the Poisson spot, and its occurrence convinced many physicists, including Poisson, that the propagation of light is a wave phenomenon.

## Harmonic Analysis and the Wave Equation

The wave equation [1] with Cauchy data [3] can be regarded as an operator differential equation, with solution

$$u(t, x) = \cos t\sqrt{-\Delta}\, f(x) + \frac{\sin t\sqrt{-\Delta}}{\sqrt{-\Delta}}\, g(x) \qquad [21]$$

This brings one to investigate functions of the self-adjoint operator $\Delta$. If $M = \mathbb{R}^n$, one can do this using the Fourier transform, which is given by

$$\mathcal{F}f(\xi) = \hat{f}(\xi) = (2\pi)^{-n/2} \int f(x) e^{-ix\cdot\xi}\, dx \qquad [22]$$

One defines $\mathcal{F}^*$ by changing $e^{-ix\cdot\xi}$ to $e^{ix\cdot\xi}$ in [22], and the Fourier inversion formula says $\mathcal{F}$ and $\mathcal{F}^*$ are

inverses of each other on various function spaces, including $L^2(\mathbb{R}^n)$. Then one has

$$\varphi(\sqrt{-\Delta})f(x) = (2\pi)^{-n/2} \int \varphi(|\xi|)\hat{f}(\xi)\mathrm{e}^{\mathrm{i}x\cdot\xi}\,\mathrm{d}\xi \qquad [23]$$

Note that [23] is equal to

$$\int \Phi(x-y)f(y)\,\mathrm{d}y = \Phi * f(x) \qquad [24]$$

where

$$\Phi(x) = (2\pi)^{-n} \int \varphi(|\xi|)\mathrm{e}^{\mathrm{i}x\cdot\xi}\,\mathrm{d}\xi \qquad [25]$$

In particular, [21] becomes

$$u(t,x) = \frac{\partial}{\partial t}R_t * f(x) + R_t * g(x) \qquad [26]$$

where

$$R_t(x) = (2\pi)^{-n} \int \frac{\sin t|\xi|}{|\xi|}\mathrm{e}^{\mathrm{i}x\cdot\xi}\,\mathrm{d}\xi \qquad [27]$$

is the fundamental solution to the wave equation.

The integral [27] is not an easy integral when $n>1$, but the answer can be derived by analytic continuation from the Poisson kernel, that is,

$$\begin{aligned}\mathrm{e}^{-y\sqrt{-\Delta}}f(x) &= P_y * f(x)\\ P_y(x) &= C_n y(|x|^2+y^2)^{-(n+1)/2}\end{aligned} \qquad [28]$$

where $C_n = \pi^{-(n+1)/2}\Gamma((n+1)/2)$. One gets

$$R_t(x) = \lim_{\varepsilon\searrow 0}\frac{C_n}{n-1}\operatorname{Im}(|x|^2-(t-\mathrm{i}\varepsilon)^2)^{-(n-1)/2} \qquad [29]$$

Taking this limit for $n=2,3$ yields the formulas [8]–[9]. There are several ways to derive [28]. One, which is flexible and useful for other situations, derives it from the formula for the heat kernel,

$$\mathrm{e}^{t\Delta}f(x) = H_t * f(x), \quad H_t(x) = (4\pi t)^{-n/2}\,\mathrm{e}^{-|x|^2/4t} \qquad [30]$$

via the subordination identity:

$$\begin{aligned}\mathrm{e}^{-yA} &= \frac{y}{2\pi^{1/2}}\int_0^\infty \mathrm{e}^{-y^2/4t}\,\mathrm{e}^{-tA^2}t^{-3/2}\,\mathrm{d}t\\ &A>0, \quad y>0\end{aligned} \qquad [31]$$

with $A=\sqrt{-\Delta}$. The heat kernel can be computed via [23], which becomes a well-known Gaussian integral. The identity [31] can be proved using the fact that the Fourier integral formula for $P_y(x)$ is elementary to compute when $n=1$.

To understand functions of the Laplace operator on a cone $C(N)$, one uses

$$\Delta = \frac{\partial^2}{\partial r^2} + \frac{n-1}{r}\frac{\partial}{\partial r} + \frac{1}{r^2}\Delta_N \qquad [32]$$

where $\Delta_N$ is the Laplace operator on $N$, which follows from [2] and [18]. Here $n=\dim C(N)$. This is a modified Bessel operator. We define the operator

$$\nu = (-\Delta_N+\alpha^2)^{1/2}, \quad \alpha = -\frac{n-2}{2} \qquad [33]$$

For each $\nu_j$ in the spectrum of $\nu$, we consider the Hankel transform

$$H_{\nu_j}g(\lambda) = \int_0^\infty g(r)J_{\nu_j}(\lambda r)r\,\mathrm{d}r \qquad [34]$$

where $J_{\nu_j}$ is the Bessel function of order $\nu_j$. The Hankel inversion formula says $H_{\nu_j}$ is unitary on $L^2(\mathbb{R}^+, r\,\mathrm{d}r)$, and is its own inverse. Consequently, we can write the action of $\varphi(\sqrt{-\Delta})$ on $L^2(C(N))$ as

$$\varphi(\sqrt{-\Delta})g(r,x) = \int_0^\infty K_\varphi(r,s,\nu)g(s,x)s^{n-1}\,\mathrm{d}s \qquad [35]$$

where $K_\varphi(r,s,\nu)$ is a family of operators on $L^2(N)$, given by

$$K_\varphi(r,s,\nu) = (rs)^\alpha \int_0^\infty \varphi(\lambda)J_\nu(\lambda r)J_\nu(\lambda s)\lambda\,\mathrm{d}\lambda \qquad [36]$$

To obtain the wave kernel on $C(N)$, one can analytically continue formulas for the Poisson kernel, for $\mathrm{e}^{-y\sqrt{-\Delta}}$. Such formulas arise from the Lipschitz–Hankel identity:

$$\begin{aligned}&\int_0^\infty \mathrm{e}^{-y\lambda}J_\nu(r\lambda)J_\nu(s\lambda)\,\mathrm{d}\lambda\\ &\quad = \frac{1}{\pi}(rs)^{-1/2}Q_{\nu-1/2}\left(\frac{r^2+s^2+y^2}{2rs}\right)\end{aligned} \qquad [37]$$

Here $Q_{\nu-1/2}(\tau)$ is a Legendre function. The identity [37] is one of the more difficult identities in the theory of Bessel functions. It is useful to know that it can be derived by applying a slight variant of the subordination identity [31] to the more elementary identity

$$\int_0^\infty \mathrm{e}^{-t\lambda^2}J_\nu(r\lambda)J_\nu(s\lambda)\lambda\,\mathrm{d}\lambda = \frac{1}{2t}\mathrm{e}^{-(r^2+s^2)/4t}I_\nu\left(\frac{rs}{2t}\right) \qquad [38]$$

(where $I_\nu(y)=\mathrm{e}^{-\pi\mathrm{i}\nu/2}J_\nu(\mathrm{i}y)$ for $y>0$), which describes the behavior of the heat kernel on $C(N)$.

Carrying out the analytic continuation of [37] to imaginary $y$ yields results stated in the section on basic propagation phenomena, once one

understands the behavior of families of functions of the operator $\nu$ so produced. An approach taken by Cheeger and Taylor (1982) to this was to synthesize these operators from $e^{is\nu}$, $s \in \mathbb{R}$, and deduce their behavior from the behavior of the solution operator to the wave equation on the base $N$.

One can apply similar considerations to $M = \mathbb{R}^n \setminus B$, which is the truncated cone $[1, \infty) \times S^{n-1}$, with metric tensor [18], where $g$ is the metric tensor on $S^{n-1}$, and Laplace operator given by [32], with $\Delta_N$ the Laplace operator on $S^{n-1}$. The problem of diffraction of waves by the ball $B$ can be recast as solving

$$\frac{\partial^2 u}{\partial t^2} - \Delta u = 0 \quad \text{on } \mathbb{R} \times M \\ u|_{\mathbb{R}\times\partial M} = f, \quad u(t,x) = 0 \quad \text{for } t \ll 0 \tag{39}$$

with $f$ compactly supported on $\mathbb{R} \times \partial M$. Taking the partial Fourier transform with respect to $t$ yields the reduced wave equation

$$(\Delta + \lambda^2)v = 0 \quad \text{for } |x| > 1, \quad v|_{S^{n-1}} = g(x, \lambda) \tag{40}$$

and the condition $u(t,x) = 0$ for $t \ll 0$ yields for $v$ the outgoing radiation condition

$$r^{(n-1)/2}\left(\frac{\partial v}{\partial r} - i\lambda v\right) \to 0 \quad \text{as } r \to \infty \tag{41}$$

The solution is

$$v(x, \lambda) = r^{-(n-2)/2} \frac{H_\nu^{(1)}(\lambda r)}{H_\nu^{(1)}(\lambda)} g(x, \lambda) \tag{42}$$

with $\nu$ as in [33] and $H^{(1)}$ the Hankel function.

The behavior of $H_{\nu_j}^{(1)}(\lambda r)/H_{\nu_j}^{(1)}(\lambda)$ as $\nu_j, \lambda \to \infty$ with ratio in a small neighborhood of 1 can be shown to control the behavior of the solution $u$ to [39] near grazing rays. There is an asymptotic formula for this, which is one of the most delicate analytical results in the theory of Bessel functions. The result is that, uniformly for $z$ near 1, as $\mu \to \infty$,

$$H_\mu^{(1)}(\mu z) \sim 2e^{-\pi i/3}\left(\frac{4\zeta}{1 - z^2}\right)^{1/4} \times \left\{ A_+(\mu^{2/3}\zeta) \sum_{k \geq 0} a_k(\zeta)\mu^{1/3-2k} + A_+'(\mu^{2/3}\zeta) \sum_{k \geq 0} b_k(\zeta)\mu^{5/3-2k} \right\} \tag{43}$$

Here

$$A_+(\xi) = \mathrm{Ai}(e^{-2\pi i/3}\xi) \tag{44}$$

where Ai is the Airy function. The coefficients $a_k(\zeta)$ and $b_k(\zeta)$ are smooth functions of their argument, $\zeta = \zeta(z)$, which is defined by

$$\frac{2}{3}\zeta^{3/2} = \int_z^1 \sqrt{1 - t^2}\,\frac{dt}{t} \tag{45}$$

Making use of [43] in [44], one can obtain a parametrix for $u$ (i.e., a solution modulo a $C^\infty$ error) whose form is a special case of the formula [50], which we will present in the next section.

## Geometrical Optics and Extensions

By results of the last section, the solution to [1] when $M = \mathbb{R}^n$ has the form

$$u(t, x) = \sum_{\pm} \int e^{\pm it|\xi| + ix\cdot\xi}\hat{h}_\pm(\xi)\, d\xi \tag{46}$$

where the functions $h_\pm$ are produced from the initial data via simpler transformations. For a general metric tensor, one can produce a parametrix (i.e., an approximation to $u(t,x)$ with a $C^\infty$ error) in the following form:

$$u(t, x) = \sum_{\pm} \int a^\pm(t, x, \xi)\, e^{i\varphi^\pm(t,x,\xi)}\hat{h}_\pm(\xi)\, d\xi \tag{47}$$

Here the phase functions $\varphi^\pm(t,x,\xi)$ are smooth for $\xi \neq 0$ and homogeneous of degree 1 in $\xi$. The amplitudes $a^\pm(t,x,\xi)$ are smooth and have asymptotic expansions as $|\xi| \to \infty$:

$$a^\pm(t, x, \xi) \sim \sum_{k \geq 0} a_k^\pm(t, x, \xi) \tag{48}$$

with $a_k^\pm(t,x,\xi)$ homogeneous of degree $-k$ in $\xi$. One applies $\partial_t^2 - \Delta$ to both sides of [47], and obtains an operator of a similar form, with new amplitudes $b^\pm(t,x,\xi) \sim \sum b_k^\pm(t,x,\xi)$. Setting the terms in this asymptotic expansion equal to zero yields, first for $\varphi^\pm(t,x,\xi)$, a partial differential equation known as the eikonal equation:

$$\frac{\partial \varphi^\pm}{\partial t} = \pm|\nabla_x \varphi^\pm| \tag{49}$$

where $|v|$ is the norm of a vector $v \in T_x M$, determined by the metric tensor. Setting $b_k^\pm(t,x,\xi) = 0$ for $k \geq 1$ yields linear differential equations for the amplitude terms in [48], known as transport equations.

Operators of the form [47] are special cases of Fourier integral operators. Seminal works of Keller (1953) and Lax (1957) gave an important stimulus to work on these operators, and work of Hörmander (1971) turned this into a systematic and powerful theory. A particular advance regards

producing a parametrix valid for all $t$. Generally, one can solve [49] and the associated transport equations for $t$ in some interval, past which the eikonal equation might break down. Hörmander's theory treats products of Fourier integral operators, yielding global constructions. This facilitates the treatment of caustics mentioned earlier. Stationary-phase methods can be brought to bear to relate the singularities of $Th$ to those of $h$, when $T$ is a Fourier integral operator.

To construct parametrices for waves reflecting off a boundary, one can again reduce the problem to one of the form [39]. Waves that reflect transversally are given by parametrices of the form [47], although with the role of the variables changed, so that $t$ in [47]–[49] is replaced by a coordinate that vanishes on $\mathbb{R} \times \partial M$.

A parametrix that treats grazing rays can be written in the form of a Fourier–Airy integral operator:

$$u(y) = \int_{\mathbb{R}^n} \left[ a\, A_+(\zeta) + \mathrm{i}|\xi|^{-1/3} b\, A'_+(\zeta) \right] \times A_+(\zeta_0)^{-1} \, \mathrm{e}^{\mathrm{i}\theta} \widehat{F}(\xi) \, \mathrm{d}\xi \qquad [50]$$

Here $y = (y_1, \ldots, y_{n+1})$ denotes a coordinate system on a neighborhood of a boundary point of $\mathbb{R} \times M$, with $y_{n+1} = 0$ on $\mathbb{R} \times \partial M$. We have a pair of phase functions $\theta(y, \xi)$ and $\zeta(y, \xi)$, homogeneous in $\xi$ of degree 1 and 2/3, respectively, and a pair of amplitudes $a(y, \xi)$ and $b(y, \xi)$, each having asymptotic expansions of the form [48]. The function $A_+$ is the Airy function [44]. The phase functions satisfy a coupled pair of eikonal equations:

$$\begin{aligned} \langle \nabla_y \theta, \nabla_y \theta \rangle + \zeta \langle \nabla_y \zeta, \nabla_y \zeta \rangle &= 0 \\ \langle \nabla_y \theta, \nabla_y \zeta \rangle &= 0 \end{aligned} \qquad [51]$$

where $\langle \cdot, \cdot \rangle$ denotes the Lorentz inner product on $T_y(\mathbb{R} \times M)$ given by $\mathrm{d}t^2 - g$. More precisely, [51] is to hold in the region where $\zeta \le 0$, and also to infinite order at $y_{n+1} = 0$, for $\zeta \ge 0$. One requires $\partial\theta/\partial\xi_j$ to have linearly independent $y$-gradients, for $j = 1, \ldots, n$, and

$$\zeta(y, \xi) = \zeta_0(\xi) = \xi_1^{-1/3} \xi_n \quad \text{for } y_{n+1} = 0 \qquad [52]$$

The terms in the asymptotic expansions of $a(y, \xi)$ and $b(y, \xi)$ satisfy coupled systems of transport equations. One can arrange that $b(y, \xi) = 0$ for $y_{n+1} = 0$. Then $u|_{\mathbb{R}\times\partial M} = TF$, where $T$ is a Fourier integral operator, which can be inverted, modulo a smooth error, by Hörmander's theory, producing a parametrix for [39].

The construction of solutions to [51] satisfying [52] is due to Melrose. This followed earlier works of Ludwig (1967), Melrose (1975), and Taylor (1976), which produced solutions satisfying [52] to infinite order at $\xi_n = 0$. This earlier construction is adequate to produce a grazing ray parametrix, but the sharper result [52] is extremely valuable for constructing a gliding ray parametrix. This has the form

$$u(y) = \int_{\mathbb{R}^n} [a \ \mathrm{Ai}(\zeta) + \mathrm{i}|\xi|^{-1/3} b \, \mathrm{Ai}'(\zeta)] \times \mathrm{Ai}(\zeta_0)^{-1} \, \mathrm{e}^{\mathrm{i}\theta} \widehat{F}(\xi) \, \mathrm{d}\xi \qquad [53]$$

It differs from [50] in the use of Ai rather than $A_+$. Since Ai has real zeros, it is also convenient to pick $T > 0$ and evaluate $\theta, \zeta, a$, and $b$ at $(\xi_1, \ldots, \xi_{n-1}, \xi_n + \mathrm{i}T)$, and take $\zeta_0 = \xi^{-1/3}(\xi_n + \mathrm{i}T)$. The treatment of the eikonal and transport equations is as above, though the Fourier–Airy integral operator [50] has a different behavior from [53], reflecting the difference between how singularities in solutions to the wave equation are carried by grazing and by gliding rays.

# Wavelets: Application to Turbulence

## Introduction about Turbulence and Wavelets

### What is Turbulence?

Turbulence is a highly nonlinear regime encountered in fluid flows. Such flows are described by continuous fields, for example, velocity or pressure, assuming that the characteristic scale of the fluid motions is much larger than the mean free path of the molecular motions. The prediction of the spacetime evolution of fluid flows from first principles is given by the solutions of the Navier–Stokes equations. The turbulent regime develops when the nonlinear term of Navier–Stokes equations strongly dominates the linear term; the ratio of the norms of both terms is the Reynolds number *Re*, which characterizes the level of turbulence. In this regime nonlinear instabilities dominate, which leads to the flow sensitivity to initial conditions and unpredictability.

The corresponding turbulent fields are highly fluctuating and their detailed motions cannot be predicted. However, if one assumes some statistical stability of the turbulence regime, averaged quantities, such as mean and variance, or other related quantities, for example, diffusion coefficients, lift or drag, may still be predicted.

When turbulent flows are statistically stationary (in time) or homogeneous (in space), as it is classically supposed, one studies their energy spectrum, given by the modulus of the Fourier transform of the velocity autocorrelation.

Unfortunately, since the Fourier representation spreads the information in physical space among the phases of all Fourier coefficients, the energy spectrum loses all structural information in time or space. This is a major limitation of the classical way of analyzing turbulent flows. This is why we have proposed to use the wavelet representation instead and define new analysis tools that are able to preserve time and space locality.

The same is true for computing turbulent flows. Indeed, the Fourier representation is well suited to study linear motions, for which the superposition principle holds and whose generic behavior is, either to persist at a given scale, or to spread to larger ones. In contrast, the superposition principle does not hold for nonlinear motions, their archetype being the turbulent regime, which therefore cannot be decomposed into a sum of independent motions that can be separately studied. Generically, their evolution involves a wide range of scales, exciting smaller and smaller ones, even leading to finite-time singularities, e.g., shocks. The "art" of predicting the evolution of such nonlinear phenomena consists of disentangling the active from the passive elements: the former should be deterministically computed, while the latter could either be discarded or their effect statistically modeled. The wavelet representation allows to analyze the dynamics in both space and scale, retaining only those degrees of freedom which are essential to predict the flow evolution. Our goal is to perform a kind of "distillation" and retain only the elements which are essential to compute the nonlinear dynamics.

### How One Studies Turbulence?

When studying turbulence one is uneasy about the fact that there are two different descriptions, depending on which side of the Fourier transform one looks from.

- On the one hand, looking from the Fourier space representation, one has a theory which assumes the existence of a nonlinear cascade in an intermediate range of wavenumbers sets, called the "inertial range" where energy is conserved and transferred towards high wavenumbers, but only on average (i.e., considering either ensemble or time or space averages). This implies that a turbulent flow is excited at wavenumbers lower than those of the inertial range and dissipated at wavenumbers higher. Under these hypotheses, the theory predicts that the slope of the energy spectrum in the inertial range scales as $k^{-5/3}$ in dimension 3 and as $k^{-3}$ in dimension 2, $k$ being the wavenumber, i.e., the modulus of the wave vector.
- On the other hand, if one studies turbulence from the physical space representation, there is not yet any universal theory. One relies instead on empirical observations, from both laboratory and numerical experiments, which exhibit the formation and persistence of coherent vortices, even at very high Reynolds numbers. They correspond to the condensation of the vorticity field into some organized structures that contain most of the energy ($L^2$-norm of velocity) and enstrophy ($L^2$-norm of vorticity).

Moreover, the classical method for modeling turbulent flows consists in neglecting high-wavenumber motions and replacing them by their average, supposing their dynamics to be either linear or slaved to the low wavenumber motions. Such a method would work if there exists a clear separation between low and high wavenumbers, that is, a spectral gap.

Actually, there is now strong evidence, from both laboratory and direct numerical simulation (DNS) experiments, that this is not the case. Conversely, one observes that turbulent flows are nonlinearly active all along the inertial range and that coherent vortices seem to play an essential dynamical role there, especially for transport and mixing. One may then ask the following questions: Are coherent vortices the elementary building blocks of turbulent flows? How can we extract them? Do their mutual interactions have a universal character? Can we compress turbulent flows and compute their evolution with a reduced number of degrees of freedom corresponding to the coherent vortices?

The DNS of turbulent flows, based on the integration of the Navier–Stokes equations using either grid points in physical space or Fourier modes in spectral space, requires a number of degrees of freedom per time step that varies as $Re^{9/4}$ in dimension 3 (and as $Re$ in dimension 2). Due to the inherent limitation of computer performances, one can presently only perform DNS of turbulent flows up to Reynolds numbers $Re = 10^6$. To compute higher Reynolds flows, one should then design *ad hoc* turbulence models, whose parameters are empirically adjusted to each type of flows, in particular to their geometry and boundary conditions, using data from either laboratory or numerical experiments.

### What are Wavelets?

The wavelet transform unfolds signals (or fields) into both time (or space) and scale, and possibly directions in dimensions higher than 1. The starting point is a function $\psi \in L^2(R)$, called the "mother wavelet", which is well localized in physical space $x \in \mathbb{R}$, is oscillating ($\psi$ has at least a vanishing integral, or better, its first $m$ moments vanish), and is smooth (its Fourier transform $\hat{\psi}(k)$ exhibits fast decay for wave numbers $|k|$ tending to infinity). The mother wavelet then generates a family of dilated and translated wavelets

$$\psi_{a,b}(x) = a^{-1/2}\psi\left(\frac{x-b}{a}\right)$$

with $a \in R^+$ the scale parameter and $b \in R$ the position parameter, all wavelets being normalized in $L^2$-norm.

The wavelet transform of a function $f \in L^2(R)$ is the inner product of $f$ with the analyzing wavelets $\psi_{a,b}$, which gives the wavelet coefficients: $\widetilde{f}(a,b) = \langle f, \psi_{a,b}\rangle = \int f(x)\psi_{a,b}(x)\,\mathrm{d}x$. They measure the fluctuations of $f$ around the scale $a$ and the position $b$. $f$ can then be reconstructed without any loss as the inner product of its wavelet coefficients $\widetilde{f}$ with the analyzing wavelets

$$\psi_{a,b} \ : f(x) = C_\psi^{-1} \int\!\!\int \widetilde{f}(a,\ b)\ \psi_{a,b}(x) a^{-2} \mathrm{d}a\,\mathrm{d}b$$

$C_\psi = \int |\hat{\psi}|^2 |k|^{-1}\,\mathrm{d}k$ being a constant which depends on the wavelet $\psi$.

Like the Fourier transform, the wavelet transform realizes a change of basis from physical space to wavelet space which is an isometry. It thus conserves the inner product (Plancherel theorem), and in particular energy (Parseval's identity). Let us mention that, due to the localization of wavelets in physical space, the behavior of the signal at infinity does not play any role. Therefore, the wavelet analysis and synthesis can be performed locally, in contrast to the Fourier transform where the nonlocal nature of the trigonometric functions does not allow to perform a local analysis.

Moreover, wavelets constitute building blocks of various function spaces out of which some can be used to contruct orthogonal bases. The main difference between the continuous and the orthogonal wavelet transforms is that the latter is non-redundant, but only preserves the invariance by translation and dilation only for a discrete subset of wavelet space which corresponds to the dyadic grid $\lambda = (j, i)$, for which scale is sampled by octaves $j$ and space by positions $2^{-j}i$. The advantage is that all orthogonal wavelet coefficients are decorrelated, which is not the case for the continuous wavelet transform whose coefficients are redundant and correlated in space and scale. Such a correlation can be visualized by plotting the continuous wavelet coefficients of a white noise and the patterns one thus observes are due to the reproducing kernel of the continuous wavelet transform, which corresponds to the correlation between the analyzing wavelets themselves.

In practice, to analyze turbulent signals or fields, one should use the continuous wavelet transform with complex-valued wavelets, since the modulus of the wavelet coefficients allows to read the evolution of the energy density in both space (or time) and scales. If one uses real-valued wavelets instead, the modulus of the wavelet coefficients will present the same oscillations as the analyzing wavelets and it will then become difficult to sort out features

belonging to the signal or to the wavelets. In the case of complex-valued wavelets, the quadrature between the real and the imaginary parts of the wavelet coefficients eliminates these spurious oscillations; this is why we recommend to use complex-valued wavelets, such as the Morlet wavelet. To compress turbulent flows, and *a fortiori* to compute their evolution at a reduced cost, compared to standard methods (finite difference, finite volume, or spectral methods), one should use orthogonal wavelets. This avoids redundancy, since one has the same number of grid points as wavelet coefficients. Moreover there exists a fast algorithm to compute the orthogonal wavelet coefficients which is even faster than the fast Fourier transform, having $O(N)$ operations instead of $O(N \log_2 N)$.

The first paper about the continuous wavelet transform has been published by Grossmann and Morlet (1984). Then, discrete wavelets were constructed, leading to frames (Daubechies *et al.* 1986) and orthogonal bases (Lemarié and Meyer, 1986). From there the formalism of multiresolution analysis (MRA) has been constructed which led to the fast wavelet algorithm (Mallat 1989). The first application of wavelets to analyze turbulent flows has been published by Farge and Rabreau (1988). Since then a long-term research program has been developed for analyzing, computing and modeling turbulent flows using either continuous wavelets, orthogonal wavelets, or wavelet packets.

## Wavelet Analysis

### Wavelet Spectra

**Wavelet space** To study turbulent signals one uses the continuous wavelet transform for analysis, and the orthogonal wavelet transform for compression and computation. To perform a continuous wavelet transform, one can choose:

- either a real-valued wavelet, such as the Marr wavelet, also called "Mexican hat," which is the second derivative of a Gaussian,

$$\psi(x) = (1 - x^2) \exp\left(\frac{-x^2}{2}\right) \qquad [1]$$

- or a complex-valued wavelet, such as the Morlet wavelet,

$$\begin{cases} \widehat{\psi}(k) = \dfrac{1}{2\pi} \exp\left(-\dfrac{(k-k_\psi)^2}{2}\right) & \text{for } k > 0 \\ \widehat{\psi}(k) = 0 \quad \text{for } k \leq 0 \end{cases} \qquad [2]$$

with the wavenumber $k_\psi$ denoting the barycenter of the wavelet support in Fourier space computed as

$$k_\psi = \frac{\int_0^\infty k|\widehat{\psi}(k)|\mathrm{d}k}{\int_0^\infty |\widehat{\psi}(k)|\mathrm{d}k} \qquad [3]$$

For the orthogonal wavelet transform, there is a large collection of possible wavelets and the choice depends on which properties are preferred, for instance: compact support, symmetry, smoothness, number of cancelations, computational efficiency.

From our own experience, we tend to prefer the Coifman wavelet 12, which is compactly supported, has four vanishing moments, is quasi-symmetric, and is defined with a filter of length 12, which leads to a computational cost for the fast wavelet transform in $24N$ operations, since two filters are used.

As stated above, we recommend the complex-valued continuous wavelet transform for analysis. In this case, one plots the modulus and the phase of the wavelet coefficients in wavelet space, with a linear horizontal axis for the position $b$, and a logarithmic vertical axis for the scale $a$, with the largest scale at the bottom and the smallest scale at the top.

In **Figure 1a** we show the wavelet analysis of a turbulent signal, corresponding to the time evolution of the velocity fluctuations of two successive vortex breakdowns, measured by hot-wire anemometry at $N = 32768 = 2^{15}$ instants (Cuypers *et al.* 2003). The modulus of the wavelet coefficients (**Figure 1b**) shows that during the vortex breakdown, which is due to strong nonlinear flow instability, energy is spread over a wide range of scales. The phase of the wavelet coefficients (**Figure 1c**) is plotted only where the modulus is non-negligible, otherwise the phase information would be meaningless. In **Figure 1c**, one observes that the lines of constant phase point towards the instants where the signal is less regular, that is, during vortex breakdowns.

**Local wavelet spectrum** Since the wavelet transform conserves energy and preserves locality in physical space, one can extend the concept of energy spectrum and define a local energy spectrum, such that

$$\widetilde{E}(k,x) = \frac{1}{C_\psi k_\psi}\left|\widetilde{f}\left(\frac{k_\psi}{k}, x\right)\right|^2 \quad \text{for } k \geq 0 \qquad [4]$$

where $k_\psi$ is the centroid wavenumber of the analyzing wavelet $\psi$ and $C_\psi$ is defined in the

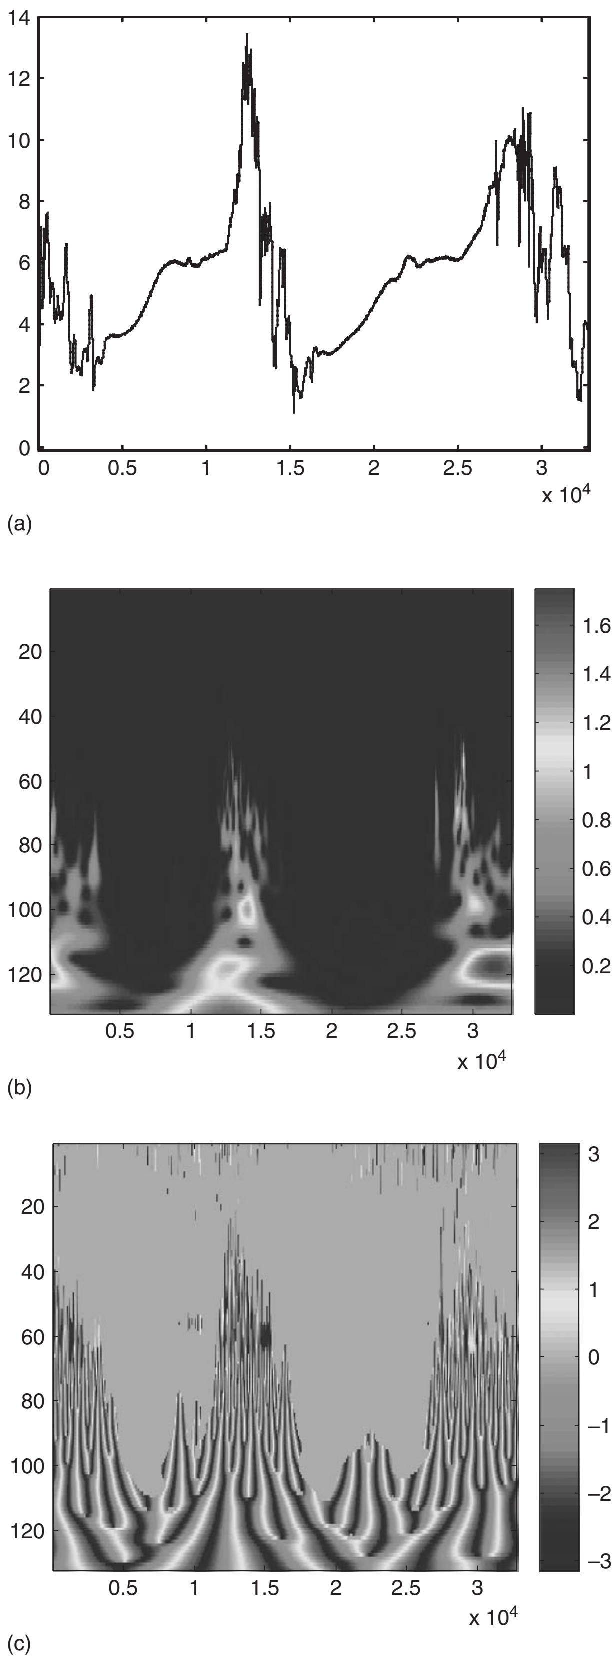

**Figure 1** Example of a one-dimensional continuous wavelet analysis. (a) the signal to be analyzed, (b) the modulus of its wavelet coefficients, (c) the phase of its wavelet coefficients.

admissibility condition (respectively, eqns [10] and [1] in the article Wavelets: Mathematical Theory).

By measuring $\widetilde{E}(k,x)$ at different instants or positions, one estimates which elements in the signal contribute most to the global Fourier energy spectrum, inorder to suggest a way to decompose the signal into different components. For example, if one considers turbulent flows, one can compare the energy spectrum of the coherent structures (such as isolated vortices in incompressible flows or shocks in compressible flows) and the energy spectrum of the incoherent background flow, since both elements exhibit different correlations and therefore different spectral slopes.

**Global wavelet spectrum** Although the wavelet transform analyzes the flow using localized functions rather than complex exponentials, one can show that the global wavelet energy spectrum converges towards the Fourier energy spectrum, provided the analyzing wavelet has enough vanishing moments. More precisely, the global wavelet spectrum, defined by integrating [4] over all positions,

$$\widetilde{E}(k) = \int_{-\infty}^{\infty} \widetilde{E}(k,x)\mathrm{d}x \qquad [5]$$

gives the correct exponent for a power-law Fourier energy spectrum $E(k) \propto k^{-\beta}$ if the analyzing wavelet has at least $M > (\beta - 1)/2$ vanishing moments. Thus, the steeper the energy spectrum one studies, the more vanishing moments the analyzing wavelet should have.

The inertial range which corresponds to the scales when turbulent flows are dominated by nonlinear interactions, exhibits a power-law behavior as predicted by the statistical theory of homogeneous and isotropic turbulence.

The ability to correctly evaluate the slope of the energy spectrum is an important property of the wavelet transform which is related to its ability to detect and characterize singularities. We will not discuss here how wavelet coefficients could be used to study singularities and fractal measures, since it is presented in detail elsewhere (*see* Wavelets: Applications).

### Relation to Classical Analysis

**Relation to Fourier spectrum** The global wavelet energy spectrum $\widetilde{E}(k)$ is actually a smoothed version of the Fourier energy spectrum $E(k)$. This can be

seen from the following relation between the two spectra:

$$\widetilde{E}(k) = \frac{1}{C_\psi k_\psi} \int_0^\infty E(k') \left| \widehat{\psi}\left(\frac{k_\psi k'}{k}\right) \right|^2 \mathrm{d}k' \qquad [6]$$

which shows that the global wavelet spectrum is an average of the Fourier spectrum weighted by the square of the Fourier transform of the analyzing wavelets at wavenumber $k$. Note that the larger $k$, the larger the averaging interval, because wavelets are bandpass filters with $\Delta k/k$ constant. This property of the global wavelet energy spectrum is particularly useful to study turbulent flows. Indeed, the Fourier energy spectrum of a single realization of a turbulent flow is too oscillating to be able to clearly detect a slope, while it is no more the case for the global wavelet energy spectrum, which is a better estimator of the spectral slope.

The real-valued Marr wavelet [1] has only two vanishing moments and thus can correctly measure the energy spectrum exponents up to $\beta < 5$. In the case of the complex-valued Morlet wavelet [2], only the zeroth-order moment is null, but the higher $m$th order moments are very small ($\propto k_\psi^m \, \mathrm{e}^{(-k_\psi^2/2)}$), provided that $k_\psi$ is larger than 5. For instance, the Morlet wavelet transform with $k_\psi = 6$ gives accurate estimates of the power–law exponent of the energy spectrum up to $\beta < 7$.

There is also a family of wavelets with an infinite number of cancelations

$$\widehat{\psi}_n(k) = \alpha_n \exp\left(-\frac{1}{2}\left(k^2 + \frac{1}{k^{2n}}\right)\right) \quad n \geq 1 \qquad [7]$$

where $\alpha_n$ is chosen for normalization.

These wavelets can therefore correctly measure any power–law energy spectrum, and thus detect the difference between a power–law energy spectrum and a Gaussian energy spectrum ($E(k) \propto \mathrm{e}^{(-(k/k_0)^2)}$). For instance, it is important in turbulence to determine the wavenumber after which the energy spectrum decays exponentially, since this wavenumber defines the end of the inertial range, dominated by nonlinear interactions, and the beginning of the dissipative range, dominated by linear dissipation.

**Relation to structure functions** In this subsection we will point out the limitations of classical measures of intermittency and present a set of wavelet-based alternatives.

The classical measures based on structure functions can be thought of as a special case of wavelet filtering using a nonsmooth wavelet defined as the difference of two Diracs (DOD). It is this lack of regularity of the underlying wavelet that limits the adequacy of classical measures to analyze smooth signals. Wavelet-based diagnostics can overcome these limitations, and produce accurate results, whatever the signal to be analyzed.

We will link the scale-dependent moments of the wavelet coefficients and the structure functions, which are classically used to study turbulence. In the case of second-order statistics, the global wavelet spectrum corresponds to the second-order structure function. Furthermore, a rigorous bound for the maximum exponent detected by the structure functions can be computed, but there is a way to overcome this limitation by using wavelets.

The increments of a signal, also called the modulus of continuity, can be seen as its wavelet coefficients using the DOD wavelet

$$\psi^\delta(x) = \delta(x+1) - \delta(x) \qquad [8]$$

We thus obtain

$$f(x+a) - f(x) = \widetilde{f}_{x,a} = \langle f, \psi^\delta_{x,a} \rangle \qquad [9]$$

with $\psi_{x,a}(y) = 1/a[\delta((y-x)/a+1) - \delta((y-x)/a)]$. Note that the wavelet is normalized with respect to the $L^1$-norm. The $p$th-order structure function $S_p(a)$ therefore corresponds to the $p$th-order moment of the wavelet coefficients at scale $a$

$$S_p(a) = \int (\widetilde{f}_{x,a})^p \mathrm{d}x \qquad [10]$$

As the DOD wavelet has only one vanishing moment (its mean), the exponent of the $p$th-order structure function in the case of a self-similar behavior is limited by $p$, that is, if $S_p(a) \propto a^{\zeta(p)}$, then $\zeta(p) < p$. To be able to detect larger exponents, one has to use increments with a larger stencil, or wavelets with more vanishing moments.

We now concentrate on the case $p = 2$, that is, the energy norm. Equation [6] gives the relation between the global wavelet spectrum $\widetilde{E}(k)$ and the Fourier spectrum $E(k)$ for an arbitrary wavelet $\psi$. For the DOD wavelet we find, since $\widehat{\psi^\delta}(k) = \mathrm{e}^{\mathrm{i}k} - 1 = \mathrm{e}^{\mathrm{i}k/2}(\mathrm{e}^{\mathrm{i}k/2} - \mathrm{e}^{\mathrm{i}\,k/2})$ and hence $|\widehat{\psi^\delta}(k)|^2 = 2(1 - \cos k)$, that

$$\widetilde{E}(k) = \frac{1}{C_\psi k} \int_0^\infty E(k') \left(2 - 2\cos\left(\frac{k_\psi k'}{k}\right)\right) \mathrm{d}k' \qquad [11]$$

Setting $a = k_\psi / k$, we see that the wavelet spectrum corresponds to the second-order structure function, such that

$$\widetilde{E}(k) = \frac{1}{C_\psi k} S_2(a) \qquad [12]$$

The above results show that, if the Fourier spectrum behaves like $k^{-\alpha}$ for $k \to \infty$, $\widetilde{E}(k) \propto k^{-\alpha}$ if $\alpha < 2M + 1$, where $M$ denotes the number of vanishing moments of the wavelets. Consequently, we find for $S_2(a)$ that $S_2(a) \propto a^{\zeta(p)} = (k_\psi/k)^{\zeta(p)}$ for $a \to 0$ if $\zeta(2) \leq 2M$. For the DOD wavelet, we have $M = 1$, therefore, the second-order structure function can only detect slopes smaller than 2, corresponding to an energy spectrum whose slope is shallower than $-3$. Thus, the usual structure functions give spurious results for sufficiently smooth signals. The relation between structure functions and wavelet coefficients can be generalized in the context of Besov spaces, which are classically used for nonlinear approximation theory (*see* Wavelets: Mathematical Theory).

#### Intermittency Measures

Intermittency is defined as localized bursts of high-frequency activity. This means that intermittent phenomena are localized in both physical and spectral spaces, and thus a suitable basis for representing intermittency should reflect this dual localization. The Fourier basis is well localized in spectral space, but delocalized in physical space. Therefore, when a turbulence signal is filtered using a high-pass Fourier transform and then reconstructed in physical space, for example, to calculate the flatness, some spatial information is lost. This leads to smoothing of strong gradients and spurious oscillations in the background, which come from the fact that the modulus and phase of the discarded high wavenumber Fourier modes have been lost. The spatial errors introduced by such a Fourier filtering lead to errors in estimating the flatness, and hence the signal's intermittency.

When a quantity (e.g., velocity derivative) is intermittent, it contains rare but strong events (i.e., bursts of intense activity), which correspond to large deviations reflected in the "heavy tails" of the PDF. Second-order statistics (e.g., energy spectrum, second-order structure function) are relatively insensitive to such rare events whose time or space supports are very small and thus do not dominate the integral. However, these events become increasingly important for higher-order statistics, where they finally dominate. High-order statistics therefore characterize intermittency. Of course, intermittency is not essential for all problems: second-order statistics are sufficient to measure dispersion (dominated by energy-containing scales), but not to calculate drag or mixing (dominated by vorticity production in thin boundary or shear layers).

To measure intermittency, one uses the space–scale information contained in the wavelet coefficients to define scale-dependent moments and moment ratios. Useful diagnostics to quantify the intermittency of a field $f$ are the moments of its wavelet coefficients at different scales $j$

$$M_{p,j}(f) = 2^{-j} \sum_{i=0}^{2^j-1} |\widetilde{f}_{j,i}|^p \qquad [13]$$

Note that the distribution of energy scale by scale, that is, the scalogram, can be computed from the second-order moment of the orthogonal wavelet coefficients: $E_j = 2^{j-1} M_{2,j}$. Due to orthogonality of the decomposition, the total energy is just the sum: $E = \sum_{j \geq 0} E_j$.

The sparsity of the wavelet coefficients at each scale is a measure of intermittency, and it can be quantified using ratios of moments at different scales

$$Q_{p,q,j}(f) = \frac{M_{p,j}(f)}{(M_{q,j}(f))^{p/q}} \qquad [14]$$

which may be interpreted as quotient norms computed in two different functional spaces, $L^p$-and $L^q$-spaces. Classically, one chooses $q = 2$ to define typical statistical quantities as a function of scale. Recall that for $p = 4$ we obtain the scale-dependent flatness $F_j = Q_{4,2,j}$. It is equal to 3 for a Gaussian white noise at all scales $j$, which proves that this signal is not intermittent. The scale-dependent skewness, hyperflatness, and hyperskewness are obtained for $p = 3, 5$, and 6, respectively. For intermittent signals $Q_{p,q,j}$ increases with $j$, whatever $p$ and $q$.

## Wavelet Compression

#### Principle

To study turbulent signals, we now propose to separate the rare and extreme events from the dense events, and then calculate their statistics independently. A major difficulty in turbulence research is that there is no clear scale separation between these two kinds of events. This lack of "spectral gap" excludes Fourier filtering for disentangling these two behaviors. Since the rare events are well

localized in physical space, one might try to use an on–off filter defined in physical space to extract them. However, this approach changes the spectral properties by introducing spurious discontinuities, adding an artificial scaling (e.g., $k^{-2}$ in one dimension) to the energy spectrum. To avoid these problems, we use the wavelet representation, which combines both physical and spectral space localizations (bounded from below by Heisenberg's uncertainty principle). In turbulence, the relevant rare events are the coherent vortices and the dense events correspond to the residual background flow. We have proposed a nonlinear wavelet filtering of the wavelet coefficients of vorticity to extract the coherent vortices out of turbulent flows. We now detail the different steps of this procedure.

### Extraction of Coherent Structures

**Principle** We propose a new method to extract coherent structures from turbulent flows, as encountered in fluids (e.g., vortices, shocklets) or plasmas (e.g., bursts), in order to study their role in transport and mixing.

We first replace the Fourier representation by the wavelet representation, which keeps track of both time and scale, instead of frequency only. The second improvement consists in changing our viewpoint about coherent structures. Since there is not yet a universal definition of coherent structures, we prefer starting from a minimal but more consensual statement about them, that everyone hopefully could agree with: "coherent structures are not noise." Using this apophatic method, we propose the following definition: "coherent structures are what remain after denoising."

For the noise we use the mathematical definition stating that a noise cannot be compressed in any functional basis. Another way to say this is to observe that the shortest description of a noise is the noise itself. Notice that often one calls "noise" what is actually "experimental noise," but not noise in the mathematical sense.

Considering our definition of coherent structures, turbulent signals can be split into two contributions: coherent bursts, corresponding to that part of the signal which can be compressed in a wavelet basis, and incoherent noise, corresponding to that part of the signal which cannot be compressed, neither in wavelets nor in any other basis. We will then check *a posteriori* that the incoherent contribution is spread, and therefore does not compress, in both Fourier and grid-point basis. Since we use the orthogonal wavelet representation, both coherent and incoherent components are orthogonal and therefore the $L^2$-norm, for example, energy or enstrophy, is a superposition of coherent and incoherent contributions (Mallat 1998).

Assuming that coherent structures are what remain after denoising, we need a model, not for the structures themselves, but for the noise. As a first guess, we choose the simplest model and suppose the noise to be additive, Gaussian and white, that is, uncorrelated. Having this model in mind, we use Donoho and Johnstone's theorem to compute the value to threshold the wavelet coefficients. Since the threshold value depends on the variance of the noise, which in the case of turbulence is not *a priori* known, we propose a recursive method to estimate it from the variance of the weakest wavelet coefficients, that is, those whose modulus is below the threshold value.

**Wavelet decomposition** We describe the wavelet algorithm to extract coherent vortices out of turbulent flows and apply it as example to a 3D turbulent flow. We consider the vorticity field $\boldsymbol{\omega} = \nabla \times \boldsymbol{v}$, computed at resolution $N = 2^{3J}, N$ being the number of grid points and $J$ the number of octaves in each spatial direction. Each vorticity component is developed into an orthogonal wavelet series from the largest scale $l_{\max} = 2^0$ to the smallest scale $l_{\min} = 2^{J-1}$ using a three-dimensional (3D) MRA:

$$\omega(\boldsymbol{x}) = \bar{\omega}_{0,0,0}\, \phi_{0,0,0}(\boldsymbol{x}) + \sum_{j=0}^{J-1} \sum_{i_x=0}^{2^j-1} \sum_{i_y=0}^{2^j-1} \sum_{i_z=0}^{2^j-1} \sum_{d=1}^{7} \tilde{\omega}^d_{j,i_x,i_y,i_z} \psi^d_{j,i_x,i_y,i_z}(\boldsymbol{x}) \qquad [15]$$

with $\phi_{j,i_x,i_y i,i_z}(\boldsymbol{x}) = \phi_{j,i_x}(x)\phi_{j,i_y}(y)\phi_{j,i_z}(z)$, and

$$\psi^d_{j,i_x,i_y,i_z}(\boldsymbol{x}) = \begin{cases} \psi_{j,i_x}(x)\phi_{j,i_y}(y)\phi_{j,i_z}(z) & d=1 \\ \phi_{j,i_x}(x)\psi_{j,i_y}(y)\phi_{j,i_z}(z) & d=2 \\ \phi_{j,i_x}(x)\phi_{j,i_y}(y)\psi_{j,i_z}(z) & d=3 \\ \psi_{j,i_x}(x)\phi_{j,i_y}(y)\psi_{j,i_z}(z) & d=4 \\ \psi_{j,i_x}(x)\psi_{j,i_y}(y)\phi_{j,i_z}(z) & d=5 \\ \phi_{j,i_x}(x)\psi_{j,i_y}(y)\psi_{j,i_z}(z) & d=6 \\ \psi_{j,i_x}(x)\psi_{j,i_y}(y)\psi_{j,i_z}(z) & d=7 \end{cases} \qquad [16]$$

where $\phi_{j,i}$ and $\psi_{j,i}$ are the one-dimensional scaling function and the corresponding wavelet, respectively. Due to orthogonality, the scaling coefficients are given by $\bar{\omega}_{0,0,0} = \langle \omega, \phi_{0,0,0} \rangle$ and the wavelet coefficients are given by $\tilde{\omega}^d_{j,i_x,i_y,i_z} = \langle \omega, \psi^d_{j,i_x,i_y,i_z} \rangle$, where $\langle \cdot,\cdot \rangle$ denotes the $L^2$-inner product.

**Nonlinear thresholding** The vorticity field is then split into $\boldsymbol{\omega}_C$ and $\boldsymbol{\omega}_I$ by applying a nonlinear thresholding to the wavelet coefficients. The threshold is defined as $\epsilon = (\frac{4}{3} Z \ln N)^{1/2}$. It only depends on the total enstrophy $Z = \frac{1}{2}\int |\boldsymbol{\omega}|^2 \mathrm{d}\boldsymbol{x}$ and on the number of grid points $N$ without any adjustable parameter. The choice of this threshold is based on theorems by Donoho and Johnstone proving optimality of the wavelet representation to denoise signals in the presence of Gaussian white noise, since this wavelet-based estimator minimizes the maximal $L^2$-error for functions with inhomogeneous regularity (Mallat 1998).

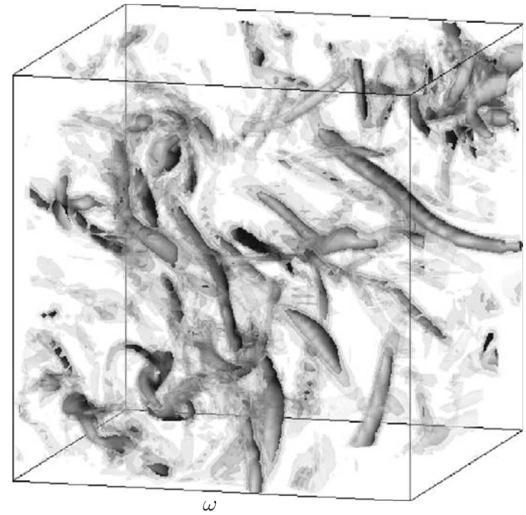
**Wavelet reconstruction** The coherent vorticity field $\boldsymbol{\omega}_C$ is reconstructed from the wavelet coefficients whose modulus is larger than $\epsilon$ and the incoherent vorticity field $\boldsymbol{\omega}_I$ from the wavelet coefficients whose modulus is smaller or equal to $\epsilon$. The two fields thus obtained, $\boldsymbol{\omega}_C$ and $\boldsymbol{\omega}_I$, are orthogonal, which ensures a separation of the total enstrophy into $Z = Z_C + Z_I$ because the interaction term $\langle \boldsymbol{\omega}_C, \boldsymbol{\omega}_I \rangle$ vanishes. We then use Biot–Savart's relation $\boldsymbol{v} = \nabla \times (\nabla^{-2}\boldsymbol{\omega})$ to reconstruct the coherent velocity $\boldsymbol{v}_C$ and the incoherent velocity $\boldsymbol{v}_I$ from the coherent and incoherent vorticities, respectively.

### Application to 3D Turbulence

We consider a 3D homogeneous isotropic turbulent flow, computed by DNS at resolution $N = 256^3$, which corresponds to a Reynolds number based on the Taylor microscale $R_\lambda = 168$ (Farge *et al.* 2003). The computation uses a pseudospectral code, with a Gaussian random vorticity field as initial condition, and the flow evolution is integrated until a statistically stationary state is reached. Figure 2 shows the modulus of the vorticity fluctuations of the total flow, zooming on a $64^3$ subcube to enhance structural details. The flow exhibits elongated, distorted, and folded vortex tubes, as observed in laboratory and numerical experiments.

We apply to the total flow the wavelet compression algorithm described above. We find that only 2.9% wavelet modes correspond to the coherent flow, which retains 79% of the energy ($L^2$-norm of velocity) and 75% of the enstrophy ($L^2$-norm of vorticity), while the remaining 97.1% incoherent modes contain only 1% of the energy and 21% of the enstrophy. We display the modulus of the coherent (Figure 3) and incoherent (Figure 4) vorticity fluctuations resulting from the wavelet decomposition.

Note that the values of the three isosurfaces chosen for visualization ($|\omega| = 6Z^{1/2}$, $8Z^{1/2}$ and $10Z^{1/2}$, with $Z$ the total enstrophy) are the same for the total and coherent vorticities, but they have been reduced by a factor 2 for the incoherent vorticity whose fluctuations are much smaller. In the coherent vorticity (Figure 3) we recognize the same vortex tubes as those present in the total vorticity (Figure 2). In contrast, the remaining vorticity (Figure 4) is much more homogeneous and



$\omega$

does not exhibit coherent structures. Hence, the wavelet compression retains all the vortex tubes and preserves their structure at all scales. Consequently, the coherent flow is as intermittent as the total flow, while the incoherent flow is structureless and non intermittent. Modeling the effect of the incoherent flow onto the coherent flow should then be much simpler than with methods based on Fourier filtering.

Figure 5 shows the velocity PDF in semilogarithmic coordinates. We observe that the coherent velocity has

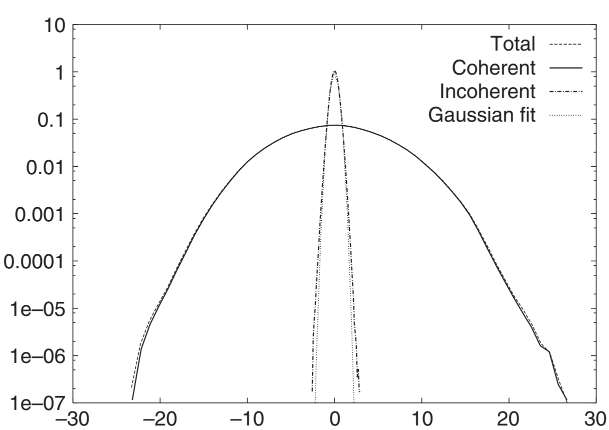

**Figure 5** Velocity PDF, resolution $N = 256^3$ with a zoom at $64^3$. the same Gaussian distribution as the total velocity, while the incoherent velocity remains Gaussian, but its variance is much smaller. The corresponding energy spectra are plotted on Figure 6. We observe that the spectrum of the coherent energy is identical to the spectrum of the total energy all along the inertial range. This implies that the vortex tubes are responsible for the $k^{-5/3}$ energy scaling, which corresponds to a long-range correlation, characteristic of 3D turbulence as predicted by Kolmogorov's theory. In contrast, the incoherent energy has a scaling close to $k^2$, which corresponds to an energy equipartition between all wave vectors $\boldsymbol{k}$, since the isotropic spectrum is obtained by integrating energy in 3D $\boldsymbol{k}$-space over 2D shells $k = |\boldsymbol{k}|$. The incoherent velocity field is therefore spatially uncorrelated, which is consistent with the observation that incoherent vorticity is structureless and homogeneous.

From these observations, we propose the following scenario to interpret the turbulent cascade: the coherent energy injected at large scales is transferred towards small scales by nonlinear interactions between vortex tubes. In the meantime, these nonlinear interactions also produce incoherent energy at all scales, which is dissipated at the smallest scales by molecular kinematic viscosity. Thus, the coherent flow causes direct transfer of the coherent energy into incoherent energy. Conversely, the incoherent flow does not trigger any energy transfer to the coherent flow, as it is structureless and uncorrelated. We conjecture that the coherent flow is dynamically active, while the incoherent flow is slaved to it, being only passively advected and mixed by the coherent vortex tubes. This is a different view from the classical interpretation since it does not suppose any scale separation. Both

coherent and incoherent flows are active all along the inertial range, but they are characterized by different probability distribution functions and correlations: non-Gaussian and long-range correlated for the former, while Gaussian and uncorrelated for the latter.

## Wavelet Computation

### Principle

The mathematical properties of wavelets (*see* Wavelets: Mathematical Theory) motivate their use for solving of partial differential equations (PDEs).

The localization of wavelets, both in scale and space, leads to effective sparse representations of functions and pseudodifferential operators (and their inverse) by performing nonlinear thresholding of the wavelet coefficients of the function and of the matrices representing the operators. Wavelet coefficients allow to estimate the local regularity of solutions of PDEs and thus can define autoadaptive discretizations with local mesh refinements. The characterization of function spaces in terms of wavelet coefficients and the corresponding norm equivalences lead to diagonal preconditioning of operators in wavelet space.

Moreover, the existence of the fast wavelet transform yields algorithms with optimal linear complexity. The currently existing algorithms can be classified in different ways. We can distinguish between Galerkin, collocation, and hybrid schemes. Hybrid schemes combine classical discretizations, for example, finite differences or finite volumes, and wavelets, which are only used to speed up the linear algebra and to define adaptive grids. On the other hand, Galerkin and collocation schemes employ wavelets directly for the discretization of the solution and the operators. Wavelet methods have been developed to solve Burger's, Stokes, Kuramoto–Sivashinsky, nonlinear Schrödinger, Euler, and Navier–Stokes equations. As an example, we present an adaptive wavelet algorithm, of Galerkin type, to solve the 2D Navier–Stokes equations.

### Adaptive Wavelet Scheme

We consider the 2D Navier–Stokes equations written in terms of vorticity $\omega$ and stream function $\Psi$, which are both scalars in two dimensions,

$$\partial_t \omega + \boldsymbol{v} \cdot \nabla \omega - \nu \nabla^2 \omega = \nabla \times \boldsymbol{F} \qquad [17]$$

$$\nabla^2 \Psi = \omega \quad \text{and} \quad \boldsymbol{v} = \nabla^{\perp} \Psi \qquad [18]$$

for $\boldsymbol{x} \in [0,1]^2, t > 0$. The velocity is denoted by $\boldsymbol{v}, \boldsymbol{F}$ is an external force, $\nu > 0$ is the molecular kinematic viscosity, and $\nabla^{\perp} = (-\partial_y, \partial_x)$.

The above equations are completed with boundary conditions and a suitable initial condition.

**Time discretization** Introducing a classical semi-implicit time discretization with a time step $\Delta t$ and setting $\omega^n(\boldsymbol{x}) \approx \omega(\boldsymbol{x}, n\Delta t)$, we obtain

$$(1 - \nu \Delta t \nabla^2)\omega^{n+1} = \omega^n + \Delta t(\nabla \times F^n - \boldsymbol{v}^n \cdot \nabla \omega^n) \qquad [19]$$

$$\nabla^2 \Psi^{n+1} = \omega^{n+1} \quad \text{and} \quad \boldsymbol{v}^{n+1} = \nabla^{\perp} \Psi^{n+1} \qquad [20]$$

Hence, in each time step two elliptic problems have to be solved and a differential operator has to be applied.

Formally the above equations can be written in the abstract form $Lu = f$, where $L$ is an elliptic operator with constant coefficients. This corresponds to a Helmholtz type equation for $\omega$ with $L = (1 - \nu \Delta t \nabla^2)$ and a Poisson equation for $\Psi$ with $L = \nabla^2$.

**Spatial discretization** For the spatial discretization, we use the method of weighted residuals, that is, a Petrov–Galerkin scheme. The trial functions are orthogonal wavelets $\phi$ and the test functions are operator adapted wavelets, called "vaguelettes," $\theta$. To solve the elliptic equation $Lu = f$ at time step $t^{n+1}$, we develop $u^{n+1}$ into an orthogonal wavelet series, that is, $u^{n+1} = \sum_\lambda \widetilde{u}_\lambda^{n+1} \psi_\lambda$, where $\lambda = (j, i_x, i_y, d)$ denotes the multi-index for scale $j$, space $i$, and direction $d$. Requiring that the residual vanishes with respect to all test functions $\theta_\lambda$, we obtain a linear system for the unknown wavelet coefficients $\widetilde{u}_\lambda^{n+1}$ of the solution $u$:

$$\sum_\lambda \widetilde{u}_\lambda^{n+1} \langle L\psi_\lambda, \theta_{\lambda'} \rangle = \langle f, \theta_{\lambda'} \rangle \qquad [21]$$

The test functions $\theta$ are defined such that the stiffness matrix turns out to be the identity. Therefore, the solution of $Lu = f$ reduces to a change of basis, that is, $u^{n+1} = \sum_\lambda \langle f, \theta_\lambda \rangle \psi_\lambda$. The right-hand side (RHS) $f$ can then be developed into a biorthogonal operator adapted wavelet basis $f = \sum_\lambda \langle f, \theta_\lambda \rangle \zeta_\lambda$, with $\theta_\lambda = L^{\star -1} \psi_\lambda$ and $\zeta_\lambda = L\psi_\lambda$, $^\star$ denoting the adjoint operator. By construction, $\theta$ and $\zeta$ are biorthogonal, that is, such that $\langle \theta_\lambda, \zeta_{\lambda'} \rangle = \delta_{\lambda, \lambda'}$. It can be shown that both have similar localization properties in physical and Fourier space as $\psi$, and that they form a Riesz basis.

**Adaptive discretization** To get an adaptive space discretization for the linear problem $Lu = f$, we

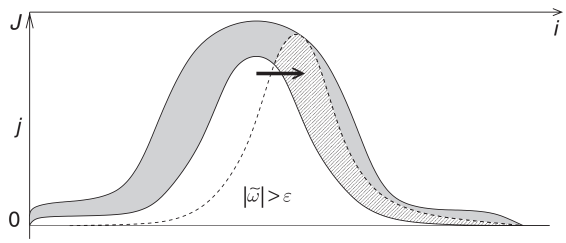

**Figure 7** Illustration of the dynamic adaption strategy in wavelet coefficient space.

consider only the significant wavelet coefficients of the solution. Hence, we only retain coefficients $\widetilde{u}^n_\lambda$ whose modulus is larger than a given threshold $\varepsilon$, that is, $|\widetilde{u}^n_\lambda| > \varepsilon$. The corresponding coefficients are shown in Figure 7 (white area under the solid line curve).

**Adaption strategy** To be able to integrate the equation in time we have to account for the evolution of the solution in wavelet coefficient space (indicated by the arrow in Figure 7). Therefore, we add at time step $t^n$ the neighbors to the retained coefficients, which constitute a security zone (gray area in Figure 7). The equation is then solved in this enlarged coefficient set (white and gray areas below the curves in Figure 7) to obtain $\widetilde{u}^{n+1}_\lambda$. Subsequently, we threshold the coefficients and retain only those whose modulus $|\widetilde{u}^{n+1}_\lambda| > \varepsilon$ (coefficients under the dashed curve in Figure 7). This strategy is applied in each time step and hence allows to automatically track the evolution of the solution in both scale and space.

**Evaluation of the nonlinear term** For the evaluation of the nonlinear term $f(u^n)$, where the wavelet coefficients $\widetilde{u}^n$ are given, there are two possibilities:

- *Evaluation in wavelet coefficient space*. As illustration, we consider a quadratic nonlinear term, $f(u) = u^2$. The wavelet coefficients of $f$ can be calculated using the connection coefficients, that is, one has to calculate the bilinear expression, $\sum_\lambda \sum_{\lambda'} \widetilde{u}_\lambda \mathcal{I}_{\lambda\lambda'\lambda''} \widetilde{u}_{\lambda'}$ with the interaction tensor $\mathcal{I}_{\lambda\lambda'\lambda''} = \langle \psi_\lambda \psi_{\lambda'}, \theta_{\lambda''} \rangle$. Although many coefficients of $\mathcal{I}$ are zero or very small, the size of $\mathcal{I}$ leads to a computation which is quite untractable in practice.
- *Evaluation in physical space*. This approach is similar to the pseudospectral evaluation of the nonlinear terms used in spectral methods, therefore it is called pseudowavelet technique. The advantage of this scheme is that general nonlinear terms, for example, $f(u) = (1-u)\,e^{-C/u}$, can be treated more easily. The method can be summarized as follows: starting from the significant wavelet coefficients, $|\widetilde{u}_\lambda| > \varepsilon$, one reconstructs $u$ on a locally refined grid and gets $u(x_\lambda)$. Then one can evaluate $f(u(x_\lambda))$ pointwise and the wavelet coefficients $\widetilde{f}_\lambda$ are calculated using the adaptive decomposition.

Finally, one computes the scalar products of the RHS of [21] with the test functions $\theta$ to advance the solution in time. We compute $\widetilde{u}_\lambda = \langle f, \theta_\lambda \rangle$ belonging to the enlarged coefficient set (white and gray regions in Figure 7).

The algorithm is of $O(N)$ complexity, where $N$ denotes the number of wavelet coefficients retained in the computation.

### Application to 2D Turbulence

To illustrate the above algorithm we present an adaptive wavelet computation of a vortex dipole in a square domain, impinging on a no-slip wall at Reynolds number $Re = 1000$. To take into account the solid wall, we use a volume penalization method, for which both the fluid flow and the solid container are modeled as a porous medium whose porosity tends towards zero in the fluid and towards infinity in the solid region.

The 2D Navier–Stokes equations are thus modified by adding the forcing term $\boldsymbol{F} = -(1/\eta)\chi \boldsymbol{v}$ in eqn [18], where $\eta$ is the penalization parameter and $\chi$ is the characteristic function whose value is 1 in the solid region and 0 elsewhere. The equations are solved using the adaptive wavelet method in a periodic square domain of size 1.1, in which the square container of size 1 is imbedded, taking $\eta = 10^{-3}$. The maximal resolution corresponds to a fine grid of $1024^2$ points. Figure 8a shows snapshots of the vorticity field at times $t = 0.2, 0.4, 0.6,$ and $0.8$ (in arbitrary units). We observe that the vortex dipole is moving towards the wall and that strong vorticity gradients are produced when the dipole hits the wall. The computational grid is dynamically adapted during the flow evolution, since the nonlinear wavelet filter automatically refines the grid in regions where strong gradients develop. Figure 8b shows the centers of the retained wavelet coefficients at corresponding times.

Note that during the computation only 5% out of $1024^2$ wavelet coefficients are used. The time evolution of total kinetic energy and the total enstrophy $\boldsymbol{F} = -(\frac{1}{y})\chi \boldsymbol{v}$, are plotted in Figure 9 to

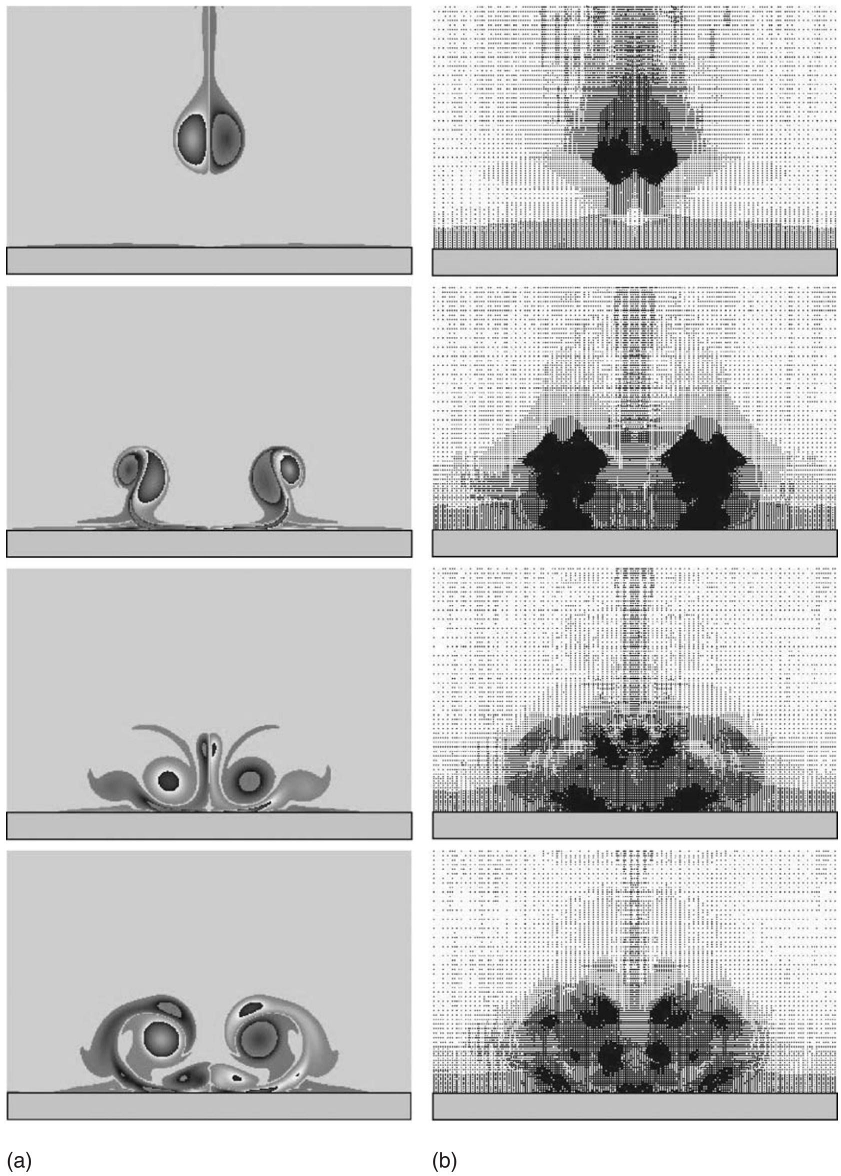

Figure 8 Dipole wall interaction at $Re = 1000$. (a) Vorticity field, (b) corresponding centers of the active wavelets, at $t = 0.2, 0.4, 0.6$, and 0.8 (from top to bottom).

show the production of enstrophy and the concomitant dissipation of energy when the vortex dipole hits the wall.

This computation illustrates the fact that the adaptive wavelet method allows an automatic grid refinement, both in the boundary layers at the wall and also in shear layers which develop during the flow evolution far from the wall. Therewith, the number of grid points necessary for the computation is significantly reduced, and we conjecture that the resulting compression rate will increase with the Reynolds number.

# Wavelets: Applications

**M Yamada**, Kyoto University, Kyoto, Japan

## Introduction

Wavelet analysis was first developed in the early 1980s in the field of seismic signal analysis in the form of an integral transform with a localized kernel function with continuous parameters of dilation and translation. When a seismic wave or its derivative has a singular point, the integral transform has a scaling property with respect to the dilation parameter; thus, this scaling behavior can be available to locate the singular point. In the mid-1980s, the orthonormal smooth wavelet was first constructed, and later the construction method was generalized and reformulated as multiresolution analysis (MRA). Since then, several kinds of wavelets have been proposed for various purposes, and the concept of wavelet has been extended to new types of basis functions. In this sense, the most important effect of wavelets may be that they have awakened deep interest in bases employed in data analysis and data processing. Wavelets are now widely used in various fields of research; some of their applications are discussed in this article.

From the perspective of time–frequency analysis, the wavelet analysis may be regarded as a windowed Fourier analysis with a variable window width, narrower for higher frequency. The wavelets can therefore give information on the local frequency structure of an event; they have been applied to various kinds of one-dimensional (1D) or multidimensional signals, for example, to identify an event or to denoise or to sharpen the signal.

1D wavelets $\psi^{(a,b)}(x)$ are defined as

$$\psi^{(a,b)}(x) = \frac{1}{\sqrt{|a|}}\psi\left(\frac{x-b}{a}\right)$$

where $a(\neq 0), b$ are real parameters and $\psi(x)$ is a spatially localized function called "analyzing wavelet" or "mother wavelet." Wavelet analysis gives a decomposition of a function into a linear combination of those wavelets, where a perfect reconstruction requires the analyzing wavelet to satisfy some mathematical conditions.

For the continuous wavelet transform (CWT), where the parameters $(a, b)$ are continuous, the analyzing wavelet $\psi(x)L^2(\boldsymbol{R})$ has to satisfy the admissibility condition

analyzing wavelet $\psi(x)L^2(\boldsymbol{R})$ has to satisfy the admissibility condition

$$C_\psi \equiv \int_{-\infty}^{\infty} \frac{|\hat{\psi}(\omega)|^2}{|\omega|}\, \mathrm{d}\omega < \infty$$

where $\hat{\psi}(\omega)$ is the Fourier transform of $\psi(x)$:

$$\hat{\psi}(\omega) = \int_{-\infty}^{\infty} \mathrm{e}^{-\mathrm{i}\omega x}\psi(x)\,\mathrm{d}x$$

The admissibility condition is known to be equivalent to the condition that $\psi(x)$ has no zero-frequency component, that is, $\hat{\psi}(0)=0$, under some mild condition for the decay rate at infinity. Then the CWT and its inverse transform of a data function $f(x) \in L^2(\boldsymbol{R})$ is defined as

$$T_\psi(a,b) = \frac{1}{\sqrt{C_\psi}} \int_{-\infty}^{\infty} \overline{\psi^{(a,b)}(x)} f(x)\,\mathrm{d}x$$

$$f(x) = \frac{1}{\sqrt{C_\psi}} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} T_\psi(a,b)\psi^{(a,b)}(x)\,\frac{\mathrm{d}a\,\mathrm{d}b}{a^2}$$

In the case of the discrete wavelet transform (DWT), the parameters $(a,b)$ are taken discrete; a typical choice is $a = 1/2^j, b = k/2^j$, where $j$ and $k$ are integers:

$$\psi_{j,k}(x) = 2^{j/2}\psi(2^j x - k)$$

In order that the wavelets $\{\psi_{j,k}(x)\,|\,j,k \in \boldsymbol{Z}\}$ may constitute a complete orthonormal system in $L^2(\boldsymbol{R})$, the analyzing wavelet should satisfy more stringent conditions than the admissibility condition for the CWT, and is now constructed in the framework of MRA. A data function is then decomposed by the DWT as

$$f(x) = \sum_{j=-\infty}^{\infty} \alpha_{j,k}\psi_{j,k}(x), \quad \alpha_{j,k} = \int_{-\infty}^{\infty} \overline{\psi_{j,k}(x)} f(x)\,\mathrm{d}x$$

Even when the discrete wavelets do not constitute a complete orthnormal system, they often form a wavelet frame if linear combinations of the wavelets are dense in $L^2(\boldsymbol{R})$ and if there are two constants $A$, $B$ such that the inequality

$$A\|f\|^2 \le \sum_{j,k} |\langle \psi_{j,k}, f\rangle|^2 \le B\|f\|^2$$

holds for an arbitrary $f(x) \in L^2(\boldsymbol{R})$. For the wavelet frame $\{\psi_{j,k}\}$, there is a corresponding dual frame, $\{\tilde{\psi}_{j,k}\}$, which permits the following expansion of $f(x)$:

$$f(x) = \sum_{j,k} \langle \psi_{j,k}, f\rangle \tilde{\psi}_{j,k}(x) = \sum_{j,k} \langle \tilde{\psi}_{j,k}, f\rangle \psi_{j,k}(x)$$

The wavelet frame is also employed in several applications.

From the prospect of applications, the CWTs are better adapted for the analysis of data functions, including the detection of singularities and patterns, while the DWTs are adapted to the data processing, including signal compression or denoising.

## Singularity Detection and Multifractal Analysis of Functions

Since its birth, the wavelet analysis has been applied for the detection of singularity of a data function. Let us define the Hölder exponent $h(x_0)$ at $x_0$ of a function $f(x)$ is defined here as the largest value of the exponent $h$ such that there exists a polynomial $P_n(x)$ of degree $n$ that satisfies for $x$ in the neighborhood of $x_0$:

$$|f(x) - P_n(x - x_0)| = \mathrm{O}(|x - x_0|^h)$$

The data function is not differentiable if $h(x_0) < 1$, but if $h(x_0) > 1$ then it is differentiable and a singularity may arise in its higher derivatives. The wavelet transform is applied to find the Hölder exponent $h(x_0)$, because $T_\psi(a,b)$ has an asymptotic behavior $T_\psi(a,b) = \mathrm{O}(a^{h(x_0+1/2)})(a \to 0)$ if the analyzing wavelet has $N(>h(x_0))$ vanishing moments, that is,

$$\int_{-\infty}^{\infty} x^m \psi(x)\,\mathrm{d}x = 0, \quad m \in \boldsymbol{Z}, 0 \le m < N$$

A commonly used analyzing wavelet for this purpose may be the $N$-time derivative of the Gaussian function $\psi(x) = \mathrm{d}^N(\mathrm{e}^{-x^2/2})/\mathrm{d}x^N$. This method works well to examine a single or some finite number of singular points of the data function.

When the data function is a multifractal function with an infinite number of singular point of various strengths, the multifractal property of the data function is often characterized by the singularity spectrum $D(h)$ which denotes the Hausdorff dimension of the set of points where $h(x) = h$. The singularity spectrum is, however, difficult to obtain directly from the CWT, and the Legendre transformation is introduced to bypass the difficulty.

Fully developed 3D fluid turbulence may be a typical example of wavelet application to the singularity detection. The Kolmogorov similarity law of fluid turbulence for the longitudinal velocity increment $\Delta u(r) \equiv \boldsymbol{e}\cdot(\boldsymbol{u}(\boldsymbol{x}+r\boldsymbol{e}) - \boldsymbol{u}(\boldsymbol{x}))$, where $\boldsymbol{u}(\boldsymbol{x})$ is the velocity field and $\boldsymbol{e}$ is a constant unit vector,

predicts a scaling property of the structure function; for $r$ in the inertial subrange,

$$\langle (\Delta u(r))^p \rangle \sim r^{\zeta_p}, \quad \zeta_p = p/3$$

where $\langle \cdot \rangle$ denotes the statistical mean. In reality, however, the scaling exponent $\zeta_p$ measured in experiments shows a systematic deviation from $p/3$, which is considered to be a reflection of intermittency, namely the spatial nonuniformity or multifractal property of active vortical motions in turbulence. For simplicity, let us consider the velocity field on a linear section of the turbulence field. According to the multifractal formalism, the turbulence velocity field has singularities of various strengths described by the singularity spectrum $D(h)$, which is related to the scaling exponent $\zeta_p$ through the Legendre transform, $D(h) = \inf_p(ph - \zeta_p + 1)$. This relation is often used to determine $D(h)$ from the knowledge of $\zeta_p$ (structure function method). However, this method does not necessarily work well because, for example, it does not capture the singular points of the Hölder exponent larger than 1 and it is unstable for $h < 0$.

These difficulties are not restricted to the turbulence research, but arise commonly when the structure function is employed to determine the singularity spectrum. In these problems, the CWT $T_\psi(a, b)$ provides an alternative method. An ingenious technique is to take only the modulus maxima of $T_\psi(a, b)$ (for each of fixed $a$) to construct a partition function

$$Z(a, q) = \sum_{l \in L_{\max}} \left[ \sup_{(a, b') \in l} |T_\psi(a, b')| \right]^q$$

where $q \in \boldsymbol{R}$, and $L_{\max}$ denotes the set of all maxima lines, each of which is a continuous curve for small value of $a$, and there exists at least one maxima line toward a singular point of the Hölder exponent $h(x_0) < N$. In the limit of $a \to 0$, defining the exponent $\tau(q)$ as $Z(a, q) \sim a^{\tau(q)}$, one can obtain the singularity spectrum through the Legendre transform:

$$D(h) = \inf_q \left[ q\left(h + \tfrac{1}{2}\right) - \tau(q) \right]$$

This method (wavelet-transform modulus-maxima (WTMM) method) is advantageous in that it works also for singularities of $h > 1$ and $h < 0$. Several simple examples of multifractal functions have been successfully analyzed by this method. For fluid turbulence, this method gives a singularity spectrum $D(h)$ which has a peak value of $\sim 1$ at $h \sim 1/3$, consistently with Kolmogorov similarity law, but has a convex shape around $h = 1/3$ suggesting a multifractal property. For a fractal signal, we note that the WTMM method enlightens the hierarchical organization of the singularities, in the branching structure of the WT skeleton defined by the maxima lines arrangement in the $(a, b)$ half-plane.

Though the above discussion also applies to the DWT, the detection of the Hölder exponent $h$ in experimental situations is usually performed by the CWT, which has no restriction on possible values of $a$, while the DWT is often employed for theoretical discussions of singularity and multifractal structure of a function.

## Multiscale Analysis

Wavelet transform expands a data function in the time–frequency or the position–wavenumber space, which has twice the dimension of the original signal, and makes it easier to perform a multiscale analysis and to identify events involved in the signal. In the wavelet transform, as stated above, the time resolution is higher at higher frequency, in contrast with the windowed Fourier transform where the time and the frequency resolutions are independent of frequency. Another advantage of wavelet is a wide variety of analyzing wavelet, which enables us to optimize the wavelet according to the purpose of data analysis. Both the CWT and the DWT are available for these time–frequency or position–wavenumber analysis. However, the CWT has properties quite different from those of familiar orthonormal bases of discrete wavelets.

### Multidimensional CWT

The CWT can be formulated in an abstract way. We can regard $G = \{(a, b) \mid a(\neq 0), b \in \boldsymbol{R}\}$ as an affine group on $\boldsymbol{R}$ with the group operation of $(a, b)(a', b') = (aa', ab' + b)$ associated with the invariant measure $\mathrm{d}\mu = \mathrm{d}a\,\mathrm{d}b/a^2$. The group $G$ has its unitary representation in the Hilbert space $H = L^2(\boldsymbol{R})$:

$$(U(a, b)f)(x) = \frac{1}{\sqrt{|a|}} f\left(\frac{x - b}{a}\right)$$

and then we can consider the CWT can be constructed as a linear map $W$ from $L^2(\boldsymbol{R})$ to $L^2(G; \mathrm{d}a\,\mathrm{d}b/a^2)$:

$$W : f(x) \mapsto T_\psi(a, b) = \frac{1}{\sqrt{C_\psi}} \langle U(a, b)\psi, f \rangle$$

where $\langle \cdot, \cdot \rangle$ is the inner product of $L^2(\boldsymbol{R})$ with the complex conjugate taken at the first element, and

$\psi(x)$ is a unit vector (analyzing wavelet) satisfying the abstract admissibility condition

$$C_\psi = \int_G |\langle U(a,b)\psi, \psi\rangle|^2 \, d\mu < \infty$$

This formulation is applicable also to a locally compact group $G$ and its unitary and square integrable representation in a Hilbert space $H$. Note that even the canonical coherent states are included in this framework by taking the Weyl–Heisenberg group and $L^2(\boldsymbol{R})$ for $G$ and $H$, respectively. This abstract formulation allows us to extend the CWT to higher-dimensional Euclidean spaces and other manifolds: for example, 2D sphere $S^2$ for geophysical application and 4D manifold of spacetime taking the Poincaré group into consideration.

In $\boldsymbol{R}^n$, the CWT of $f(\boldsymbol{x}) \in L^2(\boldsymbol{R}^n)$ and its inverse transform are given by

$$T_\psi(a, r, \boldsymbol{b}) = \frac{1}{\sqrt{C_\psi}} \int_{\boldsymbol{R}^n} \overline{\psi^{(a,r,\boldsymbol{b})}(\boldsymbol{x})} f(\boldsymbol{x}) \, d\boldsymbol{x}$$

$$f(\boldsymbol{x}) = \frac{1}{\sqrt{C_\psi}} \int_G T(a, r, \boldsymbol{b}) \psi^{(a,r,\boldsymbol{b})}(\boldsymbol{x}) \frac{da \, dr \, d\boldsymbol{b}}{a^{n+1}}$$

where $r \in \mathrm{SO}(n), \boldsymbol{b} \in \boldsymbol{R}^n, dr$ is the normalized invariant measure of $G = \mathrm{SO}(n)$, and the wavelets are defined as $\psi^{(a,\, r,\, b)}(\boldsymbol{x}) = (1/a^{n/2})\psi(r^{-1}(\boldsymbol{x} - \boldsymbol{b})/a)$, with the analyzing wavelet satisfying the admissibility condition

$$C_\psi = \int_{\boldsymbol{R}^n} \frac{|\hat{\psi}(\boldsymbol{\omega})|}{|\boldsymbol{\omega}|^n} \, d\boldsymbol{\omega} < \infty$$

Note that these wavelets are constructed not only by dilation and translation but also by rotation which therefore gives the possibility for directional pattern detection in a data function. In the case of 2D sphere $S^2$, on the other hand, the dilation operation should be reinterpreted in such a way that at the North Pole, for example, it is the normal dilation in the tangent plane followed by lifting it to $S^2$ by the stereographic projection from the South Pole.

Generally, the abstract map $W$ thus defined is injective and therefore reversal, but not surjective in contrast with the Fourier case. Actually in the case of 1D CWT, $T_\psi(a, b)$ is subject to an integral condition:

$$T_\psi(a, b) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \frac{da \, db}{a^2} K(a, b; a', b') T_\psi(a', b')$$

$$K(a, b; a', b') = \int_{-\infty}^{\infty} \overline{\psi^{(a,b)}(x)} \psi^{(a',b')}(x) \, dx$$

which defines the range of the CWT, a subspace of $L^2(\boldsymbol{R})$. Therefore, if one wants to modify $T_\psi(a, b)$ by, for example, assigning its value as zero in some parameter region just as in a filter process, care should be taken for the resultant $T_\psi(a, b)$ to be in the image of the CWT. The reason may be understood intuitively by noticing that the wavelets $\psi^{(a,b)}(x)$ are linearly dependent on each other. The expression of a data function by a linear combination of the wavelets is therefore not unique, and thus is redundant. The CWT gives only $T_\psi(a, b)$ of the least norm in $L^2(\boldsymbol{R}^2; da \, db/a^2)$. In physical interpretations of the CWT, however, this nonuniqueness is often ignored.

## Pattern Detection

**Edge detection** The edges of an object are often the most important components for pattern detection. The edge may be considered to consist of points of sharp transition of image intensity. At the edge, the modulus of the gradient of the image $f(x, y)$ is expected to take a local maximum in the 1D direction perpendicular to the edge. Therefore, the local maxima of $|\nabla f(x, y)|$ may be the indicator of the edge. However, the image textures can also give similar sharp transitions of $f(x, y)$, and one should take into account the scale dependence which distinguishes between edges and textures. One of the practically possible ways for this purpose is to use dyadic wavelets $\psi_j^m(x, y) = 2^j \psi^m(2^j x, 2^j y)$ which are generated from the two wavelets $(\psi^1, \psi^2) = (-\partial\theta/\partial x, -\partial\theta/\partial y)$, where $\theta$ is a localized function (multiscale edge detection method). The dyadic wavelet transform of the image $f(x, y)$

$$T_j^m(b_1, b_2) = \langle f(x, y), \psi_j^m(x - b_1, y - b_2)\rangle, \quad m = 1, 2$$

defines the multiscale edges as a set of points $\boldsymbol{b} = (b_1, b_2)$ where the modulus of the wavelet transform, $|(T_j^1, T_j^2)|$, takes a locally maximum value (WTMM) in a 1D neighborhood of $\boldsymbol{b}$ in the direction of $(T_j^1(\boldsymbol{b}), T_j^2(\boldsymbol{b}))$. Scale dependence of the magnitude of the modulus maxima is related to the Hölder exponent of $f(x, y)$ similarly to 1D case, and thus gives information to distinguish between the edges and the textures.

Inversely, the information of WTMM $\boldsymbol{b}_{j,p} = \{(b_{1,j,p}, b_{2,j,p})\}$ of multiscale edges can be made use of for an approximate reconstruction of the original image, although the perfect reconstruction cannot be expected because of the noncompleteness of the modulus maxima wavelets. Assuming that $\{\psi_{j,p}^1, \psi_{j,p}^2\} = \{\psi_j^1(\boldsymbol{x} - \boldsymbol{b}_{j,p}), \psi_j^2(\boldsymbol{x} - \boldsymbol{b}_{j,p})\}$ constitutes a frame of the linear closed space generated by

$\{\psi^1_{j,p}, \psi^2_{j,p}\}$, an approximate image $\hat{f}$ is obtained by inverting the relation

$$L\hat{f} \equiv \sum_m \sum_{j,p} \langle \hat{f}, \psi^m_{j,p} \rangle \psi^m_{j,p} = \sum_m \sum_{j,p} T^m_j(\boldsymbol{b}_{j,p}) \psi^m_{j,p}$$

using, for example, a conjugate gradient algorithm, where a fast calculation is possible with a filter bank algorithm for the dyadic wavelet ("algorithm à trous"). This algorithm gives only the solution of minimum norm among all possible solutions, but it is often satisfactory for practical purposes and thus is applicable also to data compression.

**Directional detection** For oriented features such as segments or edges in images to be detected, a directionally selective wavelet for the CWT is desired. A useful wavelet for this purpose is one that has the effective support of its Fourier transform in a convex cone with apex at the origin in wave number space. A typical example of the directional wavelet may be the 2D Morlet wavelet:

$$\psi(\boldsymbol{x}) = \exp(\mathrm{i}\boldsymbol{k}_0 \cdot \boldsymbol{x}) \exp(-|A\boldsymbol{x}|^2)$$

where $\boldsymbol{k}_0$ is the center of the support in Fourier space, and $A$ is a $2 \times 2$ matrix diag$[\epsilon^{1/2}, 1](\epsilon \leq 1)$, where the admissibility condition for the CWT is approximately satisfied for $|k_0| \geq 5$. Another example is the Cauchy wavelet which has the support strictly in a convex cone in wave number space.

These wavelets have the directional selectivity with preference to a slender object in a specific direction. One of their applications is the analysis of the velocity field of fluid motion from an experimental data, where many tiny plastic balls distributed in fluid give a lot of line segments in a picture taken with a short exposure. The directional wavelet analysis of the picture classifies the line segments according to their directions, indicating the directions of fluid velocity. Another example may be a wave-field analysis where many waves in different directions are superimposed; the directional wavelets allow one to decompose the wave field into the component waves. Directional wavelets have also been applied successfully to detect symmetry of objects such as crystals or quasicrystals.

**Denoising and separation of signals** The wavelet frame as well as the CWT give a redundant representation of a data function. If, instead of the original data, the redundant expression is transmitted, the redundancy is used to reduce the noise included in the received data because the redundancy requires the data to belong to a subspace, and the projection of the received data to the subspace reduces the noise component orthogonal to it. More specifically, the wavelet frame gives a representation of a data function as $f(t) = \sum_{j,k} \alpha_{j,k}\psi_{j,k}$, where the expansion coefficients $\alpha_{j,k} = \langle \psi_{j,k}, f(x) \rangle$ satisfy the defining equation of the subspace

$$\alpha_{j',k'} = \sum \alpha_{j,k} \langle \psi_{j',k'}, \psi_{j,k} \rangle$$

If the frame coefficients are transmitted, the projection operator $P$, which is defined on the right-hand side of the above equation, reduces the noise in the received coefficients $\alpha_{j,k}$ contaminated during the transmission.

However, this method is not applicable if the transmitted signal is not redundant. Then some *a priori* criterion is necessary to discriminate between signal and noise. Various criteria have been proposed in different fields. If the signal and the noise, or plural signals have different power-law forms of spectra, then their discrimination may be possible by the DWT at higher-frequency region where the difference in the magnitude of the coefficients is significant. In this approach, the wavelets of Meyer type, that is, an orthogonal wavelet with a compact support in Fourier space, may be preferable because the wavelets of different scales are separated, at least to some extent, in Fourier space.

In fluid dynamics, the vorticity field of 2D turbulence is found to be decomposed into coherent and incoherent vorticity fields, according as the CWT is larger than a threshold value or not, respectively. These two fields give different Fourier spectra of the velocity field ($k^{-5}$ for coherent part while $k^{-3}$ for incoherent part), showing that the coherent structures are responsible for the deviation from $k^{-3}$ predicted by the classical enstrophy cascade theory. In an astronomical application, on the other hand, the data processing is performed by a more sophisticated method taking into account interscale relation in the wavelet transform, because an astronomical image contains various kinds of objects, including stars, double-stars, galaxies, nebulas, and clusters. In a medical image however contrast analysis is indispensable for diagnostic imaging to get a clear detailed picture of organic structure. A scale-dependent local contrast is defined as the ratio of the CWT to that given by an analyzing wavelet with a larger support. A multiplicative scheme to improve the contrast is constructed by using the local contrast.

### Signal Compression

Signal compression is quite an important technology in digital communication. Speech, audio, image, and digital video are all important fields of signal

compression, and plenty of compression methods have been put to practical use, but we mention here only a few.

The MRA for orthogonal wavelets gives a successive procedure to decompose a subspace of $L^2(\boldsymbol{R})$ into a direct sum of two subspaces corresponding to higher- and lower-frequency parts; only the latter of which is decomposed again into its higher- and lower-frequency parts. Algebraically, this procedure was already known before the discovery of MRA in filter theory in electrical engineering, where a discretely sampled signal is convoluted with a filter series to give, for example, a high-pass-filtered or low-pass-filtered series. An appropriate designed pair of a high-pass and a low-pass filters followed by the downsampling yields two new series corresponding to the higher- and lower-frequency parts, respectively, which are then reversible by another two reconstruction filters with the upsampling. These four filters which are often employed in a widely used technique of "subband coding" then constitute a perfect reconstruction filter bank. Under some conditions, successive applications of this decomposition process to the series of lower-frequency parts, which is equivalent to the nesting structure of MRA, have been used for data compression (quadrature mirror filter). A famous example is a data compression system of FBI for finger prints, consisting of wavelet coding with scalar quantization.

In MRA, however, it is only the lower-frequency parts that are successively decomposed. If both the lower- and the higher-frequency parts are repeatedly decomposed by the decomposition filters, then the successive convolution processes correspond to a decomposition of data function by a set of wavelet-like functions, called "wavelet packet," where there are choices whether to decompose the higher- and/or the lower-frequency parts. The best wavelet packet, in the sense of the entropy, for example, within a specified number of decompositions, often provides with a powerful tool for data compression in several areas, including speech analysis and image analysis. We also note that from the viewpoint of the best basis which minimizes the statistical mean square error of the thresholded coefficients, an orthonormal wavelet basis gives a good concentration of the energy if the original signal is a piecewise smooth function superimposed by a white noise, which is thus efficiently removed by thresholding the coefficients. The efficiency of a wavelet expansion of a signal is sometimes evaluated with the entropy of "probability" defined as $|\alpha_{j,k}|^2/||f||^2$. A better wavelet can be selected by reducing the entropy, practically from among some set of wavelets, and its restricted expansion coefficients give a compressed signal. One of the systematic methods to generate such a suitable basis is also to employ the wavelet packets.

## Numerical Calculation

Application of wavelet transform, especially of the DWT, to numerical solver for a differential equation (DE) has long been studied. At the first sight, the wavelets appear to give a good DE solver because the wavelet expansion is generally quite efficient compared to Fourier series due to its spatial localization. But its implementation to an efficient computer code is not so straightforward; research is still continuing for concrete problems. Application of the CWT to spectral method for partial differential equation (PDE) has been studied extensively. There is no wavelet which diagonalizes the differential operator $\partial/\partial x$; therefore, an efficient numerical method is necessary for derivatives of wavelets. Products of wavelets also yield another numerical problem. MRA brings about mesh points which are adaptive to some extent, but finite element method still gives more flexible mesh points.

For some scaling-invariant differential or integral operators, including $\partial^2/\partial x^2$, Abel transformations, and Reisz potential, adaptive biorthogonal wavelets can be provided with block-diagonal Galerkin representations, which has been applied to data processing. Generally, simultaneous localization of wavelets, both in space and in scale, leads to a sparse Galerkin representation for many pseudodifferential operators and their inverses. A thresholding technique with DWT has been introduced to coherent vortex simulation of the 2D Navier–Stokes equations, to reduce the relevant wavelet coefficients. Another promising application of wavelet occurs as a preprocessor for an iterative Poisson solver, where a wavelet-based preconditioning leads to a matrix with a bounded condition number.

## Other Wavelets and Generalizations

Several new types of wavelets have been proposed: "coiflet" whose scaling function has vanishing moments giving expansion coefficients approximately equal to values of the data functions, and "symlet" which is an orthonormal wavelet with a nearly symmetric profile. Multiwavelets are wavelets which give a complete orthonormal system in $L^2$ space. In 2D or multidimensional applications of the DWT, separable orthonormal wavelets consisting of tensor products of 1D orthonormal wavelets are frequently used, while nonseparable orthonormal wavelets are also available. Another generalization

of wavelets is the Malvar basis which is also a generalization of local Fourier basis, and gives a perfect reconstruction. A new direction of wavelet is the second-generation wavelets which are constructed by lifting scheme and free from the regular dyadic procedure, and thus applicable to compact regions as $S^2$ and a finite interval.

## Introduction

The wavelet transform unfolds functions into time (or space) and scale, and possibly directions. The continuous wavelet transform has been discovered by Alex Grossmann and Jean Morlet who published the first paper on wavelets in 1984. This mathematical technique, based on group theory and square-integrable representations, allows us to decompose a signal, or a field, into both space and scale, and possibly directions. The orthogonal wavelet transform has been discovered by Lemarié and Meyer (1986). Then, Daubechies (1988) found orthogonal bases made of compactly supported wavelets, and Mallat (1989) designed the fast wavelet transform (FWT) algorithm. Further developments were done in 1991 by Raffy Coifman, Yves Meyer, and Victor Wickerhauser who introduced wavelet packets and applied them to data compression. The development of wavelets has been interdisciplinary, with contributions coming from very different fields such as engineering (sub-band coding, quadrature mirror filters, time–frequency analysis), theoretical physics (coherent states of affine groups in quantum mechanics), and mathematics (Calderon–Zygmund operators, characterization of function spaces, harmonic analysis). Many reference textbooks are available, some of them we recommend are listed in the "Further reading" section. Meanwhile, a large spectrum of applications has grown and is still developing, ranging from signal analysis and image processing via numerical analysis and turbulence modeling to data compression.

In this article, we will first define the continuous wavelet transform and then the orthogonal wavelet transform based on a multiresolution analysis. Properties of both transforms will be discussed and illustrated by examples. For a general introduction to wavelets, *see* Wavelets: Applications.

## Continuous Wavelet Transform

Let us consider the Hilbert space of square-integrable functions $L^2(\mathbb{R}) = \{f : \||f\|_2 < \infty\}$, equipped with the scalar product $\langle f, g \rangle = \int_{\mathbb{R}} f(x) g^\star(x)\, dx$ ($^\star$ denotes the complex conjugate in the case of complex-valued functions) and where the norm is defined by $\|f\|_2 = \langle f, f \rangle^{1/2}$.

### Analyzing Wavelet

The starting point for the wavelet transform is to choose a real- or complex-valued function $\psi \in L^2(\mathbb{R})$, called the "mother wavelet," which fulfills the admissibility condition,

$$C_\psi = \int_0^\infty \left|\widehat{\psi}(k)\right|^2 \frac{dk}{|k|} < \infty \qquad [1]$$

where

$$\widehat{\psi}(k) = \int_{-\infty}^{\infty} \psi(x)\, e^{-\imath 2\pi k x}\, dx \qquad [2]$$

denotes the Fourier transform, with $\imath = \sqrt{-1}$ and $k$ the wave number. If $\psi$ is integrable, that is, $\psi \in L^1(\mathbb{R})$, this implies that $\psi$ has zero mean,

$$\int_{-\infty}^{\infty} \psi(x)\, dx = 0 \qquad \text{or} \qquad \widehat{\psi}(0) = 0 \qquad [3]$$

In practice, however, one also requires the wavelet $\psi$ to be well localized in both physical and Fourier

$$\int_{-\infty}^{\infty} x^m \psi(x)\,\mathrm{d}x = 0 \qquad \text{for } m = 0,\, M-1 \qquad [4]$$

that is, monomials up to degree $M-1$ are exactly reproduced. In Fourier space, this property is equivalent to

$$\frac{\mathrm{d}^m}{\mathrm{d}k^m}\widehat{\psi}(k)\,|_{k=0} = 0 \quad \text{for } m = 0, M-1 \qquad [5]$$

therefore, the Fourier transform of $\psi$ decays smoothly at $k=0$.

## Analysis

From the mother wavelet $\psi$, we generate a family of continuously translated and dilated wavelets,

$$\psi_{a,b}(x) = \frac{1}{\sqrt{a}}\psi\left(\frac{x-b}{a}\right) \quad \text{for } a > 0 \text{ and } b \in \mathbb{R} \qquad [6]$$

where $a$ denotes the dilation parameter, corresponding to the width of the wavelet support, and $b$ the translation parameter, corresponding to the position of the wavelet. The wavelets are normalized in energy norm, that is, $\|\psi_{a,b}\|_2 = 1$.

In Fourier space, eqn [6] reads

$$\widehat{\psi}_{a,b(k)} = \sqrt{a}\widehat{\psi}(ak)\,\mathrm{e}^{-\imath 2\pi kb} \qquad [7]$$

where the contraction with $1/a$ in [6] is reflected in a dilation by $a$ [7] and the translation by $b$ implies a rotation in the complex plane.

The continuous wavelet transform of a function $f$ is then defined as the convolution of $f$ with the wavelet family $\psi_{a,b}$:

$$\widetilde{f}(a,b) = \int_{-\infty}^{\infty} f(x)\psi^*_{a,b}(x)\,\mathrm{d}x \qquad [8]$$

where $\psi^*_{a,b}$ denotes, in the case of complex-valued wavelets, the complex conjugate.

Using Parseval's identity, we get

$$\widetilde{f}(a,b) = \int_{-\infty}^{\infty} \widehat{f}(k)\widehat{\psi}^*_{a,b}(k)\,\mathrm{d}k \qquad [9]$$

and the wavelet transform could be interpreted as a frequency decomposition using bandpass filters $\widehat{\psi}_{a,b}$ centered at frequencies $k = k_\psi/a$. The wave number $k_\psi$ denotes the barycenter of the wavelet support in Fourier space

$$k_\psi = \frac{\int_0^\infty k|\widehat{\psi}(k)|\,\mathrm{d}k}{\int_0^\infty |\widehat{\psi}(k)|\,\mathrm{d}k} \qquad [10]$$

Note that these filters have a variable width $\Delta k/k$; therefore, when the wave number increases, the bandwidth becomes wider.

## Synthesis

The admissibility condition [1] implies the existence of a finite energy reproducing kernel, which is a necessary condition for being able to reconstruct the function $f$ from its wavelet coefficients $\widetilde{f}$. One then recovers

$$f(x) = \frac{1}{C_\psi}\int_0^\infty \int_{-\infty}^{\infty} \widetilde{f}(a,b)\psi_{a,b}(x)\frac{\mathrm{d}a\mathrm{d}b}{a^2} \qquad [11]$$

which is the inverse wavelet transform.

The wavelet transform is an isometry and one has Parseval's identity. Therefore, the wavelet transform conserves the inner product and we obtain

$$\langle f, g\rangle = \int_{-\infty}^{\infty} f(x)g^*(x)\,\mathrm{d}x = \frac{1}{C_\psi}\int_0^\infty \int_{-\infty}^{\infty} \widetilde{f}(a,b)\widetilde{g}^*(a,b)\frac{\mathrm{d}a\mathrm{d}b}{a^2} \qquad [12]$$

As a consequence, the total energy $E$ of a signal can be calculated either in physical space or in wavelet space, such as

$$E = \int_{-\infty}^{\infty} |f(x)|^2\,\mathrm{d}x = \frac{1}{C_\psi}\int_0^\infty \int_{-\infty}^{\infty} |\widetilde{f}(a,b)|^2\frac{\mathrm{d}a\mathrm{d}b}{a^2} \qquad [13]$$

This formula is also the starting point for the definition of wavelet spectra and scalogram (*see* Wavelets: Application to Turbulence).

## Examples

In the following, we apply the continuous wavelet transform to different academic signals using the Morlet wavelet. The Morlet wavelet is complex valued, and consists of a modulated Gaussian with width $k_0/\pi$:

$$\psi(x) = (\mathrm{e}^{2\imath\pi x} - \mathrm{e}^{-k_0^2/2})\,\mathrm{e}^{-2\pi^2x^2/k_0^2} \qquad [14]$$

The envelope factor $k_0$ controls the number of oscillations in the wave packet; typically, $k_0 = 5$ is used. The correction factor $\mathrm{e}^{-k_0^2/2}$, to ensure its vanishing mean, is very small and often neglected. The Fourier transform is

$$\widehat{\psi}(k) = \frac{k_0}{2\sqrt{\pi}}\,\mathrm{e}^{-(k_0^2/2)(1+k^2)}(\mathrm{e}^{-k_0^2k} - 1) \qquad [15]$$

Figure 1 shows wavelet analyses of a cosine, two sines, a Dirac, and a characteristic function. Below

the four signals we plot the modulus and the phase of the corresponding wavelet coefficients.

### Higher Dimensions

The continuous wavelet transform can be extended to higher dimensions in $L^2(\mathbb{R}^n)$ in different ways. Either we define spherically symmetric wavelets by setting $\psi(x) = \psi^{1d}(|x|)$ for $x \in \mathbb{R}^n$ or we introduce in addition to dilations $a \in \mathbb{R}^+$ and translations $b \in \mathbb{R}^n$ also rotations to define wavelets with a directional sensitivity. In the two-dimensional case, we obtain for example,

$$\psi_{a,b,\theta}(x) = \frac{1}{a}\psi\left(R_\theta^{-1}\left(\frac{x-b}{a}\right)\right) \qquad [16]$$

where $a \in \mathbb{R}^+, b \in \mathbb{R}^2$, and where $R_\theta$ is the rotation matrix

$$\begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix} \qquad [17]$$

The analysis formula [8] then becomes

$$\widetilde{f}(a,b,\theta) = \int_{\mathbb{R}^2} f(x)\psi^*_{a,b,\theta}(x)\,\mathrm{d}x \qquad [18]$$

and for the corresponding inverse wavelet transform [11] we obtain

$$f(x) = \frac{1}{C_\psi}\int_0^\infty \int_{\mathbb{R}^2}\int_0^{2\pi} \widetilde{f}(a,b,\theta)\psi_{a,b,\theta}(x)\frac{\mathrm{d}a\mathrm{d}b\mathrm{d}\theta}{a^3} \qquad [19]$$

Similar constructions can be made in dimensions larger than 2 using $n-1$ angles of rotation.

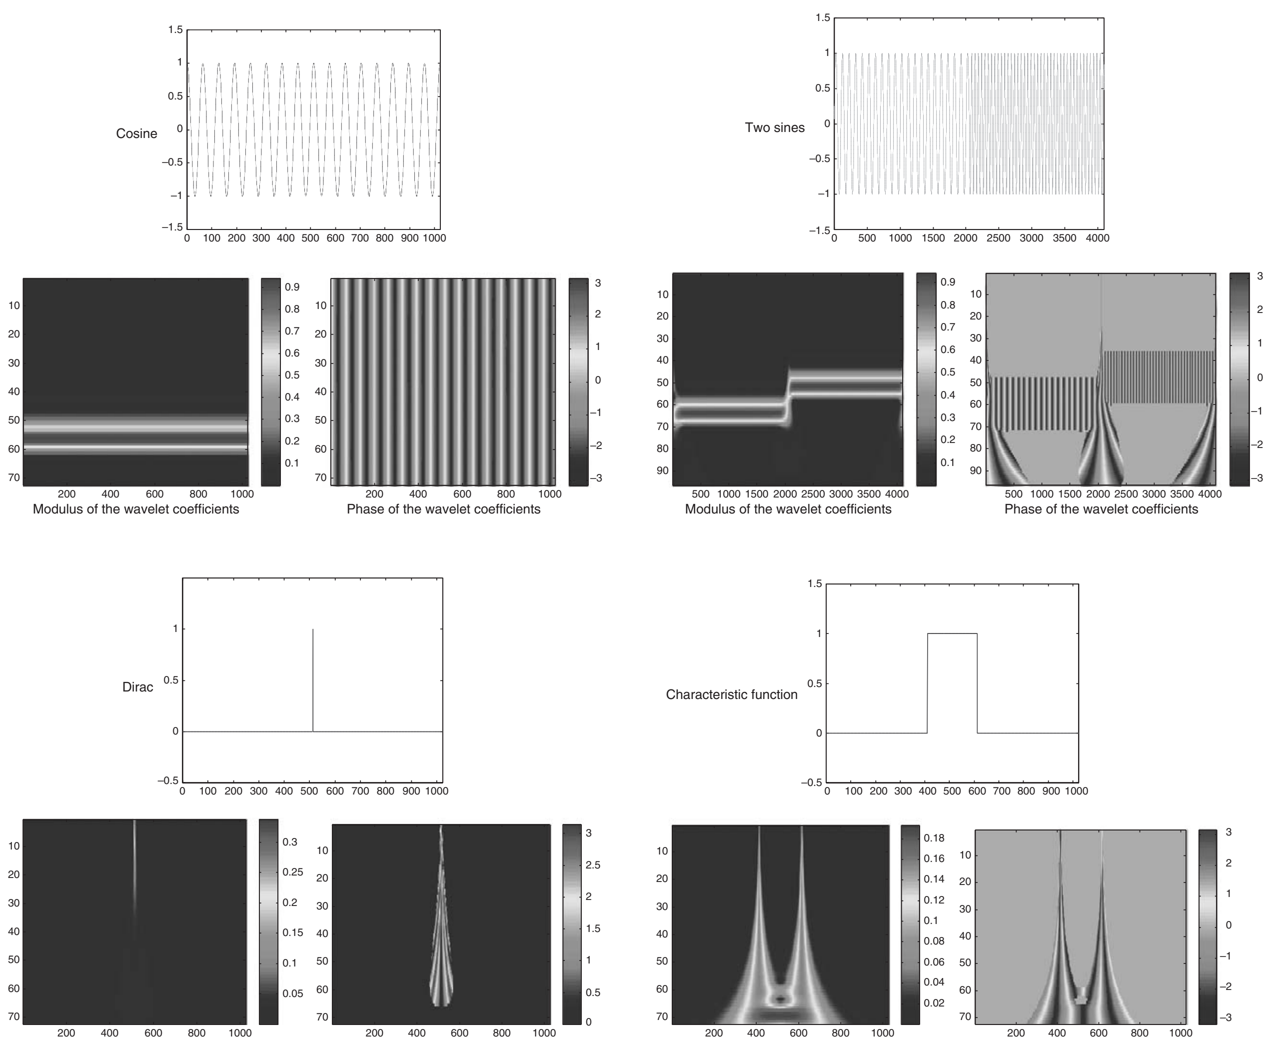

**Figure 1** Examples of a one-dimensional continuous wavelet analysis using the complex-valued Morlet wavelet. Each subfigure shows on the top the function to be analyzed and below (left) the modulus of its wavelet coefficients and below (right) the phase of its wavelet coefficients.

## Discrete Wavelets

### Frames

It is possible to obtain a discrete set of quasiorthogonal wavelets by sampling the scale and position axes $a, b$. For the scale $a$ we use a logarithmic discretization: $a$ is replaced by $a_j = a_0^{-j}$, where $a_0$ is the sampling rate of the log $a$ axis ($a_0 = \Delta(\log a)$) and where $j \in \mathbb{Z}$ is the scale index. The position $b$ is discretized linearly: $b$ is replaced by $x_{ji} = ib_0 a_0^{-j}$, where $b_0$ is the sampling rate of the position axis at the largest scale and where $i \in \mathbb{Z}$ is the position index. Note that the sampling rate of the position varies with scale, that is, for finer scales (increasing $j$ and hence decreasing $a_j$), the sampling rate increases. Accordingly, we obtain the discrete wavelets (cf. Figure 2)

$$\psi_{ji}(x') = a_j^{-1/2}\psi\left(\frac{x' - x_{ji}}{a_j}\right) \qquad [20]$$

and the corresponding discrete decomposition formula is

$$\widetilde{f}_{ji} = \langle \psi_{ji}, f \rangle = \int_{-\infty}^{\infty} f(x')\psi_{ji}^*(x')\,\mathrm{d}x' \qquad [21]$$

Furthermore, the wavelet coefficients satisfy the following estimate:

$$A\|f\|_2^2 \le \sum_{j,i} |\widetilde{f}_{ji}|^2 \le B\|f\|_2^2 \qquad [22]$$

with frame bounds $B \ge A > 0$. In the case $A = B$ we have a tight frame.

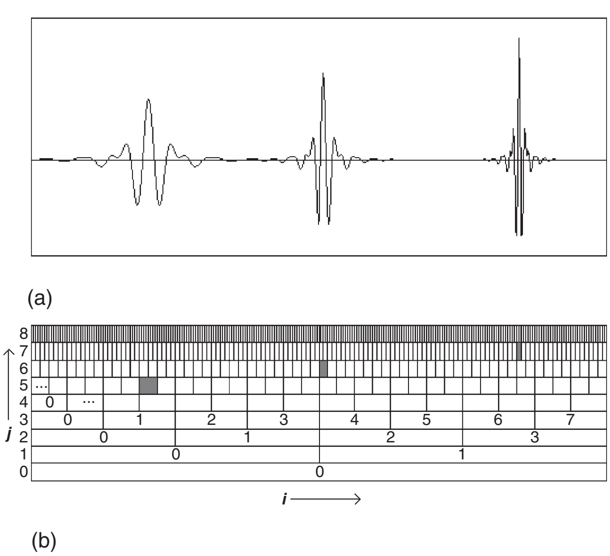

Figure 2 Orthogonal quintic spline wavelets $\psi_{j,i}(x) = 2^{j/2}\psi(2^j x - i)$ at different scales and positions: (a) $\psi_{5,6}(x)$, $\psi_{6,32}(x)$, $\psi_{7,108}(x)$, and (b) corresponding wavelet coefficients.

The discrete reconstruction formula is

$$f(x) = C \sum_{j=-\infty}^{\infty} \sum_{i=-\infty}^{\infty} \widetilde{f}_{ji}\psi_{ji}(x) + R(x) \qquad [23]$$

where $C$ is a constant and $R(x)$ is a residual, both depending on the choice of the wavelet and the sampling of the scale and position axes. For the particular choice $a_0 = 2$ (which corresponds to a scale sampling by octaves) and $b_0 = 1$, we have the dyadic sampling, for which there exist special wavelets $\psi_{ji}$ that form an orthonormal basis of $L^2(\mathbb{R})$, that is, such that

$$\langle \psi_{ji}, \psi_{j'i'} \rangle = \delta_{jj'}\delta_{ii'} \qquad [24]$$

where $\delta$ denotes the Kronecker symbol. This means that the wavelets $\psi_{ji}$ are orthogonal with respect to their translates by discrete steps $2^{-j}i$ and their dilates by discrete steps $2^{-j}$ corresponding to octaves. In this case, the reconstruction formula is exact with $C = 1$ and $R = 0$. Note that the discrete wavelet transform has lost the invariance by translation and dilation of the continuous one.

### Orthogonal Wavelets and Multiresolution Analysis

The construction of orthogonal wavelet bases and the associated fast numerical algorithm is based on the mathematical concept of multiresolution analysis (MRA). The underlying idea is to consider approximations $f_j$ of the function $f$ at different scales $j$. The amount of information needed to go from a coarse approximation $f_j$ to a finer resolution approximation $f_{j+1}$ is then described using orthogonal wavelets. The orthogonal wavelet analysis can thus be interpreted as decomposing the function into approximations of the function at coarser and coarser scales (i.e., for decreasing $j$), where the differences between the approximations are encoded using wavelets.

The definition of the MRA was introduced by Stéphane Mallat in 1988 (Mallat 1989). This technique constitutes a mathematical framework of orthogonal wavelets and the related FWT.

A one-dimensional orthogonal MRA of $L^2(\mathbb{R})$ is defined as a sequence of successive approximation spaces $V_j, j \in \mathbb{Z}$, which are closed imbedded subspaces of $L^2(\mathbb{R})$. They verify the following conditions:

$$V_j \subset V_{j+1} \quad \forall j \in \mathbb{Z} \qquad [25]$$

$$\overline{\bigcup_{j \in \mathbb{Z}} V_j} = L^2(\mathbb{R}) \qquad [26]$$

$$\bigcap_{j \in \mathbb{Z}} V_j = \{0\} \qquad [27]$$

$$f(x) \in V_j \Leftrightarrow f(2x) \in V_{j+1} \qquad [28]$$

A scaling function $\phi(x)$ is required to exist. Its translates generate a basis in each $V_j$, that is,

$$V_j V_j = \overline{\text{span}}\{\phi_{ji}\}_{i\in\mathbb{Z}} \quad [29]$$

where

$$\phi_{ji}(x) = 2^{j/2}\phi(2^j x - i), \quad j,i \in \mathbb{Z} \quad [30]$$

At a given scale $j$, this basis is orthonormal with respect to its translates by steps $i/2^j$ but not to its dilates,

$$\langle \phi_{ji}, \phi_{jk}\rangle = \delta_{ik} \quad [31]$$

The nestedness of the approximation spaces [28] generated by the scaling function $\phi$ implies that it satisfies a refinement equation:

$$\phi_{j-1,i}(x) = \sum_{n=-\infty}^{\infty} h_{n-2i}\phi_{jn}(x) \quad [32]$$

with the filter coefficients $h_n = \langle \phi_{jn}, \phi_{j-1,0}\rangle$, which determine the scaling function completely. In general, only the filter coefficients $h_n$ are known and no analytical expression of $\phi$ is given. Equation [32] implies that the approximation of a function at coarser scale can be described by linear combinations of the same function at finer scales.

The orthogonal projection of a function $f \in L^2(\mathbb{R})$ on $V_J$ is defined as

$$P_{V_J} : f \longrightarrow P_{V_J} f = f_J \quad [33]$$

with

$$f_J(x) = \sum_{k\in\mathbb{Z}} \langle f, \phi_{jk}\rangle \phi_{jk}(x) \quad [34]$$

This coarse graining at a given scale $J$ is done by filtering the function with the scaling function $\phi$. As a filter, the scaling function $\phi$ does not have vanishing mean but is normalized so that $\int_{-\infty}^{\infty} \phi(x)\,\mathrm{d}x = 1$.

As $V_{J-1}$ is included in $V_J$, we can define its orthogonal complement space in $V_J$:

$$V_J = V_{J-1} \oplus W_{J-1} \quad [35]$$

Correspondingly, the approximation of the function $f$ at scale $2^{-J}$, belonging to $V_J$, can be decomposed as a sum of orthogonal projections on $V_{J-1}$ and $W_{J-1}$, such that

$$P_{V_J} f = P_{V_{J-1}} f + P_{W_{J-1}} f \quad [36]$$

Based on the scaling function $\phi$, one can construct a function $\psi$, the so-called mother wavelet, given by the relation

$$\psi_{ji}(x) = \sum_{n\in\mathbb{Z}} g_{n-2i}\phi_{j,n}(x) \quad [37]$$

with $g_n = \langle \phi_{jn}, \psi_{j-1,0}\rangle$, and where $\psi_{ji}(x) = 2^{j/2}\psi(2^j x - i)$, $j,i \in \mathbb{Z}$ (cf. **Figure 2**). The filter coefficients $g_n$ can be computed from the filter coefficients $h_n$ using the relation

$$g_n = (-1)^{1-n} h_{1-n} \quad [38]$$

The translates and dilates of the wavelet $\psi$ constitute orthonormal bases of the spaces $W_j$,

$$W_j = \overline{\text{span}}\{\psi_{ji}\}_{i\in\mathbb{Z}} \quad [39]$$

As in the continuous case, the wavelets have vanishing mean, and also possibly vanishing higher-order moments; therefore,

$$\int_{-\infty}^{\infty} x^m \psi(x)\,\mathrm{d}x = 0 \quad \text{for } m = 0, \ldots, M-1 \quad [40]$$

Let us now consider approximations of a function $f \in L^2(\mathbb{R})$ at two different scales $j$:

- at scale $j$

$$f_j(x) = \sum_{i=-\infty}^{\infty} \overline{f}_{ji}\phi_{ji}(x) \quad [41]$$

- at scale $j-1$

$$f_{j-1}(x) = \sum_{i=-\infty}^{\infty} \overline{f}_{j-1,i}\phi_{j-1,i}(x) \quad [42]$$

with the scaling coefficients

$$\overline{f}_{ji} = \langle f, \phi_{ji}\rangle \quad [43]$$

which correspond to local averages of the function $f$ at position $i2^{-j}$ and at scale $2^{-j}$.

The difference between the two approximations is encoded by the wavelets

$$f_j(x) - f_{j-1}(x) = \sum_{i=-\infty}^{\infty} \widetilde{f}_{j-1,\,i}\psi_{j-1,i}(x) \quad [44]$$

with the wavelet coefficients

$$\widetilde{f}_{ji} = \langle f, \psi_{ji}\rangle \quad [45]$$

which correspond to local differences of the function at position $(2i+1)2^{-(j+1)}$ between approximations at scales $2^{-j}$ and $2^{-(j+1)}$.

Iterating the two-scale decomposition [44], any function $f \in L^2(\mathbb{R})$ can be expressed as a sum of a coarse-scale approximation at a reference scale $j_0$ that we set to 0 here, and their successive

differences. These details are needed to go from one scale $j$ to the next finer scale $j+1$ for $j=0,\dots,J-1$,

$$f(x) = \sum_{i=-\infty}^{\infty} \overline{f}_{0,i}\phi_{0,i}(x) + \sum_{j=0}^{\infty}\sum_{i=-\infty}^{\infty} \widetilde{f}_{ji}\psi_{ji}(x) \qquad [46]$$

For numerical applications, the sums in eqn [46] have to be truncated in both scale $j$ and position $i$. The truncation in scale corresponds to a limitation of $f$ to a given finest scale $J$, which is in practice imposed by the available sampling rate. Due to the finite length of the available data, the sum over $i$ also becomes finite. The decomposition [46] is orthogonal, as, by construction,

$$\langle \psi_{ji}, \psi_{j'i'} \rangle = \delta_{jj'}\delta_{ii'} \qquad [47]$$

$$\langle \psi_{ji}, \phi_{j'i'} \rangle = 0 \quad \text{for } j \geq j' \qquad [48]$$

in addition to [31].

### Fast Wavelet Transform

Starting with a function $f \in L^2(\mathbb{R})$ given at the finest resolution $2^{-J}$ (i.e., we know $f_J \in V_J$ and hence the coefficients $\overline{f}_{Ji}$ for $i \in \mathbb{Z}$), the FWT computes its wavelet coefficients $\widetilde{f}_{ji}$ by decomposing successively each approximation $f_J$ into a coarser scale approximation $f_{J-1}$, plus the corresponding details which are encoded by the wavelet coefficients. The algorithm uses a cascade of discrete convolutions with the low pass filter $h_n$ and the bandpass filter $g_n$, followed by downsampling, in which only one coefficient out of two is retained. The direct wavelet transform algorithm is

- initialization

$$\text{given } f \in L^2(\mathbb{R}) \text{ and } \overline{f}_{Ji} = f\left(\frac{i}{2^J}\right) \text{ for } i \in \mathbb{Z}$$

- decomposition
  for $j=J$ to 1, step –1, do

$$\overline{f}_{j-1,i} = \sum_{n\in\mathbb{Z}} h_{n-2i}\overline{f}_{jn} \qquad [49]$$

$$\widetilde{f}_{j-1,i} = \sum_{n\in\mathbb{Z}} g_{n-2i}\overline{f}_{jn} \qquad [50]$$

The inverse wavelet transform is based on successive reconstructions of fine-scale approximations $f_j$ from coarser scale approximations $f_{j-1}$, plus the differences between approximations at scale $j-1$ and the finer scale $j$ which are encoded by $\widetilde{f}_{j-1,i}$. The algorithm uses a cascade of discrete convolutions with the filters $h_n$ and $g_n$, preceded by upsampling which adds zeros in between two successive coefficients.

- reconstruction
  for $j=1$ to $J$, step 1, do

$$\overline{f}_{ji} = \sum_{n=-\infty}^{\infty} h_{i-2n}\overline{f}_{j-1,n} + \sum_{n=-\infty}^{\infty} g_{i-2n}\widetilde{f}_{j,n} \qquad [51]$$

The FWT has been introduced by Stéphane Mallat in 1989. If the scaling functions (and wavelets) are compactly supported, the filters $h_n$ and $g_n$ have only a finite number of nonvanishing coefficients. In this case, the numerical complexity of the FWT is $\mathcal{O}(N)$ where $N$ denotes the number of samples.

### Choice of Wavelets

Orthogonal wavelets are typically defined by their filter coefficients $h_n$, since in general no analytic expression for $\psi$ is available. In the following, we give the filter coefficients of $h_n$ for some typical orthogonal wavelets. The filter coefficients of $g_n$ can be obtained using the quadrature relation between the two filters [38].

- Haar D1 (one vanishing moment):

$$h_0 = 1/\sqrt{2}$$
$$h_1 = 1/\sqrt{2}$$

- Daubechies D2 (two vanishing moments):

$$h_0 = 0.482\,962\,913\,145$$
$$h_1 = 0.836\,516\,303\,736$$
$$h_2 = 0.224\,143\,868\,042$$
$$h_3 = -0.129\,409\,522\,551$$

- Daubechies D3 (three vanishing moments):

$$h_0 = 0.332\,670\,552\,950$$
$$h_1 = 0.806\,891\,509\,311$$
$$h_2 = 0.459\,877\,502\,118$$
$$h_3 = -0.135\,011\,020\,010$$
$$h_4 = -0.085\,441\,273\,882$$
$$h_5 = 0.035\,226\,291\,882$$

- Coiflets C12 (four vanishing moments): the wavelets and the corresponding scaling function are shown in Figure 3.

**Remarks** The construction of orthogonal wavelets in $L^2(\mathbb{R})$ can be modified to obtain wavelets on the interval, that is, in $L^2([0,1])$. Therewith, boundary wavelets are introduced, while in the interior of the interval the wavelets are not modified.

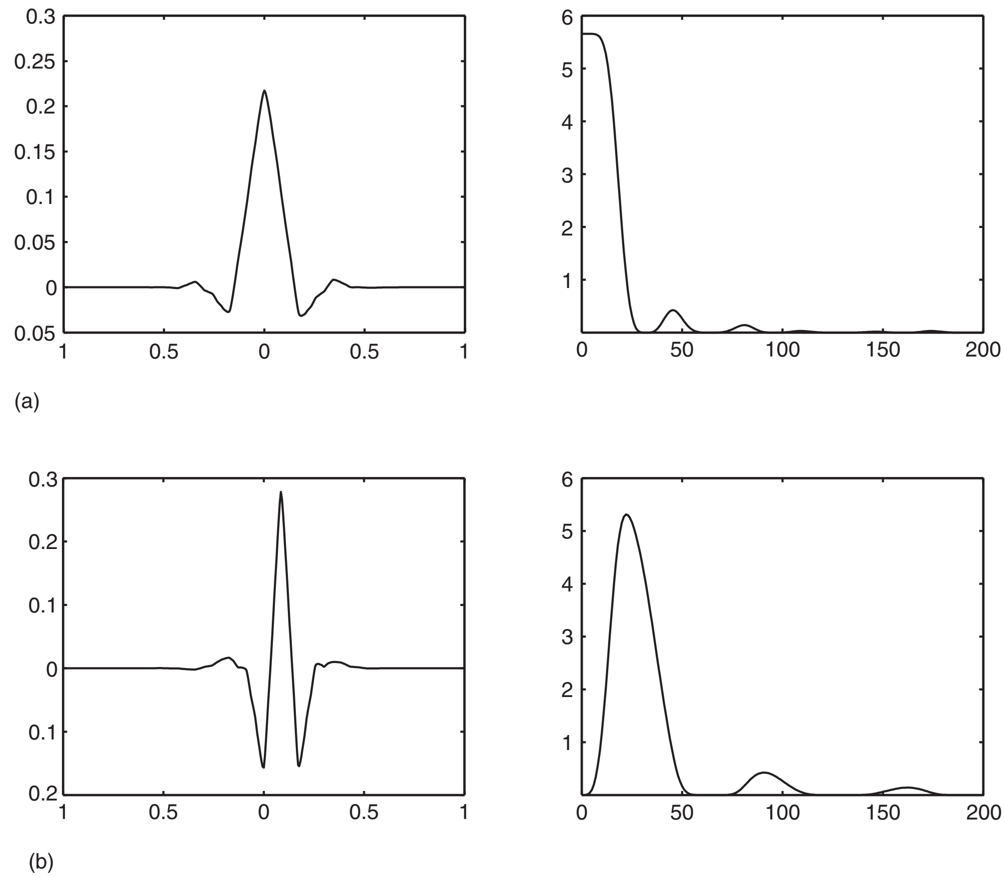

**Figure 3** Orthogonal wavelets Coiflet C12. (a) Scaling function $\phi(x)$ (left) and $|\hat{\phi}(\omega)|$. (b) Wavelet $\psi(x)$ (left) and $|\hat{\psi}(\omega)|$.

A periodic MRA of $L^2(\mathbb{T})$, where $\mathbb{T}=\mathbb{R}/\mathbb{Z}$ denotes the torus, can also be constructed by periodizing the wavelets in $L^2(\mathbb{R})$, using

$$\psi^{\mathrm{per}}(x) = \sum_{k\in\mathbb{Z}} \psi(x+k)$$

Relaxing the condition of orthogonality allows greater flexibility in the choice of the basis functions. For example, biorthogonal wavelets can be designed using different basis functions for analysis ($^{\mathrm{a}}$) and synthesis ($^{\mathrm{s}}$) which are related but no longer orthogonal. A couple of refinable scaling functions $(\phi^{\mathrm{a}}, \phi^{\mathrm{s}})$ with related wavelets $(\psi^{\mathrm{a}}, \psi^{\mathrm{s}})$ which are by construction biorthogonal generate a biorthogonal MRA $V_j^{\mathrm{a}}, V_j^{\mathrm{s}}$. From an algorithmic point of view, only two different filter couples $(g^{\mathrm{a}}, h^{\mathrm{a}})$ for the forward and $(g^{\mathrm{s}}, h^{\mathrm{s}})$ for the backward FWT are used, without changing the algorithm.

The multiresolution approach can be further generalized, for samplings on nonequidistant grids leading to the so-called second-generation wavelets.

### Higher Dimensions

The previously presented one-dimensional construction can be extended to higher dimensions. For simplicity, we will consider only the two-dimensional case, since higher dimensions can be treated analogously.

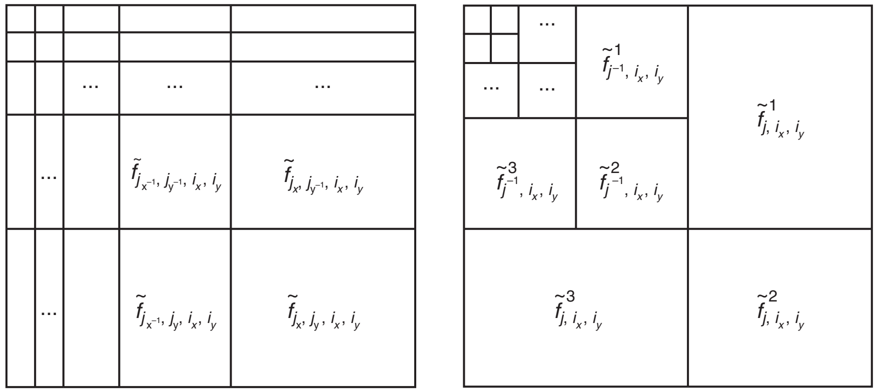
**Tensor product construction** Having developed a one-dimensional orthonormal basis $\psi_{ji}$ of $L^2(\mathbb{R})$, one could use these functions as building blocks in higher dimensions. One way of doing so is to take the tensor product of two one-dimensional bases and to define

$$\psi_{j_x,j_y,i_x,i_y}(x,y) = \psi_{j_x,i_x}(x)\psi_{j_y,i_y}(y) \qquad [52]$$

The resulting functions constitue an orthonormal wavelet basis for $L^2(\mathbb{R}^2)$. Each function $f \in L^2(\mathbb{R}^2)$ can then be developed into

$$f(x,y) = \sum_{j_x,i_x} \sum_{j_y,i_y} \widetilde{f}_{j_x,j_y,i_x,i_y} \psi_{j_x,j_y,i_x,i_y}(x,y) \qquad [53]$$

with $\widetilde{f}_{j_x,j_y,i_x,i_y} = \langle f, \psi_{j_x,j_y,i_x,i_y} \rangle$. However, in this basis the two variables $x$ and $y$ are dilatated separately



(a) (b)

**Figure 4a** Schematic representation of the 2D (b) wavelet transforms: (a) Tensor product construction and (b) 2D MRA.

and therefore no longer form an MRA. This means that the functions $\psi_{j_x,j_y}$ involve two scales, $2^{j_x}$ and $2^{j_y}$, and each of the functions is essentially supported on a rectangle with these side-lengths. Hence, the decomposition is often called rectangular wavelet decomposition (cf. Figure 4a). From the algorithmic viewpoint, this is equivalent to applying the one-dimensional wavelet transform to the rows and the columns of a matrix or a function. For some applications, such a basis is advantageous, for others not. Often the notion of a scale has a certain meaning. For an application, one would like to have a unique scale assigned to each basis function.

**Multiresolution construction** Another much more interesting construction is the construction of a truly two-dimensional MRA of $L^2(\mathbb{R}^2)$. It can be obtained through the tensor product of two one-dimensional MRAs of $L^2(\mathbb{R})$. More precisely, one defines the spaces $\boldsymbol{V}_j, j \in \mathbb{Z}$ by

$$\boldsymbol{V}_j = V_j \otimes V_j \qquad [54]$$

and $\boldsymbol{V}_j = \overline{\text{span}}\{\phi_{j,i_x,i_y}(x,y) = \phi_{j,i_x}(x)\phi_{j,i_y}(y), i_x, i_y \in \mathbb{Z}\}$ fulfilling analogous properties as in the one-dimensional case.

Likewise, we define the complement space $\boldsymbol{W}_j$ to be the orthogonal complement of $\boldsymbol{V}_j$ in $\boldsymbol{V}_{j+1}$, that is,

$$\begin{aligned}\boldsymbol{V}_{j+1} &= V_{j+1} \otimes V_{j+1} \\ &= (V_j \oplus W_j) \otimes (V_j \oplus W_j)\end{aligned} \qquad [55]$$

$$\begin{aligned}&= V_j \otimes V_j \oplus ((W_j \otimes V_j) \\ &\quad \oplus (V_j \otimes W_j) \oplus (W_j \otimes W_j))\end{aligned} \qquad [56]$$

$$= \boldsymbol{V}_j \oplus \boldsymbol{W}_j \qquad [57]$$

It follows that the orthogonal complement $\boldsymbol{W}_j = \boldsymbol{V}_{j+1} \ominus \boldsymbol{V}_j$ consists of three different types of functions and is generated by three different wavelets

$$\psi^{\varepsilon}_{j,i_x,i_y}(x,y) = \begin{cases} \psi_{j,i_x}(x)\phi_{j,i_y}(y), & \varepsilon = 1 \\ \phi_{j,i_x}(x)\psi_{j,i_y}(y), & \varepsilon = 2 \\ \psi_{j,i_x}(x)\psi_{j,i_y}(y), & \varepsilon = 3 \end{cases} \qquad [58]$$

Observe that here the scale parameter $j$ simultaneously controls the dilatation in $x$ and $y$. We recall that in $d$ dimensions this construction yields $2^d - 1$ types of wavelets spanning $\boldsymbol{W}_j$.

Using [58], each function $f \in L^2(\mathbb{R}^2)$ can be developed into a multiresolution basis as

$$f(x,y) = \sum_j \sum_{i_x,i_y} \sum_{\varepsilon=1,2,3} \tilde{f}^{\varepsilon}_{j,i_x,i_y} \psi^{\varepsilon}_{j,i_x,i_y}(x,y) \qquad [59]$$

with $\tilde{f}^{\varepsilon}_{j,i_x,i_y} = <f, \psi^{\varepsilon}_{j,i_x,i_y}>$. A schematic representation of the wavelet coefficients is shown in Figure 4b. The algorithmic structure of the one-dimensional transforms carries over to the two-dimensional case by simple tensorization, that is, applying the filters at each decomposition step to rows and columns.

**Remark** The described two-dimensional wavelets and scaling functions are separable. This advantage is the ease of generation starting from one-dimensional MRAs. However, the main drawback of this construction is that three wavelets are needed to span the orthogonal complement space $\boldsymbol{W}_j$. Another property should be mentioned. By construction, the wavelets are anisotropic, that is, horizontal, diagonal, and vertical directions are preferred.

## Approximation Properties

### Reproduction of Polynomials

A fundamental property of the MRA is the exact reproduction of polynomials. The vanishing moments of the wavelet $\psi$, that is, $\int_{\mathbb{R}} x^m \psi(x) \mathrm{d}x = 0$

for $m=0, M-1$, is equivalent to the fact that polynomials up to degree $M-1$, can be expressed exactly as a linear combination of scaling functions, $p_m(x)=\sum_{n\in\mathbb{Z}} n^m \phi(x-n)$ for $m=0,M-1$. This so-called Strang–Fix condition proves that $\psi$ has $M$ vanishing moments if and only if any polynomial of degree $M-1$ can be written as a linear combination of scaling functions $\phi$. Note that, as $p_m \notin L^2(\mathbb{R})$, the coefficients $n^m$ are not in $l^2(\mathbb{Z})$.

### Regularity and Local Decay of Wavelet Coefficients

The local or global regularity of a function is closely related to the decay of its wavelet coefficients. If a function is locally in $C^s(\mathbb{R})$ (the space of $s$-times continuously differentiable functions), it can be well approximated locally by a Taylor series of degree $s$. Consequently, its wavelet coefficients are small at fine scales, as long as the wavelet $\psi$ has enough vanishing moments. The decay of the coefficients hence determines directly the error being made when truncating a wavelet sum at some scale.

Depending on the type of norm used and whether global or local characterization is concerned, various relations of this kind have been developed. Let us take as example the case of an $\alpha$-Lipschitz function.

Suppose $f \in L^2(\mathbb{R})$, then for $[a,b] \subset \mathbb{R}$ the function $f$ is $\alpha$-Lipschitz with $0 < \alpha < 1$ for any $x_0 \in [a,b]$, that is, $|f(x_0+h) - f(x_0)| \le C|h|^\alpha$, if and only if there exists a constant $A$ such that $|\widetilde{f}_{ji}| \le A2^{-j\alpha-1/2}$ for any $(j,i)$ with $i/2^j \in [a,b]$.

This shows the relation between the local regularity of a function and the decay of its wavelet coefficients in scale.

**Example** To illustrate the local decay of the wavelet coefficients, we consider in Figure 5 the function $f(x) = \sin(2\pi x)$ for $x \le 1/4$ and $x \ge 3/4$ and $f(x) = -\sin(2\pi x)$ for $1/4 < x < 3/4$. The corresponding wavelet coefficients for quintic spline wavelets are plotted in logarithmic scale. The wavelet coefficients show that only in a local region around singularities the fine-scale coefficients are significant.

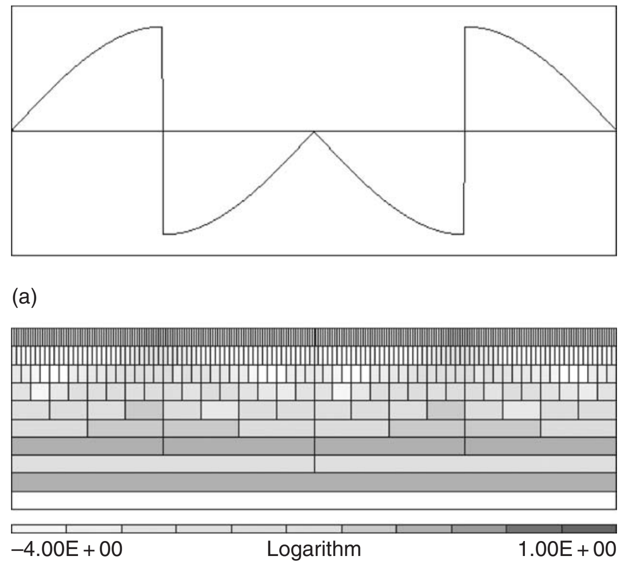


**Figure 5** Orthogonal wavelet decomposition using quintic spline wavelets: (a) function $f(x) = \sin(2\pi x)$ for $x \le 1/4$ and $x \ge 3/4$ and $f(x) = -\sin(2\pi x)$ for $1/4 < x < 3/4$ sampled on a grid $x_i = i/2^J, i=0,\ldots,2^J-1$ with $J=9$ and (b) corresponding wavelet coefficients $\log_{10}|\widetilde{f}_{j,i}|$ for $i=0,\ldots,2^j-1$ and $j=0,\ldots,J-1$.

### Linear Approximation

The exact reproduction of polynomials can be used to derive error estimates for the approximation of a function $f$ at a given scale, which corresponds to linear approximation. We consider $f$ belonging to the Sobolev space $W^{s,p}(\mathbb{R}^d)$, that is, the weak derivatives of $f$ up to order $s$ belong to $L^p(\mathbb{R}^d)$. The linear approximation of $f$ at scale $J$, corresponding to the projection of $f$ onto $V_J$, is then given by

$$f_J(x) = \sum_{j=0}^{J-1} \sum_{i\in\mathbb{Z}} \widetilde{f}_{j,i} \psi_{j,i}(x) \qquad [60]$$

The approximation error can be estimated by

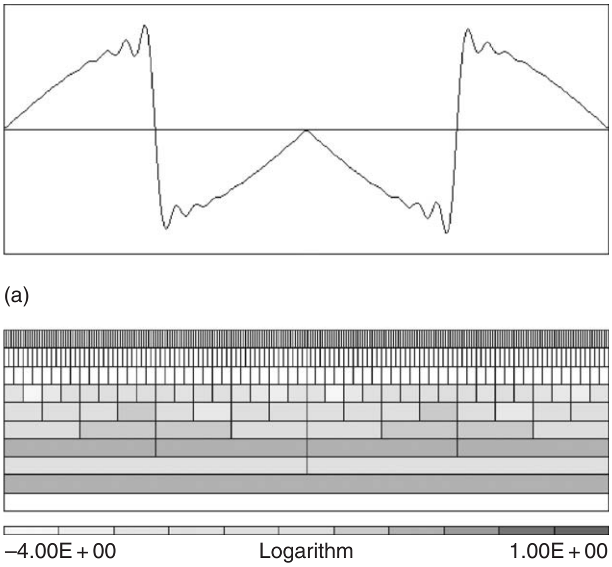
$$\|f - f_J\|_{L^p} < C2^{-J\min(s,m)/d} \qquad [61]$$

where $s$ denotes the smoothness of the function in $L^p$, $d$ the space dimension, and $m$ the number of vanishing moments of the wavelet $\psi$. In the case of poor global regularity of $f$, that is, for small $s$, a large number of scales $J$ is needed to get a good approximation of $f$.

In Figure 6, we plot the linear approximation of the function $f$ shown in Figure 5. The function $f_6$ is reconstructed using wavelet coefficients up to scale $J-1=5$, so that in total only 64 out of 512 coefficients are retained. We observe an oscillating behavior of $f_J$ near the discontinuities of $f$ which dominates the approximation error.

### Nonlinear Approximation

Retaining the $N$ largest wavelet coefficients in the wavelet expansion of $f$ in [46], without imposing any *a priori* cutoff scale, yields the best $N$-term approximation $f^N$. In contrast to the linear approximation [60], it is called nonlinear approximation, since the choice of the retained coefficients depends



(b)

**Figure 6** (a) Linear approximation $f_J$ of the function $f$ in Figure 5 for $J=6$, reconstructed from 64 wavelet coefficients using quintic splines wavelets and (b) corresponding wavelet coefficients $\log_{10}|\widetilde{f}_{j,i}|$ for $i=0,\ldots,2^j-1$ and $j=0,\ldots,J-1$. Note that the coefficients for $J>5$ have been set to zero.

on the function $f$. The mathematical theory has been formalized by Cohen, Dahmen, and De Vore.

The nonlinear approximation of the function $f$ can then be written as

$$f^N(x) = \sum_{(j,i)\in\Lambda_N} \widetilde{f}_{j,i}\,\psi_{j,i}(x) \qquad [62]$$

where $\Lambda_N$ denotes the ensemble of all multi-indices $\lambda=(j,i)$, indexing the $N$ largest coefficients (measured in the $l^p$ norm),

$$\Lambda_N = \{\lambda_k, k=1,N|\ \ \|\widetilde{f}_{\lambda_k}\|_{l^p} > \|\widetilde{f}_\mu\|_{l^p}\ \ \forall\mu\in\Lambda\} \qquad [63]$$

with $\Lambda=\{\mu=(j,i), j\geq 0, i\in\mathbb{Z}\}$. The nonlinear approximation leads to the following error estimate:

$$\|f-f^N\|_{L^p} < CN^{-s/d} \qquad [64]$$

where $s$ denotes the smoothness of $f$ in the larger space $L^q(\mathbb{R}^d)$ with

$$\frac{1}{q}=\frac{1}{p}+\frac{s}{d}$$

which corresponds to the Sobolev embedding line (Figure 7). This estimate shows that the nonlinear approximation converges faster than the linear one, if $f$ has a larger regularity in $L^q$, that is, $f\in W^{s,q}(\mathbb{R}^d)$, which is for example the case for functions with isolated singularities and for small $q$.

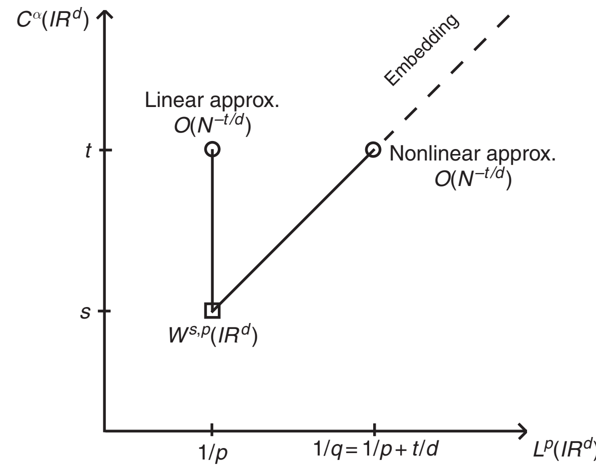


**Figure 7** Schematic representation of linear and nonlinear approximation.

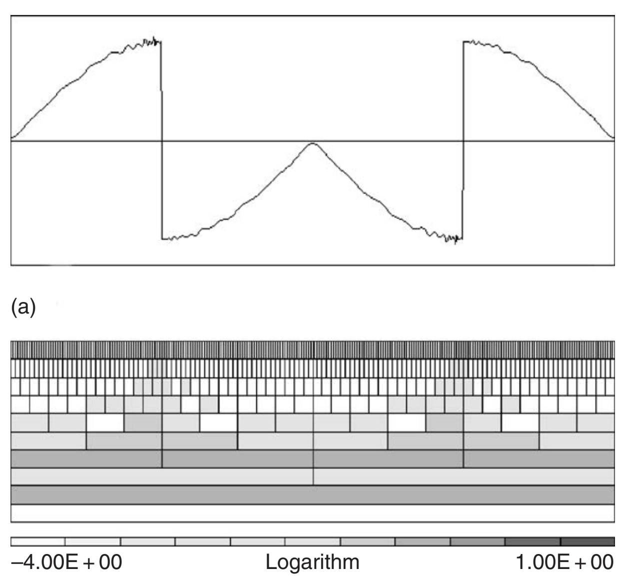
In Figure 8, we plot the nonlinear approximation of the function $f$ shown in Figure 5. The function $f^N$ is reconstructed using the strongest 64 wavelet coefficients out of 512 coefficients. Compared to the linear approximation (cf. Figure 6), the oscillations around the discontinuities disappear and the approximation error is reduced while using the same number of coefficients.

## Compression and Preconditioning of Operators

The nonlinear approximation of functions can be extended to certain operators leading to an efficient



(b)

**Figure 8** (a) Nonlinear approximation $f^N$ of the function $f$ in Figure 5 reconstructed from the 64 largest wavelet coefficients using quintic splines wavelets, (b) retained wavelet coefficients $\log_{10}|\widetilde{f}_{j,i}|$ for $i=0,\ldots,2^j-1$ and $j=0,\ldots,J-1$.

representation in wavelet space, that is, to sparse matrices. For integral operators, for example, Calderon–Zygmund operators $T$ on $\mathbb{R}$ defined by

$$Tf(x) = \int_{\mathbb{R}} K(x,y)f(y)\,dy \qquad [65]$$

where the kernel $k$ satisfies

$$|k(x,y,)| \leq \frac{C}{|x-y|}$$

and

$$\left|\frac{\partial}{\partial x}k(x,y)\right| + \left|\frac{\partial}{\partial y}k(x,y,)\right| \leq \frac{C}{|x-y|^2}$$

their wavelet representation $\langle T\psi_{j,i}, \psi_{j',i'}\rangle$ is sparse and a large number of weak coefficients can be suppressed by simple thresholding of the matrix entries while controlling the precision. The resulting numerical scheme is called BCR algorithm and is due to Beylkin *et al.* (1991).

The characterization of function spaces by the decay of the wavelet coefficients and the corresponding norm equivalences can be used for diagonal preconditioning of integral or differential operators which leads to matrices with uniformly bounded condition numbers. For elliptic differential operators, for example, the Laplace operator $\nabla^2$ the norm equivalence $\|\nabla^2 f\| \simeq \|2^{2j}\widetilde{f}_{ji}\|$ can be used for preconditioning the matrix $\langle \nabla^2\psi_{j,i}, \psi_{j',i'}\rangle$ by a simple diagonal scaling with $2^{-2j}$ to obtain a uniformly bounded condition number. For further details, we refer to the book of Cohen (2000).

### Wavelet Denoising

We consider a function $f$ which is corrupted by a Gaussian white noise $n \in \mathcal{N}(0,\sigma^2)$. The noise is spread over all wavelet coefficients $\widetilde{s}_\lambda$, while, typically, the original function $f$ is determined by only few significant wavelet coefficients. The aim is then to reconstruct the function $f$ from the observed noisy signal $s = f + n$.

The principle of the wavelet denoising can be summarized in the following procedure:

- *Decomposition*. Compute the wavelet coefficients $\widetilde{s}_\lambda$ using the FWT.
- *Thresholding*. Apply the thresholding function $\rho_\varepsilon$ to the wavelet coefficients $\widetilde{s}_\lambda$, thus reducing the relative importance of the coefficients with small absolute value.
- *Reconstruction*. Reconstruct a denoised version $s_C$ from the thresholded wavelet coefficients using the fast inverse wavelet transform.

The thresholding parameter $\varepsilon$ depends on the variance of the noise and on the sample size $N$. The thresholding function $\rho$ we consider corresponds to hard thresholding:

$$\rho_\varepsilon(a) = \begin{cases} a & \text{if } |a| > \varepsilon \\ 0 & \text{if } |a| \leq \varepsilon \end{cases} \qquad [66]$$

Donoho and Johnstone (1994) have shown that there exists an optimal $\varepsilon$ for which the relative quadratic error between the signal $s$ and its estimator $s_C$ is close to the minimax error for all signals $s \in \mathcal{H}$, where $\mathcal{H}$ belongs to a wide class of function spaces, including Hölder and Besov spaces. They showed using the threshold

$$\varepsilon_D = \sigma_n\sqrt{2\ln N} \qquad [67]$$

yields an error which is close to the minimum error. The threshold $\varepsilon_D$ depends only on the sampling $N$ and on the variance of the noise $\sigma_n$; hence, it is called universal threshold. However, in many applications, $\sigma_n$ is unknown and has to be estimated from the available noisy data $s$. For this, the present authors have developed an iterative algorithm (see Azzolini *et al.* (2005)), which is sketched in the following:

1. *Initialization*
   (a) given $s_k, k = 0, \ldots, N-1$. Set $i = 0$ and compute the FWT of $s$ to obtain $\widetilde{s}_\lambda$;
   (b) compute the variance $\sigma_0^2$ of $s$ as a rough estimate of the variance of $n$ and compute the corresponding threshold $\varepsilon_0 = (2\ln N\sigma_0^2)^{1/2}$;
   (c) set the number of coefficients considered as noise $N_{\text{noise}} = N$.
2. *Main loop repeat*
   (a) set $N'_{\text{noise}} = N_{\text{noise}}$ and count the wavelet coefficients $N_{\text{noise}}$ with modulus smaller than $\varepsilon_i$;
   (b) compute the new variance $\sigma_{i+1}^2$ from the wavelet coefficients whose modulus is smaller than $\varepsilon_i$ and the new threshold $\varepsilon_{i+1} = (2(\ln N)\sigma_{i+1}^2)^{1/2}$;
   (c) set $\text{i} = \text{i} + 1$ until $(N'_{\text{noise}} == N_{\text{noise}})$.
3. *Final step*
   (a) compute $s_C$ from the coefficients with modulus larger than $\varepsilon_i$ using the inverse FWT.

**Example** To illustrate the properties of the denoising algorithm, we apply it to a one-dimensional test signal. We construct a noisy signal $s$ by superposing a Gaussian white noise, with zero mean and variance $\sigma_W^2 = 1$, to a function $f$, normalized such that $((1/N)\sum_k |f_k|^2)^{1/2} = 10$. The number of samples is

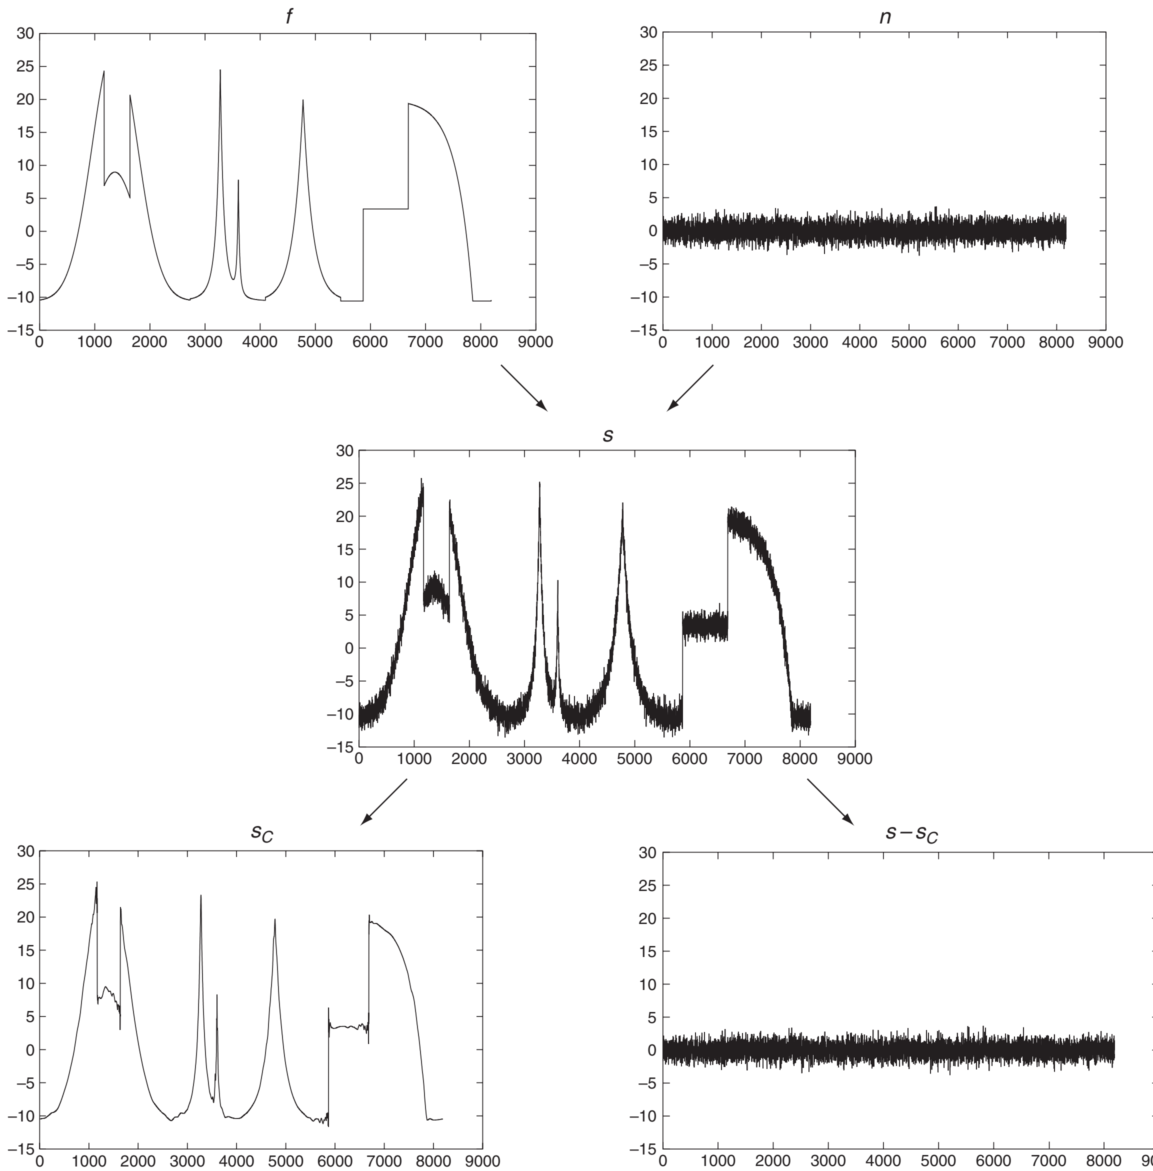


**Figure 9** Construction (top) of a 1D noisy signal $s = f + n$ (middle), and results obtained by the recursive denoising algorithm (bottom).

$N = 8192$. Figure 9a shows the function $f$ together with the noise $n$; Figure 9b shows the constructed noisy signal $s$ and Figure 9c shows the wavelet denoised signal $s_C$ together with the extracted noise.

# WDVV Equations and Frobenius Manifolds

**B Dubrovin**, SISSA-ISAS, Trieste, Italy

## Main Definition

WDVV equations of associativity (after E Witten, R Dijkgraaf, E Verlinde, and H Verlinde) is tantamount to the following problem: find a function $F(v)$ of $n$ variables $v=(v^1, v^2, \ldots, v^n)$ satisfying the conditions [1], [3], and [4] given below. First,

$$\frac{\partial^3 F(v)}{\partial v^1 \partial v^\alpha \partial v^\beta} \equiv \eta_{\alpha\beta} \qquad [1]$$

must be a constant symmetric nondegenerate matrix. Denote $(\eta^{\alpha\beta}) = (\eta_{\alpha\beta})^{-1}$ the inverse matrix and introduce the functions

$$c^\gamma_{\alpha\beta}(v) = \eta^{\gamma\epsilon} \frac{\partial^3 F(v)}{\partial v^\epsilon \partial v^\alpha \partial v^\beta}, \quad \alpha, \beta, \gamma = 1, \ldots, n \qquad [2]$$

The main condition says that, for arbitrary $v^1, \ldots, v^n$ these functions must be structure constants of an associative algebra, that is, introducing a $v$-dependent multiplication law in the $n$-dimensional space by

$$a \cdot b := \left( c^1_{\alpha\beta}(v) a^\alpha b^\beta, \ldots, c^n_{\alpha\beta}(v) a^\alpha b^\beta \right)$$

one obtains an $n$-parameter family of $n$-dimensional associative algebras (these algebras will automatically be also commutative). Spelling out this condition one obtains an overdetermined system of nonlinear PDEs for the function $F(v)$ often also called WDVV associativity equations

$$\frac{\partial^3 F(v)}{\partial v^\alpha \partial v^\beta \partial v^\lambda} \eta^{\lambda\mu} \frac{\partial^3 F(v)}{\partial v^\mu \partial v^\gamma \partial v^\delta} = \frac{\partial^3 F(v)}{\partial v^\delta \partial v^\beta \partial v^\lambda} \eta^{\lambda\mu} \frac{\partial^3 F(v)}{\partial v^\mu \partial v^\gamma \partial v^\alpha} \qquad [3]$$

for arbitrary $1 \le \alpha, \beta, \gamma, \delta \le n$. (Summation over repeated indices will always be assumed.) The last one is the so-called quasihomogeneity condition

$$EF = (3-d)F + \tfrac{1}{2} A_{\alpha\beta} v^\alpha v^\beta + B_\alpha v^\alpha + C \qquad [4]$$

where

$$E = \left( a^\alpha_\beta v^\beta + b^\alpha \right) \frac{\partial}{\partial v^\alpha}$$

for some constants $a^\alpha_\beta, b^\alpha$ satisfying

$$a^\alpha_1 = \delta^\alpha_1, \qquad b^1 = 0$$

$A_{\alpha\beta}, B_\alpha, C, d$ are some constants. $E$ is called Euler vector field and $d$ is the charge of the Frobenius manifold.

For $n=1$ one has $F(v) = (1/6)v^3$. For $n=2$ one can choose

$$F(u, v) = \tfrac{1}{2} u v^2 + f(u)$$

only the quasihomogeneity [4] makes a constraint for $f(v)$. The first nontrivial case is for $n=3$. The solution to WDVV is expressed in terms of a function $f=f(x,y)$ in one of the two forms (in the examples all indices are written as lower):

$$\begin{aligned} d \neq 0: \quad & F = \tfrac{1}{2} v_1^2 v_3 + \tfrac{1}{2} v_1 v_2^2 + f(v_2, v_3) \\ & f_{xxy}^2 = f_{yyy} + f_{xxx} f_{xyy} \\ d = 0: \quad & F = \tfrac{1}{6} v_1^3 + v_1 v_2 v_3 + f(v_2, v_3) \\ & f_{xxx} f_{yyy} - f_{xxy} f_{xyy} = 1 \end{aligned} \qquad [5]$$

The function $f(x, y)$ satisfies additional constraint imposed by [4]. Because of this the above PDEs [5] can be reduced (Dubrovin 1992, 1996) to a particular case of the Painlevé-VI equation (*see* Painlevé Equations).

The problem [1], [3], [4] is invariant with respect to linear changes of coordinates preserving the direction of the vector $\partial/\partial v^1$:

$$v^\alpha \mapsto \tilde{v}^\alpha = P^\alpha_\beta v^\beta + Q^\alpha, \ \det(P^\alpha_\beta) \neq 0, \quad P^\alpha_1 = \delta^\alpha_1$$

It is also allowed to add to $F(v)$ a polynomial of the degree at most 2. To consider more general nonlinear changes of coordinates one has to give a coordinate-free form of the above equations [1], [3], [4]. This gives rise to the notion of Frobenius manifold introduced in Dubrovin (1992).

Recall that a Frobenius algebra is a pair $(A, <,>)$, where $A$ is a commutative associative algebra with a unity $e$ over a field $k$ (we will consider only the cases $k = \mathbb{R}, \mathbb{C}$) and $<,>$ is a $k$-bilinear symmetric nondegenerate invariant form on $A$, that is,

$$<x \cdot y, z> = <x, y \cdot z>$$

for arbitrary vectors $x, y, z$ in $A$.

**Definition** Frobenius structure $(\cdot, e, <,>, E, d)$ on the manifold $M$ is a structure of a Frobenius algebra on the tangent spaces $T_v M = (A_v, <,>_v)$ depending (smoothly, analytically, etc.) on the point $v \in M$. It must satisfy the following axioms.

**FM1.** The curvature of the metric $<,>_v$ on $M$ (not necessarily positive definite) vanishes. Denote $\nabla$ the Levi-Civita connection for the metric. The unity vector field $e$ must be flat, $\nabla e = 0$.

**FM2.** Let $c$ be the 3-tensor $c(x, y, z) := <x \cdot y, z>$, $x, y, z \in T_v M$. The 4-tensor $(\nabla_w c)(x, y, z)$ must be symmetric in $x, y, z, w \in T_v M$.

**FM3.** A linear vector field $E \in \mathrm{Vect}(M)$ (called Euler vector field) must be fixed on $M$, that is, $\nabla\nabla E = 0$, such that

$$\mathrm{Lie}_E(x \cdot y) - \mathrm{Lie}_E x \cdot y - x \cdot \mathrm{Lie}_E y = x \cdot y$$
$$\mathrm{Lie}_E <,> = (2 - d) <,>$$

for some number $d \in k$ called "charge."

The last condition (also called quasihomogeneity) means that the derivations $Q_{\mathrm{Func}(M)} := E$, $Q_{\mathrm{Vect}(M)} := \mathrm{id} + \mathrm{ad}_E$ define on the space $\mathrm{Vect}(M)$ of vector fields on $M$ a structure of graded Frobenius algebra over the graded ring of functions $\mathrm{Func}(M)$.

Flatness of the metric $<,>$ implies local existence of a system of flat coordinates $v^1, \ldots, v^n$ on $M$. Usually, they are chosen in such a way that

$$e = \frac{\partial}{\partial v^1}$$

is the unity vector field. In such coordinates, the problem of local classification of Frobenius manifolds reduces to the WDVV associativity equations [1], [3], [4]. Namely, $\eta_{\alpha\beta}$ is the constant Gram matrix of the metric in these coordinates

$$\eta_{\alpha\beta} := \left\langle \frac{\partial}{\partial v^\alpha}, \frac{\partial}{\partial v^\beta} \right\rangle$$

The structure constants of the Frobenius algebra $A_v = T_v M$

$$\frac{\partial}{\partial v^\alpha} \cdot \frac{\partial}{\partial v^\beta} = c^\gamma_{\alpha\beta}(v) \frac{\partial}{\partial v^\gamma} \qquad [6]$$

can be locally represented by third derivatives [2] of a function $F(v)$ satisfying [1], [3], [4]. The function $F(v)$ is called "potential" of the Frobenius manifold. It is defined up to adding of an at most quadratic polynomial in $v^1, \ldots, v^n$.

A generalization of the above definition to the case of Frobenius supermanifolds can be found in Manin (1999). For the more general class of the so-called $F$-manifolds, the requirement of the existence of a flat invariant metric has been relaxed.

## Deformed Flat Connection

One of the main geometrical structures of the theory of Frobenius manifolds is the deformed flat connection. This is a symmetric affine connection on $M \times \mathbb{C}^*$ defined by the following formulas:

$$\begin{aligned} \tilde\nabla_x y &= \nabla_x y + z x \cdot y, \quad x, y \in TM, z \in \mathbf{C}^* \\ \tilde\nabla_{\mathrm{d}/\mathrm{d}z} y &= \partial_z y + E \cdot y - \frac{1}{z}\mathcal{V} y \\ \tilde\nabla_x \frac{\mathrm{d}}{\mathrm{d}z} &= \tilde\nabla_{\mathrm{d}/\mathrm{d}z} \frac{\mathrm{d}}{\mathrm{d}z} = 0 \end{aligned} \qquad [7]$$

where, as above, $\nabla$ is the Levi-Civita connection for the metric $<,>$ and

$$\mathcal{V} := \frac{2-d}{2} - \nabla E \qquad [8]$$

is an operator on the tangent bundle $TM$ antisymmetric with respect to $<,>$,

$$<\mathcal{V}x, y> = -<x, \mathcal{V}y>$$

Observe that the unity vector field $e$ is an eigenvector of this operator with the eigenvalue

$$\mathcal{V}e = -\frac{d}{2} e$$

The connection $\tilde\nabla = \tilde\nabla(z)$ is not metric but it satisfies

$$\nabla <x, y> = <\tilde\nabla(-z)x, y> + <x, \tilde\nabla(z)y>$$
$$x, y \in TM$$

for any $z \in \mathbb{C}^*$. As it was discovered in Dubrovin (1992), vanishing of the curvature of the connection $\tilde\nabla$ is essentially equivalent to the axioms of Frobenius manifold.

**Definition** A "deformed flat function" $f(v;z)$ on a domain in $M \times \mathbb{C}^*$ is defined by the requirement of horizontality of the differential d$f$

$$\tilde{\nabla} df = 0 \qquad [9]$$

Due to vanishing of the curvature of $\tilde{\nabla}$ locally there exist $n$ independent deformed flat functions $f_1(v;z), \ldots, f_n(v;z)$ such that their differentials, together with the flat 1-form d$z$, span the cotangent plane $T^*_{(v;z)}(M \times \mathbb{C}^*)$. They will be called "deformed flat coordinates." The global analytic properties of deformed flat coordinates can be derived, for the case of semisimple Frobenius manifolds, from the results of the section "Moduli of semisimple Frobenius manifolds" discussed later.

One can relax the definition of Frobenius manifold dropping the last axiom FM3. The potential $F(v)$ in this case satisfies [1] and [3] but not [4]. In this case, the deformed flat connection $\tilde{\nabla}$ is just a family of affine flat connections on $M$ depending on the parameter $z \in \mathbb{C}$ given by the first line in [7]. The curvature and torsion of this family of connections vanishes identically in $z$. The deformed flat functions of $\tilde{\nabla}$ defined as in [9] can be chosen in the form of power series in $z$. The flatness equations written in the flat coordinates on $M$ yield a recursion equation for the coefficients of these power series

$$\tilde{\nabla} df = 0, \quad f = \sum_{p \geq 0} \theta_p(v) z^p$$
$$\partial_\lambda \partial_\mu f = z c^\nu_{\lambda\mu}(v) \partial_\nu f$$

$$\left.\begin{aligned} \partial_\lambda \partial_\mu \theta_0(v) &= 0 \\ \partial_\lambda \partial_\mu \theta_{p+1}(v) &= c^\nu_{\lambda\mu}(v) \partial_\nu \theta_p(v) \end{aligned}\right. \quad p \geq 0 \qquad [10]$$

Thus, $f(v;0)$ is just an affine linear function of the flat coordinates $v^1, \ldots, v^n$; the dependence on $z$ can be considered as a deformation of the affine structure. This motivates the name "deformed flat coordinates." The coefficients of the expansions of the deformed flat coordinates are the leading terms of the $\varepsilon$-expansion of the Hamiltonian densities of the integrable hierarchies associated with the Frobenius manifolds (see below).

## Intersection Form of a Frobenius Manifold

Another important geometric structure on $M$ is the intersection form of the Frobenius manifold. It is a symmetric bilinear form on the cotangent bundle $T^*M$ defined by the formula

$$(\omega_1, \omega_2) = \mathrm{i}_E \omega_1 \cdot \omega_2, \quad \omega_1, \omega_2 \in T^*M \qquad [11]$$

Here the multiplication law on the cotangent planes is defined by means of the isomorphism.

$$<\,,\,>: TM \to T^*M$$

The discriminant $\Sigma \subset M$ is a proper analytic (for an analytic $M$) subset where the intersection form degenerates. One can introduce a new metric on the open subset $M \backslash \Sigma$ taking the inverse of the intersection form. A remarkable result of the theory of Frobenius manifolds is vanishing of the curvature of this new metric. Moreover, the new flat metric together with the following new multiplication:

$$x * y := x \cdot y \cdot E^{-1}$$

defines on $M \backslash \Sigma$ a structure of an almost-dual Frobenius manifold (Dubrovin 2004). In the original flat coordinates $v^1, \ldots, v^n$ the coordinate expressions for the new metric and for the associated Levi-Civita connection $\nabla^*$, called the Gauss–Manin connection, read

$$\begin{gathered} g^{\alpha\beta}(v) := (\mathrm{d}v^\alpha, \mathrm{d}v^\beta) = E^\gamma(v) c^{\alpha\beta}_\gamma(v) \\ \nabla^{*\alpha}\, \mathrm{d}v^\beta = \Gamma^{\alpha\beta}_\gamma(v)\, \mathrm{d}v^\gamma \\ \Gamma^{\alpha\beta}_\gamma(v) := -g^{\alpha\nu}(v) \Gamma^\beta_{\nu\gamma}(v) = c^{\alpha\epsilon}_\gamma(v) \left(\frac{1}{2} - \mathcal{V}\right)^\beta_\epsilon \end{gathered} \qquad [12]$$

The pair $(\,,\,)$ and $<\,,\,>$ of bilinear forms on $T^*M$ possesses the following property crucial for understanding the relationships between Frobenius manifolds and integrable systems: they form a flat pencil. That means that on the complement to the subset

$$\Sigma_\lambda := \left\{ v \in M \,|\, \det\left(g^{\alpha\beta}(v) - \lambda \eta^{\alpha\beta}\right) = 0 \right\}$$

The inverse to the bilinear form

$$(\,,\,)_\lambda := (\,,\,) - \lambda <\,,\,> \qquad [13]$$

defines a metric with vanishing curvature. Flat functions $p = p(v;\lambda)$ for the flat metric are determined from the system

$$(\nabla^* - \lambda \nabla)\, \mathrm{d}p = 0 \qquad [14]$$

They are called "periods" of the Frobenius manifold. The periods $p(v;\lambda)$ are related to the deformed flat functions $f(v;z)$ by the suitably regularized Laplace-type integral transform

$$p(v;\lambda) = \int_0^\infty \mathrm{e}^{-\lambda z} f(v;z) \frac{\mathrm{d}z}{\sqrt{z}} \qquad [15]$$

Choosing a system of $n$ independent periods, one obtains a system of flat coordinates $p^1(v;\lambda), \ldots, p^n(v;\lambda)$ for the metric $(\,,\,)_\lambda$ on $M \backslash \Sigma_\lambda$,

$$\left(\mathrm{d}p^i(v;\lambda), \mathrm{d}p^j(v;\lambda)\right)_\lambda = G^{ij} \qquad [16]$$

for some constant nondegenerate matrix $G^{ij}$.

The structure of a flat pencil on the Frobenius manifold $M$ gives rise to a natural Poisson pencil (= bi-Hamiltonian structure) on the infinite-dimensional "manifold" $\mathcal{L}(M)$ consisting of smooth maps of a circle to $M$ (the so-called loop space). In the flat coordinates $v^1, \ldots, v^n$ for the metric $< , >$ the Poisson pencil has the form

$$\begin{aligned}\{v^\alpha(x), v^\beta(y)\}_1 &= \eta^{\alpha\beta}\delta'(x-y)\\ \{v^\alpha(x), v^\beta(y)\}_2 &= g^{\alpha\beta}(v(x))\delta'(x-y)\\ &\quad + \Gamma^{\alpha\beta}_\gamma(v(x))v^\gamma_x\delta(x-y)\end{aligned} \quad [17]$$

By definition of the Poisson pencil, the linear combination $a_1\{,\}_1 + a_2\{,\}_2$ of the Poisson brackets is again a Poisson bracket for arbitrary constants $a_1, a_2$. Choosing a system of $n$ independent periods $p^i(v;\lambda), i = 1, \ldots, n$, as a new system of dependent variables, one obtains a reduction of the Poisson bracket $\{,\}_\lambda := \{,\}_2 - \lambda\{,\}_1$ for a given $\lambda$ to the canonical form

$$\{p^i(v(x);\lambda), p^j(v(y);\lambda)\}_\lambda = G^{ij}\delta'(x-y) \quad [18]$$

Under an additional assumption of existence of tau function (Dubrovin 1996, Dubrovin and Zhang), one can prove that any Poisson pencil on $\mathcal{L}(M)$ of the form [17] with a nondegenerate matrix $(\eta^{\alpha\beta})$ comes from a Frobenius structure on $M$.

## Canonical Coordinates on Semisimple Frobenius Manifolds

**Definition** The Frobenius manifold $M$ is called semisimple if the algebras $T_vM$ are semisimple for $v$ belonging to an open dense subset in $M$.

Any $n$-dimensional semisimple Frobenius algebra over $\mathbb{C}$ is isomorphic to the orthogonal direct sum of $n$ copies of one-dimensional algebras. In this section, all the manifolds will be assumed to be complex analytic.

Near a semisimple point, the roots $u_i = u_i(v)$, $i = 1, \ldots, n$, of the characteristic equation

$$\det\left(g^{\alpha\beta}(v) - \lambda\eta^{\alpha\beta}\right) = 0 \quad [19]$$

can be used as local coordinates. The vectors $\partial/\partial u_i, i = 1, \ldots, n$, are basic idempotents of the algebras $T_vM$

$$\frac{\partial}{\partial u_i}\cdot\frac{\partial}{\partial u_j} = \delta_{ij}\frac{\partial}{\partial u_i}$$

We call $u_1, \ldots, u_n$ "canonical coordinates." Observe that we violate the indices convention labeling the canonical coordinates by subscripts. We will never use summation over repeated indices when working in the canonical coordinates. Actually, existence of canonical coordinates can be proved without using [4] (see details in Dubrovin (1992)).

Choosing locally branches of the square roots

$$\psi_{i1}(u) := \sqrt{<\partial/\partial u_i, \partial/\partial u_i>}, \quad i = 1, \ldots, n \quad [20]$$

we obtain a transition matrix $\Psi = (\psi_{i\alpha}(u))$,

$$\frac{\partial}{\partial v^\alpha} = \sum_{i=1}^n \frac{\psi_{i\alpha}(u)}{\psi_{i1}(u)}\frac{\partial}{\partial u_i} \quad [21]$$

from the basis $\partial/\partial v^\alpha$ to the orthonormal basis

$$\begin{aligned}\langle f_i, f_j\rangle &= \delta_{ij}\\ f_1 &= \psi_{11}^{-1}(u)\frac{\partial}{\partial u_1}\\ f_2 &= \psi_{21}^{-1}(u)\frac{\partial}{\partial u_2}, \ldots\\ f_n &= \psi_{n1}^{-1}(u)\frac{\partial}{\partial u_n}\end{aligned} \quad [22]$$

The matrix $\Psi(u)$ satisfies orthogonality condition

$$\Psi^*(u)\Psi(u) \equiv \eta, \quad \eta = (\eta_{\alpha\beta}), \quad \eta_{\alpha\beta} := \left\langle\frac{\partial}{\partial v^\alpha}, \frac{\partial}{\partial v^\beta}\right\rangle$$

In this formula $\Psi^*$ stands for the transposed matrix. The lengths [20] coincide with the first column of this matrix.

Denote $V(u) = (V_{ij}(u))$ the matrix of the antisymmetric operator $\mathcal{V}$ [8] with respect to the orthonormal frame

$$V(u) := \Psi(u)\mathcal{V}\Psi^{-1}(u) \quad [23]$$

The antisymmetric matrix $V(u) = (V_{ij}(u))$ satisfies the following system of commuting time-dependent Hamiltonian flows on the Lie algebra $\mathrm{so}(n)$ equipped with the standard Lie–Poisson brackets $\{V_{ij}, V_{kl}\} = V_{il}\delta_{jk} - V_{jl}\delta_{ik} + V_{jk}\delta_{il} - V_{ik}\delta_{jl}$:

$$\frac{\partial V}{\partial u_i} = \{V, H_i(V;u)\}, \quad i = 1, \ldots, n \quad [24]$$

with quadratic Hamiltonians

$$H_i(V;u) = \frac{1}{2}\sum_{j\neq i}\frac{V_{ij}^2}{u_i - u_j} \quad [25]$$

The matrix $\Psi(u)$ satisfies

$$\begin{aligned}\frac{\partial\Psi}{\partial u_i} &= V_i(u)\Psi,\\ V_i(u) &:= \mathrm{ad}_{E_i}\,\mathrm{ad}_U^{-1}(V(u)),\ i = 1, \ldots, n\end{aligned} \quad [26]$$

Here the matrix unity $E_i$ has the entries $(E_i)_{ab} = \delta_{ai}\delta_{ib}, U = \mathrm{diag}(u_1, \ldots, u_n)$. Conversely, given a solution to [24] and [26], one can reconstruct the

Frobenius manifold structure by quadratures (Dubrovin 1998). The reconstruction depends on a choice of an eigenvector of the constant matrix $\mathcal{V} = \Psi^{-1}(u)\ V(u)\Psi(u)$.

The system [24] coincides with the equations of isomonodromic deformations (*see* Isomonodromic Deformations) of the following linear differential operator with rational coefficients:

$$\frac{dY}{dz} = \left(U + \frac{V}{z}\right)Y \qquad [27]$$

The latter is nothing but the last component of the deformed flat connection [7] written in the orthonormal frame [22]. Other components of the horizontality equations yield

$$\partial_i Y = (zE_i + V_i(u))Y, \quad i = 1, \ldots, n \qquad [28]$$

The compatibility conditions of the system [27] and [28] coincide with [24].

The integration of [24], [26] and, more generally, the reconstruction of the Frobenius structure can be reduced to a solution of a certain Riemann–Hilbert problem (*see* Riemann–Hilbert Problem).

The isomonodromic tau function of the semisimple Frobenius manifold is defined by

$$d \log \tau_I(u) = \sum_{i=1}^{n} H_i(V(u); u) du_i \qquad [29]$$

It is an analytic function on a suitable unramified covering of the semisimple part of $M$.

Alternatively, eqns [24] can be represented as the isomonodromy deformations of the dual Fuchsian system

$$[U - \lambda]\frac{d\phi}{d\lambda} = \left(\frac{1}{2} + V\right) \qquad [30]$$

The latter comes from the Gauss–Manin system for the periods $p = p(v; \lambda)$ of the Frobenius manifold written in the canonical coordinates [22].

## Moduli of Semisimple Frobenius Manifolds

All $n$-dimensional semisimple Frobenius manifolds form a finite-dimensional space. They depend on $n(n-1)/2$ essential parameters. To parametrize the Frobenius manifolds one can choose, for example, the initial data for the isomonodromy deformation equations [24]. Alternatively, they can be parametrized by monodromy data of the deformed flat connection according to the following construction.

The first part of the monodromy data is the spectrum $(V, <\,,\,>, \hat{\mu}, R)$ of the Frobenius manifold associated with the Poisson pencil. Here $V$ is an $n$-dimensional linear space equipped with a symmetric nondegenerate bilinear form $<\,,\,>$. Two linear operators on $V$, a semisimple operator $\hat{\mu} : V \to V$, and a nilpotent operator $R : V \to V$ must satisfy the following properties. First, the operator $\hat{\mu}$ is antisymmetric:

$$\hat{\mu}^* = -\hat{\mu} \qquad [31]$$

and the operator $R$ satisfies

$$R^* = -e^{-\pi i \hat{\mu}} R\, e^{\pi i \hat{\mu}} \qquad [32]$$

Here the adjoint operators are defined with respect to the bilinear form $<\,,\,>$. The last condition to be imposed onto the operator $R$ can be formulated in a simple way by choosing a basis $e_1, \ldots, e_n$ of eigenvectors of the semisimple operator $\hat{\mu}$,

$$\hat{\mu} e_\alpha = \mu_\alpha e_\alpha, \quad \alpha = 1, \ldots, n$$

We require the existence of a decomposition

$$R = R_0 + R_1 + R_2 + \cdots \qquad [33]$$

where for any integer $k \geq 0$ the linear operator $R_k$ satisfies

$$R_k e_\alpha \in \text{span}\{e_\beta \,|\, \mu_\beta = \mu_\alpha + k\} \ \ \forall \alpha = 1, \ldots, n \qquad [34]$$

In the nonresonant case, such that none of the differences of the eigenvalues of $\hat{\mu}$ being equal to a positive integer, all the matrices $R_1, R_2, \ldots$, are equal to zero. Observe a useful identity

$$z^{\hat{\mu}} R\, z^{-\hat{\mu}} = R_0 + zR_1 + z^2 R_2 + \cdots \qquad [35]$$

More generally, for any operator $A : V \to V$ commuting with $e^{2\pi i \hat{\mu}}$ a decomposition is defined as

$$A = \bigoplus_{k \in \mathbb{Z}} [A]_k$$
$$z^{\hat{\mu}} A\, z^{-\hat{\mu}} = \sum_{k \in \mathbb{Z}} z^k [A]_k \qquad [36]$$

In particular, $[R]_k = R_k, k \geq 0$, $[R]_k = 0$, $k < 0$.

One has to also choose an eigenvector $e$ of the operator $\hat{\mu}$ such that $R_0 e = 0$; denote $-d/2$ the corresponding eigenvalue

$$e \in V, \qquad \hat{\mu} e = -\frac{d}{2} e, \qquad R_0 e = 0 \qquad [37]$$

The second part of the monodromy data is a pair of linear operators

$$C : V \to \mathbb{C}^n, \qquad S : \mathbb{C}^n \to \mathbb{C}^n$$

The space $\mathbb{C}^n$ is assumed to be equipped with the standard complex Euclidean structure given by the sum of squares. The properties of the operators $S$, $C$ depend on the choice of an unordered set

$u^0 = (u_1^0, \ldots, u_n^0)$ of $n$ pairwise distinct complex numbers and on a choice of a ray $\ell_+$ on an auxiliary complex $z$-plane starting at the origin such that

$$\mathrm{Re}\, z\left(u_i^0 - u_j^0\right) \neq 0, \quad i \neq j,\ z \in \ell_+ \qquad [38]$$

Let us order the complex numbers in such a way that

$$e^{z(u_i^0 - u_j^0)} \to 0, \quad i < j, |z| \to \infty,\ z \in \ell_+ \qquad [39]$$

The operator $S$ must be upper triangular

$$\begin{aligned} S = (S_{ij}), \quad S_{ij} = 0,\ i > j \\ S_{ii} = 1, \qquad i = 1, \ldots, n \end{aligned} \qquad [40]$$

The operator $C$ must satisfy

$$C^* S\, C = e^{\pi i \hat{\mu}}\, e^{\pi i R} \qquad [41]$$

Here the adjoint operator $C^*$ is understood as follows:

$$C^*\colon \mathbb{C}^n \xrightarrow{\simeq} \mathbb{C}^{n*} \to V^* \xrightarrow{<,>^{-1}} V$$

The group of diagonal $n \times n$ matrices

$$D = \mathrm{diag}(\pm 1, \ldots, \pm 1)$$

acts on the pairs $(S, C)$ by

$$S \mapsto DSD, \qquad C \mapsto DC$$

One is to factor out the action of this diagonal group. Besides, the operator $C$ is defined up to a left action of certain group of linear operators depending on the spectrum.

For the generic (i.e., nonresonant) case where $e^{2\pi i \hat{\mu}}$ has simple spectrum, the operator $C$ is defined up to left multiplication by any matrix commuting with $e^{2\pi i \hat{\mu}}$. In this situation, the monodromy data $(\hat{\mu}, R, S, C)$ are locally uniquely determined by the $n(n-1)/2$ entries of the matrix $S$. Therefore, near a generic point, the variety of the monodromy data is a smooth manifold of the dimension $n(n-1)/2$. At nongeneric points, the variety can get additional strata.

The monodromy data $S$, $C$ are determined at an arbitrary semisimple point of a Frobenius manifold in terms of the analytic properties of horizontal sections of the deformed flat connection $\tilde{\nabla}$ [7] in the complex $z$-plane (the so-called "Stokes matrix" and the "central connection matrix" of the operator [27]). Locally, they do not depend on the point of the semisimple Frobenius manifold (the isomonodromicity property).

We will now describe the reconstruction procedure giving a parametrization of semisimple Frobenius manifolds in terms of the monodromy data $(\hat{\mu}, R, S, C)$.

Conversely, to reconstruct the Frobenius manifold near a semisimple point with the canonical coordinates $u_1^0, \ldots, u_n^0$, one is to solve the following boundary-value problem. Let

$$\ell = (-\ell_-) \cup \ell_+$$

be the oriented line on the complex $z$-plane chosen as in [38]. Here the ray $\ell_-$ is the opposite to $\ell_+$. Denote $\Pi_R/\Pi_L$ the right/left half-planes with respect to $\ell$. To reconstruct the Frobenius manifold, one is to find three matrix-valued functions $\Phi_0(z; u)$, $\Phi_R(z; u)$, and $\Phi_L(z; u)$:

$$\begin{aligned} \Phi_0(z; u) &: V \to \mathbb{C}^n \\ \Phi_{R/L}(z; u) &: \mathbb{C}^n \to \mathbb{C}^n \end{aligned}$$

for $u$ close to $u^0$ such that $\Phi_0(z; u)$ is analytic and invertible for $z \in \mathbb{C}, \Phi_R(z; u)/\Phi_L(z; u)$ are analytic and invertible for $z \in \Pi_R/\Pi_L$ resp., and continuous up to the boundary $\ell \backslash 0$ and

$$\Phi_{R/L}(z; u) \sim 1 + O(1/z), \quad |z| \to \infty,\ z \in \Pi_R/\Pi_L$$

The boundary values of the functions $\Phi_0(z; u)$,$\Phi_R(z; u)$, and $\Phi_L(z; u)$ must satisfy the following boundary-value problem (as above $U = \mathrm{diag}(u_1, \ldots, u_n)$):

$$\Phi_R(z; u) = \Phi_L(z; u) e^{zU} S e^{-zU}, \quad z \in \ell_+ \qquad [42]$$

$$\Phi_R(z; u) = \Phi_L(z; u) e^{zU} S^* e^{-zU}, \quad z \in \ell_- \qquad [43]$$

$$\begin{aligned} \Phi_0(z; u) z^{\hat{\mu}} z^R &= \Phi_R(z; u) e^{zU} C, \quad z \in \Pi_R \\ \Phi_0(z; u) z^{\hat{\mu}} z^R &= \Phi_L(z; u) e^{zU} SC, \quad z \in \Pi_L \end{aligned} \qquad [44]$$

Here $z^{\hat{\mu}} := e^{\hat{\mu} \log z}$, $z^R := e^{R \log z}$ are considered as $\mathrm{Aut}(V)$-valued functions on the universal covering of $\mathbb{C} \backslash 0$; the branch cut in the definition of $\log z$ is chosen to be along $\ell_-$.

The solution of the above boundary-value problem [42]–[44], if exists, is unique. It can be reduced to a certain Riemann–Hilbert problem, that is, to a problem of factorization of an analytic $n \times n$ nondegenerate matrix-valued function on the annulus

$$G(z; u), \quad r < |z| < R, \quad \det G(z; u) \neq 0$$

depending on the parameter $u = (u_1, \ldots, u_n)$ in a product

$$G(z; u) = G_0(z; u)^{-1} G_\infty(z; u) \qquad [45]$$

of two matrix-valued functions $G_0(z;\, u)$ and $G_\infty(z;\, u)$ analytic for $|z| < R$ and $r < |z| \leq \infty$ resp., with nowhere-vanishing determinant.

Existence of a solution to the Riemann–Hilbert problem for a given $u = (u_1, \ldots, u_n), u_i \neq u_j$ for $i \neq j$, means triviality of certain $n$-dimensional vector bundle over the Riemann sphere with the transition functions given by $G(z; u)$. Existence of the solution for $u = u^0$ implies solvability of the Riemann–Hilbert problem for $u$ sufficiently close to $u^0$. From these arguments, it can be deduced that the matrices $\Phi_0(z; u), \Phi_{R/L}(z; u)$ are analytic in $(z; u)$ for $u$ sufficiently close to $u^0$. Moreover, they can be analytically continued in $u$ to the universal covering of the space of configurations of $n$ distinct points on the complex plane:

$$\left(\mathbb{C}^n \backslash \cup_{i \neq j} \{u_i = u_j\}\right) / S_n \qquad [46]$$

The resulting functions are meromorphic on the universal covering, according to the results of B Malgrange and T Miwa. The structure of the global analytic continuation is given (Dubrovin 1999) in terms of a certain action of the braid group

$$B_n = \pi_1\left(\left(\mathbb{C}^n \backslash \cup_{i \neq j} \{u_i = u_j\}\right) / S_n\right)$$

on the monodromy data.

## Examples of Frobenius Manifolds

**Example 0** Trivial Frobenius manifold, $M = A_0$ a graded Frobenius algebra, $F(v) = (1/6) < e, v \cdot v \cdot v >$ is a cubic polynomial.

First nontrivial examples appeared in the setting of 2D topological field theories (Dijkgraaf *et al.* 1991, Witten 1991) (*see* Topological Quantum Field Theory: Overview). Mathematical formalization of these ideas gives rise to the following two classes of examples.

**Example 1** Frobenius structure on the base of an isolated hypersurface singularity. The construction (Hertling 2002, Sabbah 2002) uses the K Saito theory of periods of primitive forms. For the example of $A_n$ singularity $f(x) = x^{n+1}$ the Frobenius structure on the base of universal unfolding

$$M_{A_n} = \{f_s(x) = x^{n+1} + s_1 x^{n-1} + \cdots + s_n \,|\, s_1, \ldots, s_n \in \mathbb{C}\}$$

is constructed as follows (Dijkgraaf *et al.* 1991):

$$e = \frac{\partial}{\partial s_n}$$
$$E = \frac{1}{n+1} \sum (k+1) s_k \frac{\partial}{\partial s_k}$$
$$d = \frac{n-1}{n+1}$$

The multiplication is introduced by identifying the tangent space $T_s M$ with the quotient algebra

$$T_s M_{A_n} = \mathbb{C}[x]/(f_s'(x))$$

The metric has the form

$$< \partial_{s_i}, \partial_{s_j} > = -(n+1)\, \mathrm{res}_{x=\infty} \frac{\partial f_s(x)/\partial s_i \partial f_s(x)/\partial s_j}{f_s'(x)}\, dx$$

The flat coordinates $v_\alpha = v_\alpha(s)$ can be found from the expansion of the solution to the equation $f_s(x) = k^{n+1}$,

$$x = k - \frac{1}{n+1}\left(\frac{v_n}{k} + \frac{v_{n-1}}{k^2} + \cdots + \frac{v_1}{k^n}\right) + O\left(\frac{1}{k^{n+2}}\right)$$

The potentials of the Frobenius manifolds $M_{A_n}$ for $n = 1, 2, 3$ read

$$\begin{aligned} F_{A_1} &= \tfrac{1}{6} v_1^3 \\ F_{A_2} &= \tfrac{1}{2} v_1^2 v_2 + \tfrac{1}{72} v_2^4 \\ F_{A_3} &= \tfrac{1}{2} v_1 v_2^2 + \tfrac{1}{2} v_1^2 v_3 + \tfrac{1}{16} v_2^2 v_3^2 + \tfrac{1}{960} v_3^5 \end{aligned} \qquad [47]$$

The space of polynomials $M_{A_n}$ can be identified with the orbit space of $\mathbb{C}/W(A_n)$ of the Weyl group of the type $A_n$. More generally (Dubrovin 1996), the orbit space $M_W := \mathbb{C}^n/W$ of an arbitrary irreducible finite Coxeter group $W \subset O(n)$ carries a natural structure of a polynomial semisimple Frobenius manifold. Conversely, all irreducible polynomial semisimple Frobenius manifolds with positive degrees of the flat coordinates can be obtained by this construction (Hertling 2002). Generalizations for the orbit spaces of certain infinite groups were obtained in Dubrovin and Zhang (1998b) and Bertola (2000).

**Example 2** Gromov–Witten (GW) invariants (*see* Topological Sigma Models). Let $X$ be a smooth projective variety. We will assume for simplicity that $H^{\mathrm{odd}}(X) = 0$. To every such variety, one can associate a bunch of rational numbers. They are expressed in terms of intersection theory of certain cycles on the moduli spaces $X_{g,m,\beta}$ of stable genus $g$ and degree $\beta$ curves on $X$ with $m$ marked points (see details in Kontsevich and Manin (1994)):

$$\begin{aligned} X_{g,m,\beta} := \{ & f : (C_g, x_1, \ldots, x_m) \to X, \\ & f_*[C_g] = \beta \in H_2(X; \mathbf{Z})\} \end{aligned} \qquad [48]$$

Denote $n := \dim H^*(X; \mathbb{C})$. Choosing a basis $\phi_1 = 1, \phi_2, \ldots, \phi_n$ we define the numbers

$$\begin{aligned} & < \tau_{p_1}(\phi_{\alpha_1}) \ldots \tau_{p_m}(\phi_{\alpha_m}) >_{g,\beta} \\ & := \int_{[X_{g,m,\beta}]^{\mathrm{virt}}} ev_1^*(\phi_{\alpha_1}) \wedge c_1^{p_1}(\mathcal{L}_1) \\ & \quad \wedge \cdots \wedge ev_m^*(\phi_{\alpha_m}) \wedge c_1^{p_m}(\mathcal{L}_m) \end{aligned} \qquad [49]$$

for arbitrary non-negative integers $p_1, \ldots, p_m$. Here the evaluation maps $ev_i, i = 1, \ldots, m$, are given by

$$ev_i : X_{g,m,\beta} \to X, \qquad f \mapsto f(x_i)$$

The so-called tautological line bundles $\mathcal{L}_i$ over $X_{g,m,\beta}$ by definition have the fiber $T^*_{x_i} C_g, i = 1, \ldots, m$ (see the article Moduli Spaces: An Introduction regarding the construction of the so-called virtual fundamental class $[X_{g,m,\beta}]^{\text{virt}}$). The numbers [49] can be defined for an arbitrary compact symplectic manifold $X$ where one is to deal with the intersection theory on the moduli spaces of pseudoholomorphic curves fixing a suitable almost-complex structure on $X$. They depend only on the symplectic structure on $X$. In particular, the numbers

$$<\tau_0(\phi_{\alpha_1}) \ldots \tau_0(\phi_{\alpha_m})>_{g,\beta} \qquad [50]$$

are called the genus $g$ and degree $\beta$ GW invariants of $X$. In certain cases, they admit an interpretation in terms of enumerative geometry of the variety $X$ (Kontsevich and Manin 1994). The numbers [49] with some of $p_i > 0$ are called "gravitational descendents."

One can form a generating functions of the numbers [49]

$$\mathcal{F}_g^X = \sum_m \sum_{\beta \in H_2(X;\mathbf{Z})} \frac{1}{m!} t^{\alpha_1,p_1} \ldots t^{\alpha_m,p_m} <\tau_{p_1}(\phi_{\alpha_1}) \ldots \tau_{p_m}(\phi_{\alpha_m})>_{g,\beta} \qquad [51]$$

(summation over repeated indices $1 \leq \alpha_1, \ldots, \alpha_m \leq n$ will always be assumed). Here $t^{\alpha,p}$ are indeterminates labeled by pairs $(\alpha, p)$ with $\alpha = 1, \ldots, n$, $p = 0, 1, 2, \ldots$. (Usually one is to insert in the definition of $\mathcal{F}_g^X$ elements $q^\beta$ of the Novikov ring $\mathbb{C}[H_2(X; \mathbf{Z})]$. However, due to the divisor axiom (Kontsevich and Manin 1994) and these insertions can be compensated by a suitable shift in the space of couplings $\boldsymbol{t} = (t^{\alpha,p})$.) We finally introduce the full generating function called total GW potential (it is also called the free energy of the topological sigma model with the target space $X$)

$$\mathcal{F}^X(\boldsymbol{t}; \epsilon) = \sum_{g \geq 0} \epsilon^{2g-2} \mathcal{F}_g^X \qquad [52]$$

Restricting the genus-zero generating function onto the so-called small phase space

$$F^X(v) := \mathcal{F}_0^X(t^{\alpha,0} = v^\alpha, t^{\alpha,p>0} = 0) \qquad v = (v^1, \ldots, v^n) \qquad [53]$$

one obtains a solution to the WDVV associativity equations. This solution defines a structure of (formal) Frobenius manifold on $H^*(X)$ with the bilinear form $\eta$ given by the Poincaré pairing

$$\eta_{\alpha\beta} = \int_X \phi_\alpha \wedge \phi_\beta$$

the unity

$$e = \frac{\partial}{\partial v^1}$$

and the Euler vector field

$$E = \sum_{\alpha=1}^n [(1 - q_\alpha) v^\alpha + r_\alpha] \frac{\partial}{\partial v^\alpha}$$

Here the numbers $q_\alpha, r_\alpha$ are defined by the conditions

$$\phi_\alpha \in H^{2q_\alpha}(X), \qquad c_1(X) = \sum_\alpha r_\alpha \phi_\alpha$$

The resulting Frobenius manifold will be denoted $M_X$. The corresponding $n$-parameter family of $n$-dimensional algebras on the tangent spaces $T_v M_X$ is also called "quantum cohomology" $\mathrm{QH}^*(X)$. At the point $v_{\text{cl}} \in M_X$ of classical limit, the algebra $T_{v_{\text{cl}}} M_X$ coincides with the cohomology ring $H^*(X)$. In all known examples, the series [53] actually converges in a neighborhood of the point $v_{\text{cl}}$. Therefore, one obtains a genuine Frobenius structure on a domain $M_X \subset H^*(X; \mathbb{C})/2\pi \mathrm{i} H_2(X; \mathbf{Z})$. However, a general proof of convergence is still missing.

In particular, for $d = 1$, the quantum cohomology of complex projective line $\boldsymbol{P}^1$ is a two-dimensional Frobenius manifold with the potential, unity, and the Euler vector field

$$F(u, v) = \tfrac{1}{2} u v^2 + e^u, \quad e = \frac{\partial}{\partial v}, \quad E = v \frac{\partial}{\partial v} + 2 \frac{\partial}{\partial u}$$

For $d = 2$ one has a three-dimensional Frobenius manifold $QH^*(\boldsymbol{P}^2)$ with

$$\begin{aligned} F(v_1, v_2, v_3) &= \tfrac{1}{2} v_1^2 v_3 + \tfrac{1}{2} v_1 v_2^2 + \sum_{k \geq 1} N_k \frac{v_3^{3k-1}}{(3k-1)!} e^{k v_2} \\ e &= \frac{\partial}{\partial v_1} \\ E &= v_1 \frac{\partial}{\partial v_1} + 3 \frac{\partial}{\partial v_2} - v_3 \frac{\partial}{\partial v_3} \end{aligned} \qquad [54]$$

where $N_k$ = number of rational curves on $\boldsymbol{P}^2$ passing through $3k - 1$ generic points. WDVV [5] yields (Kontsevich and Manin 1994) recursion relations for

the numbers $N_k$ starting from $N_1=1$. The closed analytic formula for the function [54] is still unknown.

Only for certain very exceptional $X$ the Frobenius manifold $M_X$ is semisimple (e.g., for $X=\boldsymbol{P}^d$). The general geometrical reasons of the semisimplicity of $M_X$ are still to have been understood.

For the case $X=$Calabi–Yau manifold, the Frobenius manifold $QH^*(X)$ is never semisimple. This Frobenius structure can be computed in terms of the mirror symmetry construction (*see* Mirror Symmetry: A Geometric Survey).

## Frobenius Manifold and Integrable Systems

The identities in the cohomology ring generated by the cocycles $ev_i^*(\phi_\alpha)$ and $\psi_j:=c_1(\mathcal{L}_j)$ can be recast into the form of differential equations for the generating function [52]. The variable $x:=t^{1,0}$ corresponding to $\phi_1=1$ plays a distinguished role in these differential equations. According to the idea of Witten (1991), the differential equations for the generating functions can be written as a hierarchy of systems of $n$ evolutionary PDEs ($n=\dim H^*(\mathrm{X})$) for the unknown functions

$$w_\alpha=\langle\langle\tau_0(\phi_\alpha)\tau_0(\phi_1)\rangle\rangle=\epsilon^2\frac{\partial^2\mathcal{F}^X(\boldsymbol{t},\epsilon)}{\partial t^{1,0}\partial t^{\alpha,0}} \qquad [55]$$

The variable $x=t^{1,0}$ is the spatial variable of the equations of the hierarchy. The remaining parameters (coupling constants) $t^{\alpha,p}$ of the generating function play the role of the time variables. Witten suggested to use the two-point correlators

$$h_{\alpha,p}=\langle\langle\tau_{p+1}(\phi_\alpha)\tau_0(\phi_1)\rangle\rangle=\epsilon^2\frac{\partial^2\mathcal{F}^X(\boldsymbol{t},\epsilon)}{\partial t^{1,0}\partial t^{\alpha,p}} \qquad [56]$$

as the densities of the Hamiltonians of the flows of the hierarchy.

Existence of such a hierarchy can be proved for the case of GW invariants (and their descendents) of complex projective spaces $\boldsymbol{P}^d$ (the results of Givental (2001) along with Dubrovin and Zhang (2005) can be used). For $d=0$ one obtains, according to the celebrated result by Kontsevich conjectured by Witten (*see* Topological Gravity, Two-Dimensional), the tau function of the solution to the KdV hierarchy (*see* Korteweg–de Vries Equation and Other Modulation Equations) specified by the initial condition,

$$u(x)\,|_{t=0}=x$$

For $d=1$ the hierarchy in question is the extended Toda lattice (see details in Dubrovin and Zhang (2004); *see also* Toda Lattices). For all other $d\geq 2$, the needed integrable hierarchy is a new one. It can be associated (Dubrovin and Zhang) with an arbitrary $n$-dimensional semisimple Frobenius manifold $M$. The equations of the hierarchy have the form

$$w_t^i=A_j^i(w)w_x^j+\epsilon^2\Big[B_j^i(w)w_{xxx}^i+C_{jk}^i(w)w_x^jw_{xx}^k + D_{jkl}^i(w)w_x^jw_x^kw_x^l\Big]+O(\epsilon^4),\quad i=1,\ldots,n \qquad [57]$$

The coefficients of $\epsilon^{2g}$ are graded homogeneous polynomials in $u_x, u_{xx}$, etc., of the degree $2g+1$,

$$\deg \mathrm{d}^m u/\mathrm{d}x^m=m$$

The construction of the hierarchy is done in two steps. First, we construct the leading approximation (Dubrovin 1992). The equation of the hierarchy specifying the dependence on $t=t^{\alpha,p}$ at $\epsilon=0$ reads

$$\frac{\partial v}{\partial t^{\alpha,p}}=\partial_x\left(\nabla\theta_{\alpha,p+1}(v)\right)\qquad \alpha=1,\ldots,n,\quad p\geq 0 \qquad [58]$$

The functions $\theta_{\alpha,p}(v), v\in M$, are the coefficients of expansion [10] of the deformed flat functions normalized by $\theta_{\alpha,0}=v_\alpha$. The solution $v=v(x,\boldsymbol{t})$ of interest is determined from the implicit function equations

$$v=xe+\sum_{\alpha,p}t^{\alpha,p}\nabla\theta_{\alpha,p}(v) \qquad [59]$$

Next, one has to find solution

$$\Delta\mathcal{F}=\sum_{g\geq 1}\epsilon^{2g-2}\mathcal{F}_g(v;v_x,\ldots,v^{(3g-2)}) \qquad [60]$$

of the following universal loop equation (closely related with the Virasoro conjecture of Eguchi and Xiong (1998)):

$$\begin{aligned}&\sum_{r\geq 0}\frac{\partial\Delta\mathcal{F}}{\partial v^{\gamma,r}}\partial_x^r\left(\frac{1}{E(v)-\lambda}\right)^\gamma\\&\quad+\sum_{r\geq 1}\frac{\partial\Delta\mathcal{F}}{\partial v^{\gamma,r}}\sum_{k=1}^r\binom{r}{k}\partial_x^{k-1}\partial_e p_\alpha G^{\alpha\beta}\partial_x^{r-k+1}\partial^\gamma p_\beta\\&=-\frac{1}{16}\mathrm{tr}(\mathcal{U}-\lambda)^{-2}+\frac{1}{4}\mathrm{tr}\Big[(\mathcal{U}-\lambda)^{-1}\mathcal{V}\Big]^2\\&\quad+\frac{\epsilon^2}{2}\sum\left(\frac{\partial^2\Delta\mathcal{F}}{\partial v^{\gamma,k}\partial v^{\rho,l}}+\frac{\partial\Delta\mathcal{F}}{\partial v^{\gamma,k}}\frac{\partial\Delta\mathcal{F}}{\partial v^{\rho,l}}\right)\\&\quad\times\partial_x^{k+1}\partial^\gamma p_\alpha G^{\alpha\beta}\partial_x^{l+1}\partial^\rho p_\beta\\&\quad+\frac{\epsilon^2}{2}\sum\frac{\partial\Delta\mathcal{F}}{\partial v^{\gamma,k}}\partial_x^{k+1}\\&\quad\times\left[\nabla\frac{\partial p_\alpha(v;\lambda)}{\partial\lambda}\cdot\nabla\frac{\partial p_\beta(v;\lambda)}{\partial\lambda}\cdot v_x\right]^\gamma G^{\alpha\beta}\end{aligned} \qquad [61]$$

Here $\mathcal{U}=\mathcal{U}(v)$ is the operator of multiplication by $E(v), p_\alpha = p_\alpha(v;\lambda), \alpha = 1,\ldots,n$, is a system of flat coordinates [16] of the bilinear form [13]. The substitution

$$v_\alpha \mapsto w_\alpha = v_\alpha + \epsilon^2 \partial_x \partial_{t^{\alpha,0}} \Delta\mathcal{F}(v; v_x, v_{xx}, \ldots; \epsilon^2) \quad \alpha = 1,\ldots,n \qquad [62]$$

transforms [58] to [57]. The terms of the expansion [60] are not polynomial in the derivatives. For example (Dubrovin and Zhang 1998a),

$$\mathcal{F}_1 = \frac{1}{24}\sum_{i=1}^{n} \log u_i' + \log \frac{\tau_I(u)}{J^{1/24}(u)}$$
$$J(u) = \det\left(\frac{\partial v^\alpha}{\partial u_i}\right) = \pm \prod_{i=1}^{n} \psi_{i1}(u) \qquad [63]$$

(the canonical coordinates have been used) where $\tau_I(u)$ is the isomonodromic tau function [29]. The transformation [62] applied to the solution [59] expresses higher-genus GW invariants of a variety $X$ with semisimple quantum cohomology $QH^*(X)$ via the genus-zero invariants. For the particular case of $X = \boldsymbol{P}^2$, the formula [63] yields (Dubrovin and Zhang 1998a)

$$\frac{\phi''' - 27}{8(27 + 2\phi' - 3\phi'')} = -\frac{1}{8} + \sum_{k\geq 1} k N_k^{(1)} \frac{e^{kz}}{(3k)!}$$

Here

$$\phi(z) = \sum_{k\geq 0} N_k \frac{e^{kz}}{(3k-1)!}$$

is the generating function of the genus-zero GW invariants of $\boldsymbol{P}^2$ (see [54]) and $N_k^{(1)}=$ the number of elliptic plane curves of the degree $k$ passing through $3k$ generic points.

# Weakly Coupled Oscillators

**E M Izhikevich**, The Neurosciences Institute, San Diego, CA, USA
**Y Kuramoto**, Hokkaido University, Sapporo, Japan

## Introduction

Practically any physical, chemical, or biological system can exhibit rhythmic oscillatory activity, at least when the conditions are right. Winfree (2001) reviews the ubiquity of oscillations in nature, ranging from autocatalytic chemical reactions to pacemaker cells in the heart, to animal gates, and to circadian rhythms. When coupled, even weakly, oscillators interact via adjustment of their phases, that is, their timing, often leading to synchronization. In this chapter, we review the most important concepts needed to study and understand the dynamics of coupled oscillators.

From a mathematical point of view, an oscillator is a dynamical system,

$$\dot{x} = f(x), \quad x \in \mathbb{R}^m \qquad [1]$$

having a limit-cycle attractor – periodic orbit $\gamma \subset \mathbb{R}^m$. Its period is the minimal $T > 0$ such that

$$\gamma(t) = \gamma(t + T) \quad \text{for any } t$$

and its frequency is $\Omega = 2\pi/T$. Let $x(0) = x_0 \in \gamma$ be an arbitrary point on the attractor, then the state of the system, $x(t)$, is uniquely defined by its phase $\vartheta \in \mathbb{S}^1$ relative to $x_0$, where $\mathbb{S}^1$ is the unit circle.

Throughout this article, we assume that the periodic orbit $\gamma$ is exponentially stable, which implies normal hyperbolicity. In this case, there is a continuous transformation $\Theta : U \to \mathbb{S}^1$ defined in a neighborhood $U \supset \gamma$ such that $\vartheta(t) = \Theta(x(t))$ for any trajectory in $U$, that is, $\Theta$ maps solutions of [1] to solutions of

$$\dot{\vartheta} = \Omega \qquad [2]$$

Such a transformation removes the amplitude but saves the phase of oscillation.

Accordingly, there is a continuous transformation that maps solutions of the weakly coupled network of $n$ oscillators,

$$\dot{x}_i = f_i(x_i) + \varepsilon g_i(x_1, \ldots, x_n, \varepsilon), \quad \varepsilon \ll 1 \qquad [3]$$

onto solutions of the phase system

$$\dot{\vartheta}_i = \Omega_i + \varepsilon h_i(\vartheta_1, \ldots, \vartheta_n, \varepsilon), \quad \vartheta_i \in \mathbb{S}^1 \qquad [4]$$

which is easier for studying the collective properties of [3].

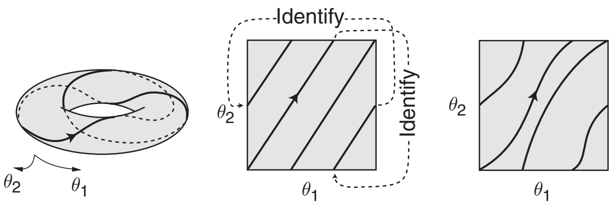

**Figure 1** A 2-torus and its representation on the square. (Modified from Hoppensteadt and Izhikevich 1997.)

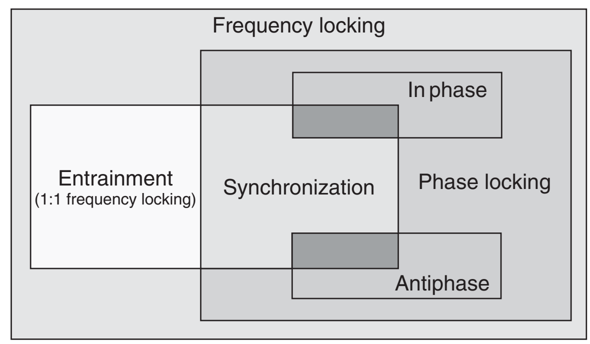

**Figure 2** Various degrees of locking of oscillators. (Modified from Izhikevich 2006.)

The oscillators are said to be frequency locked when [4] has a stable periodic orbit $\vartheta(t) = (\vartheta_1(t), \ldots, \vartheta_n(t))$ on the $n$-torus $\mathbb{T}^n$, as in Figure 1a. The "rotation vector" or "winding ratio" of the orbit is the set of integers $q_1 : q_2 : \cdots : q_n$ such that $\vartheta_1$ makes $q_1$ rotations while $\vartheta_2$ makes $q_2$ rotations, etc., as in the 2 : 3 frequency locking in Figure 1a. The oscillators are entrained when they are $1:1:\cdots:1$ frequency locked. The oscillators are phase locked when there is an $(n-1) \times n$ integer matrix $K$ having linearly independent rows such that $K\vartheta(t) = \text{const}$. For example, the two oscillators in Figure 1b are phase locked with $K = (2, 3)$, while those in Figure 1c are not. The oscillators are synchronized when they are entrained and phase locked. Synchronization is in-phase when $\vartheta_1(t) = \cdots = \vartheta_n(t)$ and out-of-phase otherwise. Two oscillators are said to be synchronized antiphase when $\vartheta_1(t) - \vartheta_2(t) = \pi$. Frequency locking without phase locking, as in Figure 1c, is called phase trapping. The relationship between all these definitions is depicted in Figure 2.

## Phase Resetting

An exponentially stable periodic orbit is a normally hyperbolic invariant manifold, hence its sufficiently small neighborhood, $U$, is invariantly foliated by

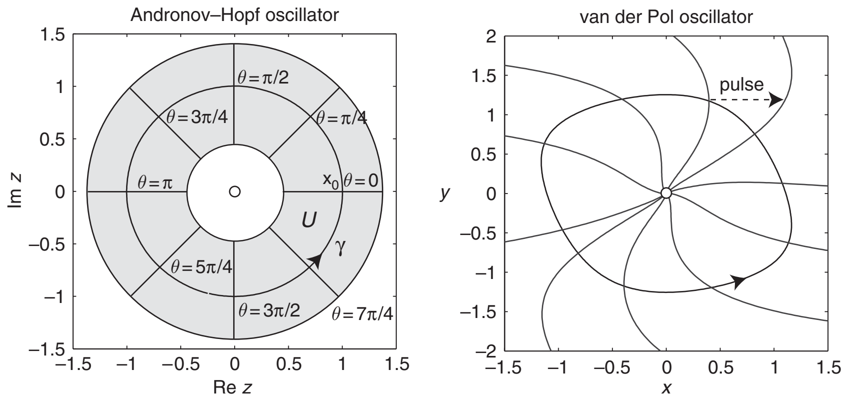

**Figure 3** Isochrons of Andronov–Hopf oscillator ($\dot{z} = (1 + i)z - z|z|^2, z \in C$) and van der Pol oscillator ($\dot{x} = x - x^3 - y, \dot{y} = x$).

stable submanifolds (Guckenheimer 1975) illustrated in **Figure 3**. The manifolds represent points having equal phases and, for this reason, they are called isochrons (from Greek "iso" meaning equal and "chronos" meaning time).

The geometry of isochrons determines how the oscillators react to perturbations. For example, the pulse in **Figure 3**, right, moves the trajectory from one isochron to another, thereby changing its phase. The magnitude of the phase shift depends on the amplitude and the exact timing of the stimulus relative to the phase of oscillation $\vartheta$. Stimulating the oscillator at different phases, one can measure the phase transition curve (Winfree 2001)

$$\vartheta_{\text{new}} = \text{PTC}(\vartheta_{\text{old}})$$

and the phase resetting curve

$$\text{PRC}(\vartheta) = \text{PTC}(\vartheta) - \vartheta$$
$$(\text{shift} = \text{new phase} - \text{old phase})$$

Positive (negative) values of the PRC correspond to phase advances (delays). PRCs are convenient when the phase shifts are small, so that they can be magnified and clearly seen, as in **Figure 4**. PTCs are convenient when the phase shifts are large and comparable with the period of oscillation.

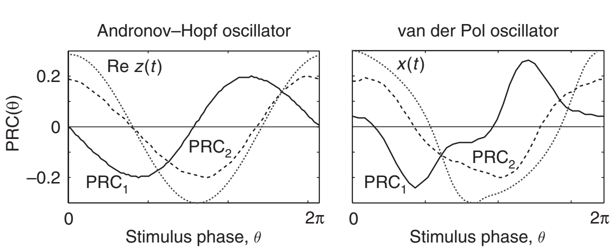

**Figure 4** Examples of phase response curves (PRCs) of the oscillators in **Figure 3**. $\text{PRC}_1(\vartheta)$ and $\text{PRC}_2(\vartheta)$ correspond to horizontal (along the first variable) and vertical (along the second variable) pulses with amplitudes 0.2. An example of oscillation is plotted as a dotted curve in each subplot (not to scale).

In **Figure 5** we depict phase portraits of the Andronov–Hopf oscillator receiving pulses of magnitude 0.5 (left) and 1.5 (right). Notice the drastic difference between the corresponding PRCs or PTCs. Winfree (2001) distinguishes two cases:

1. type 1 (weak) resetting results in continuous PRCs and PTCs with mean slope 1, and
2. type 0 (strong) resetting results in discontinuous PRCs and PTCs with mean slope 0.

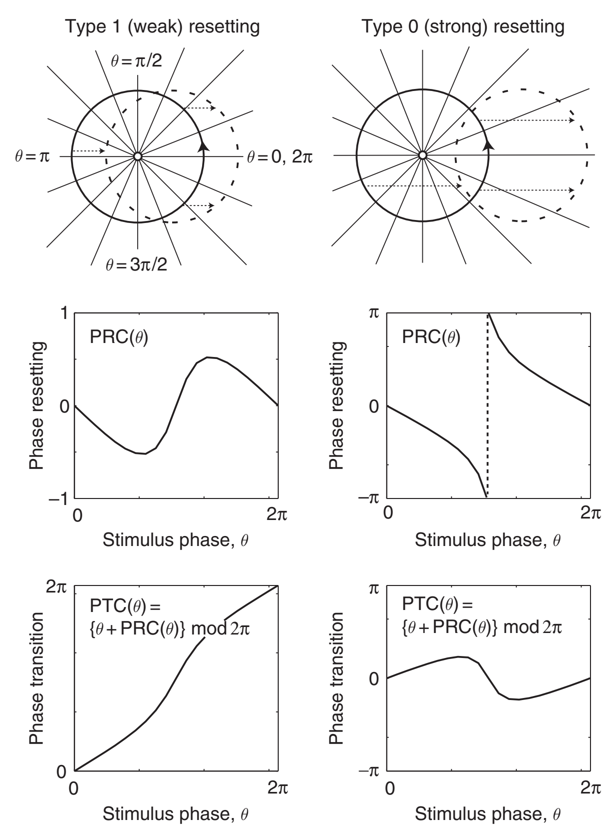

**Figure 5** Types of phase resetting of the Andronov–Hopf oscillator in **Figure 3**.

The discontinuity of type 0 PRC in Figure 5 is a topological property that cannot be removed by reallocating the initial point $x_0$ that corresponds to zero phase. The discontinuity stems from the fact that the shifted image of the limit cycle (dashed circle) goes beyond the central equilibrium at which the phase is not defined.

The stroboscopic mapping of $\mathbb{S}^1$ to itself, called Poincaré phase map,

$$\vartheta_{k+1} = \mathrm{PTC}(\vartheta_k) \qquad [5]$$

describes the response of an oscillator to a $T$-periodic pulse train. Here, $\vartheta_k$ denotes the phase of oscillation when the $k$th input pulse arrives. Its fixed points correspond to synchronized solutions, and its periodic orbits correspond to phase-locked states.

## Weak Coupling

Now consider dynamical systems of the form

$$\dot{x} = f(x) + \varepsilon s(t) \qquad [6]$$

describing periodic oscillators, $\dot{x} = f(x)$, forced by a weak time-depended input $\varepsilon s(t)$, for example, from other oscillators in a network. Let $\Theta(x)$ denote the phase of oscillation at point $x \in U$, so that the map $\Theta : U \to \mathbb{S}^1$ is constant along each isochron. This mapping transforms [6] into the phase model

$$\dot{\vartheta} = \Omega + \varepsilon Q(\vartheta) \cdot s(t)$$

with function $Q(\vartheta)$, illustrated in Figure 6, satisfying three equivalent conditions:

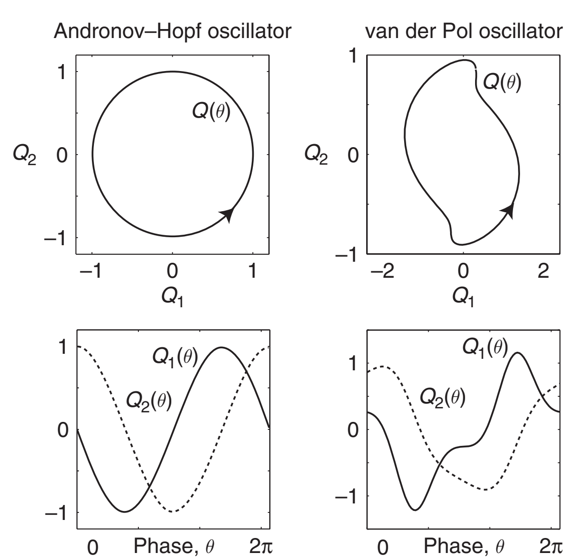

**Figure 6** Solutions $Q = (Q_1, Q_2)$ to the adjoint problem [7] for oscillators in **Figure 3**.

1. Winfree: $Q(\vartheta)$ is normalized PRC to infinitesimal pulsed perturbations;
2. Kuramoto: $Q(\vartheta) = \mathrm{grad}\ \Theta(x)$; and
3. Malkin: $Q$ is the solution to the adjoint problem

$$\dot{Q} = -\{Df(\gamma(t))\}^{\top} Q \qquad [7]$$

with the normalization $Q(t) \cdot f(\gamma(t)) = \Omega$ for any $t$.

The function $Q(\vartheta)$ can be found analytically in a few simple cases:

1. a nonlinear phase oscillator $\dot{x} = f(x)$ with $x \in \mathbb{S}^1$ and $f > 0$ has $Q(\vartheta) = \Omega / f(\gamma(\vartheta))$;
2. a system near saddle-node on invariant circle bifurcation has $Q(\vartheta)$ proportional to $1 - \cos\vartheta$; and
3. a system near supercritical Andronov–Hopf bifurcation has $Q(\vartheta)$ proportional to $\sin(\vartheta - \psi)$, where $\psi \in \mathbb{S}^1$ is a constant phase shift.

Other interesting cases, including homoclinic, relaxation, and bursting oscillators are considered by Izhikevich (2006).

Treating $s(t)$ in [6] as the input from the network, we can transform weakly coupled oscillators

$$\dot{x}_i = f_i(x_i) + \varepsilon \overbrace{\sum_{j=1}^{n} g_{ij}(x_i, x_j)}^{s_i(t)}, \quad x_i \in \mathbb{R}^m \qquad [8]$$

to the phase model

$$\dot{\vartheta}_i = \Omega_i + \varepsilon\, Q_i(\vartheta_i) \cdot \overbrace{\sum_{j=1}^{n} g_{ij}(x_i(\vartheta_i), x_j(\vartheta_j))}^{s_i(t)} \qquad [9]$$

having the form [4] with $h_i = Q_i \sum g_{ij}$, or the form

$$\dot{\vartheta}_i = \Omega_i + \varepsilon \sum_{j=1}^{n} h_{ij}(\vartheta_i, \vartheta_j)$$

where $h_{ij} = Q_i g_{ij}$. Introducing phase deviation variables $\vartheta_i = \Omega_i t + \varphi_i$, we transform this system into the form

$$\dot{\varphi}_i = \varepsilon \sum_{j=1}^{n} h_{ij}(\Omega_i t + \varphi_i,\ \Omega_j t + \varphi_j)$$

which can be averaged to

$$\dot{\varphi}_i = \varepsilon \sum_{j=1}^{n} H_{ij}(\varphi_i - \varphi_j) \qquad [10]$$

with the functions

$$H_{ij}(\chi) = \lim_{T\to\infty} \frac{1}{T} \int_0^T h_{ij}(\Omega_i t,\ \Omega_j t - \chi)\, dt \qquad [11]$$

describing the interaction between oscillators (Ermentrout and Kopell 1984). To summarize, we transformed weakly coupled system [8] into the phase model [10] with $H$ given by [11] and each $Q$ being the solution to the adjoint problem [7]. This constitutes the Malkin theorem for weakly coupled oscillators (Hoppensteadt and Izhikevich 1997, theorem 9.2).

Existence of one equilibrium of the phase model [10] implies the existence of the entire circular family of equilibria, since translation of all $\varphi_i$ by a constant phase shift does not change the phase differences $\varphi_i - \varphi_j$ and hence the form of [10]. This family corresponds to a limit cycle of [8], on which all oscillators have equal frequencies and constant phase shifts, that is, they are synchronized, possibly out of phase.

We say that two oscillators, $i$ and $j$, have resonant (or commensurable) frequencies when the ratio $\Omega_i/\Omega_j$ is a rational number, for example, it is $p/q$ for some integer $p$ and $q$. They are nonresonant when the ratio is an irrational number. In this case, the function $H_{ij}$ defined above is constant regardless of the details of the oscillatory dynamics or the details of the coupling, that is, dynamics of two coupled nonresonant oscillators is described by an uncoupled phase model. Apparently, such oscillators do not interact; that is, the phase of one of them cannot change the phase of the other one even on the long timescale of order $1/\varepsilon$.

## Synchronization

Consider [8] with $n=2$, describing two mutually coupled oscillators. Let us introduce "slow" time $\tau = \varepsilon t$ and rewrite the corresponding phase model [10] in the form

$$\varphi_1' = \omega_1 + H_{12}(\varphi_1 - \varphi_2)$$
$$\varphi_2' = \omega_2 + H_{21}(\varphi_2 - \varphi_1)$$

where $' = d/d\tau$ and $\omega_i = H_{ii}(0)$ is the frequency deviation from the natural oscillation, $i = 1, 2$. Let $\chi = \varphi_2 - \varphi_1$ denote the phase difference between the oscillators; then

$$\chi' = \omega + H(\chi) \qquad [12]$$

where

$$\omega = \omega_2 - \omega_1 \text{ and } H(\chi) = H_{21}(\chi) - H_{12}(-\chi)$$

is the frequency mismatch and the antisymmetric part of the coupling, respectively, illustrated in Figure 7, dashed curves. A stable equilibrium of [12] corresponds to a stable limit cycle of the phase model.

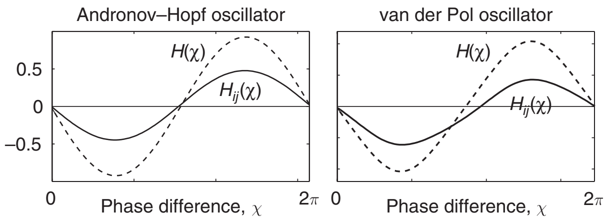

**Figure 7** Solid curves: functions $H_{ij}(\chi)$ defined by [11] corresponding to the gap–junction input $g(x_i, x_j) = (x_{j1} - x_{i1}, 0)$. Dashed curves: functions $H(\chi) = H_{ji}(\chi) - H_{ij}(-\chi)$.. Parameters are as in Figure 3.

All equilibria of [12] are solutions to $H(\chi) = -\omega$, and they are intersections of the horizontal line $-\omega$ with the graph of $H$. They are stable if the slope of the graph is negative at the intersection. If oscillators are identical, then $H(\chi)$ is an odd function (i.e., $H(-\chi) = -H(\chi)$), and $\chi = 0$ and $\chi = \pi$ are always equilibria, possibly unstable, corresponding to the in-phase and antiphase synchronized solutions. The in-phase synchronization of gap–junction coupled oscillators in Figure 7 is stable because the slope of $H$ (dashed curves) is negative at $\chi = 0$. The max and min values of the function $H$ determine the tolerance of the network to the frequency mismatch $\omega$, since there are no equilibria outside this range.

Now consider a network of $n > 2$ weakly coupled oscillators [8]. To determine the existence and stability of synchronized states in the network, we need to study equilibria of the corresponding phase model [10]. The vector $\phi = (\phi_1, \ldots, \phi_n)$ is an equilibrium of [10] when

$$0 = \omega_i + \sum_{j \neq 1}^{n} H_{ij}(\phi_i - \phi_j) \quad (\text{for all } i) \qquad [13]$$

It is stable when all eigenvalues of the linearization matrix (Jacobian) at $\phi$ have negative real parts, except one zero eigenvalue corresponding to the eigenvector along the circular family of equilibria ($\phi$ plus a phase shift is a solution of [13] too since the phase shifts $\phi_j - \phi_i$ are not affected).

In general, determining the stability of equilibria is a difficult problem. Ermentrout (1992) found a simple sufficient condition. If

1. $a_{ij} = H'_{ij}(\phi_i - \phi_j) \leq 0$, and
2. the directed graph defined by the matrix $a = (a_{ij})$ is connected, (i.e., each oscillator is influenced, possibly indirectly, by every other oscillator),

then the equilibrium $\phi$ is neutrally stable, and the corresponding limit cycle $x(t + \phi)$ of [8] is asymptotically stable.

Another sufficient condition was found by Hoppensteadt and Izhikevich (1997). If system [10] satisfies

1. $\omega_1 = \cdots = \omega_n = \omega$ (identical frequencies)
2. $H_{ij}(-\chi) = -H_{ji}(\chi)$ (pairwise odd coupling)

for all $i$ and $j$, then the network dynamics converge to a limit cycle. On the cycle, all oscillators have equal frequencies $1 + \varepsilon\omega$ and constant phase deviations.

The proof follows from the observation that [10] is a gradient system in the rotating coordinates $\varphi = \omega\tau + \phi$ with the energy function

$$E(\phi) = -\frac{1}{2}\sum_{i=1}^{n}\sum_{j=1}^{n} R_{ij}(\phi_i - \phi_j)$$

where

$$R_{ij}(\chi) = \int_0^{\chi} H_{ij}(s)\,\mathrm{d}s$$

One can check that $\mathrm{d}E(\phi)/\mathrm{d}\tau = -\sum(\phi_i')^2 \le 0$ along the trajectories of [12] with equality only at equilibria.

## Mean-Field Approximations

Let us represent the phase model [10] in the form

$$\varphi_i' = \omega_i + \sum_{j \ne i}^{n} H_{ij}(\varphi_i - \varphi_j)$$

where $' = \mathrm{d}/\mathrm{d}\tau, \tau = \varepsilon t$ is the slow time, and $\omega_i = H_{ii}(0)$ are random frequency deviations. Collective dynamics of this system can be analyzed in the limit $n \to \infty$. We illustrate the theory using the special case, $H(\chi) = -\sin\chi$, known as the Kuramoto (1984) model:

$$\varphi_i' = \omega_i + \frac{K}{n}\sum_{j=1}^{n}\sin(\varphi_j - \varphi_i), \quad \varphi_i \in [0, 2\pi] \qquad [14]$$

where $K > 0$ is the coupling strength and the factor $1/n$ ensures that the model behaves well as $n \to \infty$. The complex-valued sum of all phases,

$$re^{\mathrm{i}\psi} = \frac{1}{n}\sum_{j=1}^{n} e^{\mathrm{i}\varphi_j}$$

(Kuramoto synchronization index) [15]

describes the degree of synchronization in the network. Apparently, the in-phase synchronized state $\varphi_1 = \cdots = \varphi_n$ corresponds to $r = 1$ with $\psi$ being the population phase. In contrast, the incoherent state with all $\varphi_i$ having different values randomly distributed on the unit circle, corresponds to $r \approx 0$. Intermediate values of $r$ correspond to a partially synchronized or coherent state, depicted in Figure 8. Some phases are synchronized forming a cluster, while others roam around the circle.

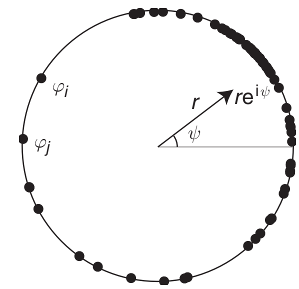

**Figure 8** Kuramoto synchronization index [15] describes the degree of coherence in the network [14].

Multiplying both sides of [15] by $e^{-\mathrm{i}\varphi_i}$ and considering only the imaginary parts, we can rewrite [14] in the equivalent form

$$\varphi_i' = \omega_i + Kr\sin(\psi - \varphi_i)$$

that emphasizes the mean-filed character of interactions between the oscillators: they all are pulled into the synchronized cluster ($\varphi_i \to \psi$) with the effective strength proportional to the cluster size $r$. This pull is offset by the random frequency deviations $\omega_i$ that pull away from the cluster.

Let us assume that $\omega_i$'s are distributed randomly around 0 with a symmetrical probability density function $g(\omega)$, for example, Gaussian. Kuramoto has shown that in the limit $n \to \infty$, the cluster size $r$ obeys the self-consistency equation

$$r = rK\int_{-\pi/2}^{+\pi/2} g(Kr\sin\varphi)\cos^2\varphi\,\mathrm{d}\varphi \qquad [16]$$

Notice that $r = 0$, corresponding to the incoherent state, is always a solution of this equation. When the coupling strength $K$ is greater than a certain critical value,

$$K_c = \frac{2}{\pi g(0)}$$

an additional, nontrivial solution $r > 0$ appears, which corresponds to a partially synchronized state. Expanding $g$ in a Taylor series, one gets the scaling $r = \sqrt{16(K - K_c)/(-g''(0)\pi K_c^4)}$. Thus, the stronger the coupling $K$ relative to the random distribution of frequencies, the more oscillators synchronize into a coherent cluster. The issue of stability of incoherent and partially synchronized states is discussed by Strogatz (2000). Other generalizations of the Kuramoto model are reviewed by Acebron *et al.* (2005). An extended version of this article with the

emphasis on computational neuroscience can be found in the recent book by Izhikevich (2006).

# Wheeler–De Witt Theory

**J Maharana**, Institute of Physics, Bhubaneswar, India

## Introduction

It is recognized that one of the outstanding problems in modern physics is to formulate the quantum theory of gravity, synthesizing the principles of quantum mechanics and general theory of relativity. The fundamental units for measuring time, length, and energy, known as Planck time, Planck length, and Planck energy, respectively, are defined to be $t_{\mathrm{Pl}} = (\hbar G/c^5)^{1/2} = 5.39 \times 10^{-44}\,\mathrm{s}$, $l_{\mathrm{Pl}} = (\hbar G/c^3)^{1/2} = 1.61 \times 10^{-33}\,\mathrm{cm}$, and $m_{\mathrm{Pl}} = (\hbar c/G)^{1/2} = 2.17 \times 10^{-5}\,\mathrm{g}$, in terms of the Newton's constant, $G$, velocity of light, $c$, and $\hbar = h/2\pi, h$ being the Planck's constant. We may conclude, on dimensional arguments, that quantum gravity effects will play an important role when we consider physical phenomena in the vicinity of these scales. Therefore, when we probe very short distances, consider collisions at Planckian energies, and envisage evolution of the universe in the Planck era, the quantum gravity will come into play in a predominant manner. The purpose of this article is to present an overview of an approach to quantize Einstein's theory of gravity, pioneered by Wheeler and De Witt almost four decades ago. We proceed to recapitulate various prescriptions for quantizing gravitation and then discuss simple derivation of the Wheeler–De Witt (WDW) equation in general relativity and some of its applications in the study of quantum cosmology. There are, broadly speaking, three different approaches to quantize gravity.

The general theory of relativity has been tested to great degree of accuracy in the classical regime. The geometrical description of spacetime plays a cardinal role in Einstein's theory. Therefore, the general relativists emphasize the geometrical attributes of the theory and the central role played by the spacetime structure in their formulation of quantum theory. It is natural to adopt a background-independent approach. In contrast, the path followed by quantum field theorists, where the prescription is valid in the weak-field approximation, the theory is quantized in a given background, usually the Minkowskian space. It is argued by the proponents of the geometric approach, that the background metric should emerge from the theory in a self-consistent manner rather than being introduced by hand when we quantize the theory. One of the earliest attempts to quantize gravity was to follow the route of canonical method. The canonical quantization approach has many advantages. One of the important features is that it is quite similar to the prescriptions adopted in quantum field theory where one uses notion of operators, commutation relations, etc. Moreover, the subtleties encountered in quantizing gravity are transparent. Therefore, the canonical procedure is preferred over the path-integral formulation, although the latter has its own advantages too. Another positive aspect of the canonical approach is that the requirement of background-independent

formulation could be maintained to some extent. Thus, there is room for exploring some of the nonperturbative attributes of the theory. The relativists favor canonical formulation, since some of the geometrical features of general theory of relativity could be incorporated here and be explored to see how far the quantum theory captures such properties of the classical theory. As we shall discuss in sequel, some of the interesting issues of quantum cosmology are addressed in this approach. However, there are limitations and short comings in this formulation and we refer the reader to the text books and review articles for further reading and critical assessments of canonical approach to quantize gravity.

The second approach is primarily the endeavor of physicists who have devoted their research to quantum field theory. Feynman's seminal work on quantization of gravity from this perspective has profoundly influenced the subsequent developments. The quantization of gravity is carried out in the weak-field approximation such that the graviton is identified as the fluctuation over the Minkowski background metric. It is a massless spin-2 field as one concludes from the properties of low-energy gravitational interaction in the classical limit. Furthermore, the gauge invariance associated with a spin-2 massless field gets intimately related with invariance of Einstein's theory under general coordinate transformation. In this setup, the field-theoretic techniques could be employed to quantize theory and to consider perturbative expansions for the scattering amplitudes. It is realized that low-energy amplitudes computed from the massless spin-2 theory match with those derived from the Einstein–Hilbert action in the weak-field approximation. Furthermore, the theory is not perturbatively renormalizable since the coupling constant carries dimension. One of the most important outcomes of the investigations from this perspective is the discovery, due to Feynman, that the introduction of ghost fields is necessary in order to maintain unitarity of the $S$-matrix when one goes beyond the tree level. As is well known, this work has profoundly influenced frontiers of research in physics leading to quantization of Yang–Mills theory which, in turn, paved way for electroweak theory and the QCD. It is worthwhile to mention in passing that the quantum phenomena associated with gravity in the nonperturbative regime cannot be addressed in this framework.

In recent years, superstring theory has been at the center stage in order to provide a unified theory of fundamental interactions. It is postulated that all elementary constituents of matter and the carriers of the interactions such as gauge bosons and graviton are excitations of one-dimensional extended objects: the strings. The superstring theories are perturbatively consistent in critical ten dimensions. The closed-superstring spectrum contains a spin-2 massless state which is identified to be the graviton. It is well known that perturbative computation of processes involving graviton turn out to be finite. Moreover, the Einstein–Hilbert term appears naturally when one derives the string effective action. Therefore, it is expected that string theory will be able to provide answers to questions related to quantum gravity. Indeed, the theory has met with success in resolving some important issues. We note that cosmological scenario has been discussed in the string theory framework and the WDW equation has played an important role in study of quantum string cosmology. We shall comment on this aspect towards the end of this article.

## The Canonical Structure of Einstein Gravity

The Einstein–Hilbert action is

$$S = \frac{1}{16\pi G}\int_M \sqrt{-g}\,\mathrm{d}^4x(R - 2\Lambda) \qquad [1]$$

where $R$ is the Ricci scalar derived from the metric, $g_{\mu\nu}$, and $\Lambda$ is the cosmological constant. The field equations are derived from the action by the standard variational technique. Note that $R$ involves second derivative of the metric. If we have compact manifolds with boundary $\partial M$ such that variations of the metric vanish on the boundary and the normal derivatives do not, it is necessary to add a surface term to this action. The exact form of this term will be discussed later. The Einstein's theory of gravitation is manifestly covariant. The associated action [1] is invariant under general coordinate transformations: under $x^\mu \to x'^\mu(x)$,

$$g'^{\mu\nu}(x') = g^{\rho\lambda}(x)\frac{\partial x'^\mu}{\partial x^\rho}\frac{\partial x'^\nu}{\partial x^\lambda} \qquad [2]$$

Therefore, we expect that the theory will be endowed with constraints expressed in terms of the canonical variables. One can implement general coordinate transformations so that there are only two pairs of canonical phase-space variables on a spacelike hypersurface. In other words, from physical considerations, graviton has only two polarizations whereas the metric has ten components. Therefore, the two physical degrees of freedom can be obtained using the freedom of choosing the "gauge" transformations in this context. It is desirable to identify the constraints and analyze their structure, most appropriately in Dirac's

formalism, and to quantize the theory canonically as the next step. This is the path we intend to follow in order to arrive at the WDW equation.

### The Classical Constraints

The Hamiltonian approach is most appropriate to employ the constraint formalism due to Dirac. We recall that the Lagrangian formulation is manifestly covariant as is reflected in the field equations; whereas the spacetime covariance is lost in the passage to the Hamiltonian approach. Furthermore, the spatial components of the metric are the dynamical degrees of freedom. We adopt the formalism introduced by Arnowitt, Deser, and Misner (ADM) for the so-called $3+1$ split of the hyperbolic Riemannian spacetime metric, $g_{\mu\nu}$. One introduces the lapse function, $N^{\perp}$, and the shift function, $N^i$. We suppress the factors of $1/16\pi G$, etc., for the time being for the general discussions and shall reintroduce them later. The family of spacelike hypersurfaces, $\Sigma_t$, are constructed, with metric $h_{ij}$ induced on it. Here $t$ is a timelike parameter, parametrize $\Sigma_t$. The distance between points on two neighboring hypersurface, $\Sigma_t$ and $\Sigma_{t+dt}$, with coordinates $(t, x^i)$ and $(t+\mathrm{d}t, x^i+\mathrm{d}x^i)$, respectively, is given by

$$\begin{aligned} \mathrm{d}s^2 &= -(N^{\perp})^2\,\mathrm{d}t^2 + h_{ij}(N^i\,\mathrm{d}t+\mathrm{d}x^i)(N^j\,\mathrm{d}t+\mathrm{d}x^j) \\ &= g_{\mu\nu}\,\mathrm{d}x^{\mu}\,\mathrm{d}x^{\nu} \end{aligned} \qquad [3]$$

The indices of tensors defined on $\Sigma_t$ are raised and lowered by $h_{ij}$ and its inverse $h^{ij}$. The relations between the components of $g_{\mu\nu}$ and $N^{\perp}, N^i, h_{ij}$ can be obtained easily,

$$g_{00} = h_{ij}N^iN^j - (N^{\perp})^2, \qquad g_{0i} = h_{ij}N^j \qquad [4]$$

The above relations can be inverted to give

$$N^i = h^{ij}g_{0i} \qquad N^{\perp} = \frac{1}{\sqrt{-g^{00}}} \qquad [5]$$

The relations between spatial components, $g_{ij}$, of $g_{\mu\nu}$ and $h_{ij}$ and some other useful relations are listed below for later conveniences:

$$\begin{aligned} g^{ij} &= h^{ij} - \frac{N^iN^j}{(N^{\perp})^2} \\ \sqrt{-g} &= N^{\perp}\sqrt{h} \\ g^{0i} &= \frac{N^i}{(N^{\perp})^2} \end{aligned} \qquad [6]$$

Note that $(N^{\perp}, N^i)$ are introduced to specify the deformation of the hypersurface and therefore, the evolution equations through the Hamiltonian will not determine them; they are arbitrary functions. Consequently, [4] implies that $g_{00}$ and $g_{0i}$ will enter the Hamiltonian as arbitrary functions. As alluded to above, $h_{ij}$ and their conjugate momenta $\pi^{ij}$ are the dynamical degrees of freedom. We may choose $(N^{\perp}, N^i) = N^{\mu}$ and $h_{ij}$ as independent variables rather than $(g_{00}, g_{0i}) = g_{0\mu}$ and $h_{ij}$ for convenience and go back to the other set of variables through [4] and [5] if we desire. Let $\pi_{\mu}$ be canonically conjugate momenta to $N^{\mu}$, then it is obvious that a Lagrangian multiplier, $\chi^{\mu}$, is necessary so that $\pi.\chi$ term has to be supplemented to the Hamiltonian due to the arbitrariness of $N^{\mu}$. We remind the reader that in electrodynamics an analogous situation arises while analyzing its canonical structure – local gauge symmetry plays a crucial role there. It is obvious that the generic form of the Hamiltonian is (we shall introduce $1/16\pi G$, etc., later)

$$\mathbf{H} = \int \mathrm{d}^3x \left(N^{\perp}\mathcal{H}_{\perp}[h_{ij}, \pi^{ij}] + N^i\mathcal{H}_i[h_{ij}, \pi^{ij}] + \chi.\pi\right) \qquad [7]$$

From the perspective of constraint analysis, it is natural that $\pi^{\mu} \approx 0$ appears as a first-class constraint as they are multiplied by arbitrary functions. Moreover, this constraint must hold good under the deformation of the surface which implies $\{\pi^{\mu}, H\}_{\mathrm{PB}}$ must vanish weakly leading to $\mathcal{H}_{\mu} \approx 0$. As a consistency requirement, these must be first-class constraints if $N^{\mu}$ are to be arbitrary functions. We identify that $\pi^{\mu} \approx 0$ and $\mathcal{H}_{\mu} \approx 0$ are the primary and secondary constraints, respectively. Thus far, we have discussed the case for pure gravity; the presence of matter fields in the full action modifies the treatment appropriately.

Let us analyze the structure of the constraints for the Einstein–Hilbert action [1]. For a compact manifold with boundary $\partial M$, we have to add the surface term which takes the form:

$$\frac{1}{8\pi G}\int_{\partial M} \mathrm{d}^3x\sqrt{h}K$$

Here $K$ stands for the trace of the extrinsic curvature of the boundary 3-surface and $h = \det h_{ij}$; note that $h_{ij}$ is the induced metric on the 3-surface. If we include matter fields, the corresponding action is to be taken into account. Once we make the $3+1$ split of the metric, the action assumes the following form:

$$\begin{aligned} S = \frac{1}{16\pi G}&\int \mathrm{d}^3x\,\mathrm{d}tN^{\perp}\sqrt{h} \\ &\times \left(K_{ij}K^{ij} - K^2 + {}^3R - 2\Lambda\right) \end{aligned} \qquad [8]$$

where

$$K_{ij} = \frac{1}{N^{\perp}}\left(-\frac{\partial h_{ij}}{\partial t} + D_iN_j + D_jN_i\right) \qquad [9]$$

Here $D_i N_j$ represents covariant derivative of $N_j$ with the connections computed from $h_{ij}$ and ${}^3R$ is curvature of the 3-surface. The canonical momenta are

$$\pi^{ij} = \frac{\sqrt{h}}{16\pi G}\left(K^{ij} - h^{ij}K^l_l\right) \qquad [10]$$

and we can invert this relation to get

$$K^{ij} = -\frac{1}{16\pi G\sqrt{h}}\left(\pi^{ij} - \frac{1}{2}h^{ij}\pi^l_l\right)$$

The Hamiltonian form of action is given by

$$S_H = \int \mathrm{d}^3x\,\mathrm{d}t\left(\dot{h}_{ij}\pi^{ij} - N_\perp\mathcal{H}^\perp - N^i\mathcal{H}_i\right) \qquad [11]$$

Notice that [8] does not involve time derivatives of $N^\perp$ and $N^i$, their corresponding canonical momenta vanish.

$$\pi_\perp \approx 0, \qquad \pi_i \approx 0 \qquad [12]$$

as expected from our earlier discussions about the role of $N^\mu$. A straightforward constraint analysis leads to the pair of constraints

$$\mathcal{H}_i = -2D_j\pi^j_i \approx 0 \qquad [13]$$

$$\mathcal{H}_\perp = \frac{16\pi G}{\sqrt{h}}\left(h_{ij}h_{kl} - \frac{1}{2}h_{ik}h_{jl}\right)\pi^{ik}\pi^{jl} - \frac{\sqrt{h}}{16\pi G}{}^3R \approx 0 \qquad [14]$$

We mention in passing that the above constraint equations get modified in the presence of matter fields in the theory. This is relevant. The WDW equation plays an important role in quantum cosmology to describe the evolution of the universe in early epochs and the equation is studied in the presence of a generic matter content, that is, a scalar field with potential. The constraint equations [13] and [14] modify to

$$\mathcal{H}^{\mathrm{T}}_i = \mathcal{H}_i + \mathcal{H}^{\mathrm{matter}}_i \approx 0 \qquad [15]$$

$$\mathcal{H}^{\mathrm{T}}_\perp = \mathcal{H}_\perp + \mathcal{H}^{\mathrm{matter}} \approx 0 \qquad [16]$$

### The Algebra of Constraints

In order to compute the classical Poisson bracket algebra of the constraints [13] and [14], we use the canonical Poisson bracket relations for the phase-space variables on $\Sigma_t$:

$$\{h_{ij}(\boldsymbol{x}), h_{kl}(\boldsymbol{x}')\} = 0 \qquad [17]$$

$$\{\pi^{ij}(\boldsymbol{x}), \pi^{kl}(\boldsymbol{x}')\} = 0 \qquad [18]$$

$$\{h_{ij}(\boldsymbol{x}), \pi^{kl}(\boldsymbol{x}')\} = \delta^k_{(i}\delta^l_{j)}\delta(\boldsymbol{x}, \boldsymbol{x}') \qquad [19]$$

Thus, Poisson brackets among the constraints [13] and [14] are

$$\{\mathcal{H}_i(\boldsymbol{x}), \mathcal{H}_j(\boldsymbol{x}')\} = -\mathcal{H}_j(\boldsymbol{x})\partial^{x'}_i\delta(\boldsymbol{x}, \boldsymbol{x}') + \mathcal{H}_i\partial^x_j\delta(\boldsymbol{x}, \boldsymbol{x}') \qquad [20]$$

$$\{\mathcal{H}_i(\boldsymbol{x}), \mathcal{H}_\perp(\boldsymbol{x}')\} = \mathcal{H}_\perp(\boldsymbol{x})\partial^x_i\delta(\boldsymbol{x}, \boldsymbol{x}') \qquad [21]$$

$$\{\mathcal{H}_\perp(\boldsymbol{x}), \mathcal{H}_\perp(\boldsymbol{x}')\} = h^{ij}(\boldsymbol{x})\mathcal{H}_i(\boldsymbol{x})\partial^{x'}_j\delta(\boldsymbol{x}, \boldsymbol{x}') - h^{ij}(\boldsymbol{x}')\mathcal{H}_i(\boldsymbol{x}')\partial^x_j\delta(\boldsymbol{x}, \boldsymbol{x}') \qquad [22]$$

When we resort to canonical quantization, the starting point is the Hamiltonian action in the first-order formalism, where the canonical variables are subjected to the constraints [13] and [14] in terms of $\mathcal{H}_\perp$ and $\mathcal{H}_i$ satisfying the algebra given by [20]–[22]. One encounters a number of important issues while proceeding to canonically quantize the theory. We shall mention only a few of them in what follows. It is important to address issues related to the role of the constraints in the quantized theory and how to deal with the Lagrange multipliers $N^\perp$ and $N^i$. A simple proposal is to solve the constraints at the classical level and identify the physical degrees of freedom and quantize the theory subsequently. There are four constraints (first class), $\mathcal{H}_\perp, \mathcal{H}_i$, therefore, out of the 12 phase-space variables, $(h_{ij}, \pi^{ij})$, only eight are independent. We need to supply four gauge conditions in order to render the theory (classically) solvable. Thus, we are left with four physical degrees of freedom in the Hamiltonian phase space and we can quantize them. The implementation of this idea is easier said than done. One obstacle is that the constraints cannot be solved in a closed form in this formalism. If we fix a gauge and quantize the theory, we obviously break the gauge invariance. It is essential to show, subsequently, that all physically observable quantities are independent of the gauge choice. Another criticism of this formalism is that we already get rid of some of the components of the metric. Therefore, the spirit of the general theory of relativity, which is based on the geometrical structure of spacetime, is somewhat diluted. There are other suggestions where $h_{ij}$ and their conjugate momenta are elevated to quantum status before supplying the gauge conditions. The issues of gauge fixing and dealing with the constraints are addressed at the quantum level. We replace the canonical Poisson bracket

algebra by the canonical commutators and proceed further. The momentum operator assumes the form

$$\hat{\pi}^{ij} = -\mathrm{i}\hbar \frac{\delta}{\delta h_{ij}}$$

and the wave functional depends on $h_{ij}$ that is, $\Psi[h]$. There are many technical problems related to the properties of the states and we shall not deal with them due to limitations of space. It is essential to discuss the role of the constraints in the quantum theory. We demand that the quantum constraints annihilate the physical states (recall the Gauss law constraint in gauge theories). However, the issue of operator ordering is to be dealt with which in turn is connected with the Hermiticity properties of the quantum constraints. The Hamiltonian constraint $\mathcal{H}_\perp \approx 0$ (henceforth denoted as $\mathcal{H}$ and defined as the Hamiltonian) is a product of the metric $\hat{h}_{ij}$ and $\boldsymbol{\pi}^{ij}$. There is certain ambiguity in defining the constraint. Therefore, one has to choose a convention. The condition that the Hamiltonian, $\hat{\mathcal{H}}^{\mathrm{T}}$, consisting of gravitational and matter components, annihilates the state is expressed as

$$\hat{\mathcal{H}}^{\mathrm{T}} \Psi = 0 \qquad [23]$$

When we adopt coordinate representation for $\boldsymbol{\pi}^{ij}$, the above equation takes the form

$$\left[-16\pi G\, G_{ijkl} \frac{\delta}{\delta h_{ij}} \frac{\delta}{\delta h_{kl}} - \frac{\sqrt{h}}{16\pi G}\left({}^3R - 2\Lambda\right) + \mathcal{H}^{\mathrm{matter}}\right] \Psi[h, \phi] = 0 \qquad [24]$$

This is the celebrated WDW equation. Here we have considered a simple case where matter Hamiltonian density generically contains a single scalar field, $\phi$, and therefore $\Psi$ is functional of 3-metric on $\Sigma_t$ and $\phi$. $G_{ijkl}$ is the De Witt metric in the superspace:

$$G_{ijkl} = \frac{1}{\sqrt{h}}\left(h_{ik} hjl + h_{il} h_{jk} - h_{ij} h_{kl}\right) \qquad [25]$$

**Remarks** The space of all 3-metrics and the scalar field $(h_{ij}, \phi)$, on $\Sigma_t$, for the description of classical evolutions is called the superspace (no connection with the superspace of supersymmetry). Thus, $\Psi[h_{ij}, \phi]$ is a functional on superspace. Furthermore, $\Psi$ carries no explicit dependence on $t$. This is a consequence of the fact that "time" plays the role of a parameter in the general theory of relativity, thus the dynamical variables $h_{ij}$ and $\phi$ already provide the evolutionary processes although $t$ does not make its appearance. As mentioned earlier, we always discuss the case when $\Sigma_t$ is compact. Another point to note is that the quantum momentum constraint, $\hat{\mathcal{H}}_i$, as an operator annihilates the wave function which is a statement of the quantum-mechanical invariance of the theory under three-dimensional diffeomorphisms. However, the WDW equation conveys invariance of the theory under reparametrization, although careful analysis is necessary to prove this point. Now we proceed to discuss the solutions of the WDW equation.

## WDW Equation and the Solutions

It is recognized that the WDW equation [24] is a second-order hyperbolic functional differential equation and naturally it has enormous number of solutions. Therefore, if we want the WDW equation to have any predictive power, it is necessary to introduce boundary conditions. One of the possible choice is to specify the wave function on the boundary of the superspace. Indeed, the central issue of quantum cosmology is about the choice of various boundary conditions which has been an important topic of debates. This point will be briefly discussed later. Notice that the boundary condition has to be introduced keeping in mind how the universe is expected to behave as it evolves. There is a proposition that the boundary condition for the quantum evolution of the universe be given the status of a physical law. Therefore, the role of the wave functional, $\Psi[h_{ij}(\boldsymbol{x}), \phi(\boldsymbol{x}), B]$, its evolution, and interpretation are central to the development of quantum cosmology. Thus, $\Psi$ represents the amplitude for the universe to have $h_{ij}(\boldsymbol{x})$ on the 3-surface, $B$, and matter field $\phi(\boldsymbol{x})$. It is argued that path-integral formalism should be adopted as an alternative to the canonical prescription to solve for the wave function, rather the transition amplitude, satisfying the WDW equation. Here the first step is to define the Euclidean version of the gravitational action keeping in mind the subtleties. As is well known, we deal with propagator (or transition amplitude) in the path-integral approach where the functional integral is carried out over a set of 4-metrics and matter fields with Euclidean action inside the integral acting as the weight factor. We recall that while formulating quantum mechanics in the path-integral approach, we sum over all possible paths in the functional integral. However, in the semiclassical approximation, the amplitude is dominated by the action corresponding to the classical path and we approximate the wave function as $\psi \sim \mathrm{e}^{(\mathrm{i}/\hbar)S_{\mathrm{cl}}}$ and it gets modified appropriately in the Euclidean formulation. In this background, we briefly discuss how the wave function of the universe is obtained in the path-integral formalism.

According to the proposal of Hartle and Hawking, one adopts path-integral formalism for the Euclidean action where the functional integral is not only carried out over the 4-metric, $g_{\mu\nu}$, and the scalar field $\phi$, but also one takes sum over the class of manifolds, $M$. Note that $B$ is a part of the boundary of this set of manifold. If $\bar{h}_{ij}$ and $\bar{\phi}$ are the induced metric and the configuration of the scalar field, $\phi$, on the boundary, $B$, then the propagator (henceforth we just call it the wave function) $\Psi[\bar{h}_{ij}, \bar{\phi}, B]$ can be given a functional-integral representation. Indeed, obtaining the most general form of the path integral, summing over the 4-manifolds, is quite a formidable task. On the other hand, if one chooses a class of 4-manifolds which can be decomposed as a product (foliation) $\boldsymbol{R} \times B$, the wave function is expressed as

$$\Psi[\bar{h}, \bar{\phi}, B] = \int \mathcal{D}N^\mu \int \mathcal{D}h_{ij}\mathcal{D}\phi\, f(N^\mu)\Delta_{\mathrm{FP}}\mathrm{e}^{-S_{\mathrm{E}}[g_{\mu\nu},\phi]} \qquad [26]$$

We have introduced the gauge-fixing condition as $f(N^\mu)$, which is usually taken to be $\dot{N}^\mu = l^\mu$ and then the corresponding Faddeev–Popov determinant, $\Delta_{\mathrm{FP}}$, has to be inserted into the path-integral measure. We recall from our earlier discussions that $N^\mu$ has to be unrestricted on the boundary, $B$, since they have no dynamical role when we express the action in terms of the variables defined on the 3-surface. As noted in the previous discussion, explicit time dependence does not appear after the $3+1$ split and $(h_{ij}(\boldsymbol{x}), \phi(\boldsymbol{x}))$ have no dependence on $t$. Therefore, we introduce a parameter to designate the paths over which the functional integral is to be taken. Recall that in the quantum-mechanical case, the paths are parametrized as $q_i(t)$ for the coordinates. However, when we resort to a parametrization of the variables for the case at hand, certain conditions must be fulfilled. We are permitted to integrate over $h_{ij}$ and $\phi$ over only those paths, while parametrizing them as $(h_{ij}(\boldsymbol{x}, \tau), \phi(\boldsymbol{x}, \tau))$, so that they match the arguments of the wave function on the boundary $B$. Therefore, we may define the metric and the scalar field configuration so that at $\tau = 1$ they assume their functional values on the boundary: in other words, $\bar{h}_{ij}(\boldsymbol{x}) = h_{ij}(\boldsymbol{x}, \tau = 1)$ and $\bar{\phi}(\boldsymbol{x}) = \phi(\boldsymbol{x}, \tau = 1)$. It is worthwhile to go back to the quantum-mechanical analogy once more. When we compute amplitudes/propagators in quantum mechanics, the functional integral is defined for the amplitude of going from a configuration $q_i$ to $q_f$ while summing over all possible paths originating from one endpoint $q_i$ and ending at the final point $q_f$. On this occasion, we have imposed the constraint on the final endpoint belonging to the boundary $B$. Thus, in order to determine the wave function of the universe, we are required to specify the initial configurations of $h_{ij}$ and $\phi$ at $\tau = 0$. We shall not enter into important issues related with the properties of the Euclidean action, the problems associated with the choice of contours of the path integrals, and related topics. The reader will find detailed discussions in the lectures and monographs referred in the "Further reading" section.

It is important to re-emphasize that boundary conditions are to be introduced while solving the WDW equation. It was argued by De Witt that the wave function will be determined uniquely from the mathematical consistency of the theory and that hope has not been realized. Whether one attempts to solve the functional differential WDW equation or obtain the wave function in the path-integral formalism, the issue of boundary condition is unavoidable. There are mainly three different kinds of boundary conditions in quantum cosmology: Hartle–Hawking (HH) no-boundary proposal, Vilenkin's tunneling mechanism, and Linde's boundary condition. We shall briefly discuss the first two proposals. Instead of stating the boundary conditions in full generality, we shall envisage quantum cosmology in a minisuperspace and provide illustrative examples to compare the main features of HH and Vilenkin solutions to the WDW equation.

It is realized that the discussion and solutions of quantum cosmology in the superspace is rather difficult, since we deal with functional differential equations and the configuration space is infinite dimensional. Therefore, it is worthwhile to consider a system, as a simple model, which has finite degrees of freedom. Thus, we assume that the metric and matter fields depend only on cosmic time to begin with. There is a physical motivation behind this assumption, since the present classical state of the universe is described by the Friendmann–Robertson–Walker (FRW) metric corresponding to an isotropic and homogeneous universe. Notice that the classical evolution equation resembles that of the motion of a particle. The quantum evolution equations are now given by differential equations of quantum mechanics rather than functional differential equations. Similarly, the path-integral formulation becomes analogous to the quantum-mechanical frame work. Of course, adopting such a simplified approach deprives us from describing some of the important aspects of quantum gravity. However, within this framework, several essential features can be exhibited and deep insight might be gained into the physics of the very early universe. The first step in getting the minisuperspace metric is to assume that the lapse is homogeneous, that is, $N^\perp = N^\perp(t)$

and the shift is set to zero, $N^i = 0$. Thus, the metric takes the form

$$ds^2 = -(N^{\perp}(t))^2 dt^2 + h_{ij}(\boldsymbol{x}, t) dx^i dx^j \quad [27]$$

The relevant choice of 3-metric for FRW isotropic and homogeneous universe is

$$h_{ij}(\boldsymbol{x}, t) dx^i dx^j = a(t)^2 d\Omega_3^2 \quad [28]$$

Note that $d\Omega_3^2$ is the metric on a 3-sphere. It is straightforward to derive the Friedmann equations for such a geometry.

The HH no-boundary condition can be interpreted as a topological proposition about the set of path over which we have to sum. The 3-surface $B$ is to be taken as the only surface of compact 4-manifold $M$ which is endowed with the metric $g_{\mu\nu}$, and $\bar{h}_{ij}$ and $\bar{\phi}$ are the induced metric and the scalar field on the surface. The wave function is obtained by using the matching condition supplemented with initial condition. For the minisuperspace case, initial conditions impose constraints on the scale factor $a(\tau = 0)$ and $(da/d\tau)(\tau = o)$, and $N^{\perp}$ is to be gauge fixed. These conditions are to be implemented in the context of determining the wave function of the universe. In the case of the tunneling boundary condition of Vilenkin, the qualitative scenario is as follows. If we look at the solution to the WDW equation (in the path-integral approach, Vilenkin considers Lorentzian action), the solution, crudely speaking, has both ingoing and outgoing modes at the boundary. In his proposal, the outgoing mode at the boundary is to be accepted. The exact prescription is lot more subtle than the above statement, since one has to define the meaning of outgoing mode carefully in the absence of a timelike Killing vector when we write the WDW equation on the superspace. The qualitative picture for Vilenkin's boundary condition, in the minisuperspace, is like tunneling solutions in quantum mechanics when a particle penetrates through a potential barrier.

Let us consider a minisuperspace model with the scalar field and potential $V(\phi)$. The action is

$$S = \frac{1}{2}\int dt a^3 \left[ -\frac{1}{N^{\perp}}\left(\frac{\dot{a}}{a}\right)^2 + \frac{(\dot{\phi})^2}{N^{\perp}} - N^{\perp} V(\phi) + \frac{N^{\perp}}{a^2} \right] \quad [29]$$

A few comments are in order here. For the FRW metric, we have $\sqrt{g}R = 6(-a\dot{a} + ka) +$ a total derivative term; the total derivative term can be removed by adding a boundary term and $k$ is positive since we take the spatial part to be closed. We have redefined the scale factor, the scalar field, the potential term, and $k$ such that the Einstein–Hilbert action with matter field assumes the form of [29] and this action facilitates the definition of conjugate momenta without cumbersome numerical factors, and the Hamiltonian takes a simple form. The conjugate momenta and resulting Hamiltonian are

$$\pi_a = -\frac{a\dot{a}}{N^{\perp}}, \qquad \pi_{\phi} = \frac{a^3\dot{\phi}}{N^{\perp}} \quad [30]$$

$$H_c = \frac{N^{\perp}}{2}\left[ -\frac{\pi_a^2}{a} + \frac{\pi_{\phi}^2}{a^3} + a^3 V(\phi) - a \right] = N^{\perp} H \quad [31]$$

and the constraint is $H = 0$. In the quantum cosmology context, we solve the WDW equation: $H\Psi = 0$. Since the exact solution is not possible, one resorts to some approximation with simple assumptions. The differential equation is

$$\left[ \frac{\partial^2}{\partial a^2} - \frac{1}{a^2}\frac{\partial^2}{\partial \phi^2} + a^4 V(\phi) - a^2 \right]\Psi = 0 \quad [32]$$

Let us consider the case when $V(\phi)$ does not grow very fast, that is, $V(\phi)/V(\phi)' << 1$ and consider the solution to the WDW equation where $\Psi$ has weak dependence on $\phi$. Consequently, we may ignore the $\phi$ derivative term in [32]. The purpose of these assumptions is to reduce the problem to a one-dimensional quantum mechanics problem and then employ WKB method. It is hoped that at least some of the nonperturbative aspects can still be captured. When the effective potential appearing in [32] is negative (this is a classically inaccessible region), the wave function is

$$\Psi(a, \phi) \approx e^{\pm(1/3V(\phi))(1 - a^2 V(\phi))^{3/2}} \quad [33]$$

We expect the wave function have oscillatory behavior in the classically allowed domain and it does have that property,

$$\Psi(a, \phi) \approx e^{\pm(i/3V(\phi))(a^2 V(\phi) - 1)^{3/2}} \quad [34]$$

The choice of signs is decided from the boundary conditions imposed and the usual matching of the wave functions of the two regions is done as is the case with the WKB approximation. Note that we are considering the metric and the scalar field on

the boundary which were denoted by $\bar{h}_{ij}$ and $\bar{\phi}$; strictly speaking, we should denote the solutions as $\bar{a}$ and $\bar{\phi}$. But from now on, we drop this bar on $a$ and $\phi$.

Let us momentarily assume that $V$ is $\phi$-independent and therefore, we have an effective cosmological constant. The problem is identical to the motion of a particle in a potential well. There are two turning points. In one region, the particle starts from $a = 0$, reaches one turning point $r_1$ and returns back. In another case, it starts from $a = \infty$, travels up to $a = r_2$ and reflects back. In the quantum-mechanical case, the particle can tunnel through the barrier. The wave function has both decaying and growing modes under the barrier, and boundary conditions tell us which mode to choose. One possibility is that the particle starts from $a = 0$, tunnels through and proceeds towards $a = \infty$, that is, it has outgoing mode. The other possibility is that the wave function has both outgoing and ingoing modes. In this simple scenario, the former corresponds to Vilenkin's tunneling boundary condition, where the universe is created at $a = 0$ and it keeps growing. The latter is HH no-boundary proposal where the wave function has both modes and the universe contracts and expands.

Now we discuss the two boundary conditions in the presence of the potential, with the approximations mentioned above. The proposition of Vilenkin amounts to the following conditions on the wave function: the region of the boundary which is nonsingular is $\phi$ finite and $a = 0$. Other than this domain, either $a$ or $\phi$ diverge on any other region of the boundary; both can diverge in this singular boundary. Notice from the expression for [33] and [34] that the tunneling region corresponds to $a^2V(\phi) < 1$, whereas, the oscillatory domain is $a^2V(\phi) > 1$. If we use the saddle-point approximation, $\Psi \approx e^{\pm iS_{cl}}$. Vilenkin's boundary condition corresponds to $\Psi \approx e^{-iS_{cl}}$, with

$$S_{cl} = \frac{(\sqrt{a^2V(\phi) - 1})^3}{3V(\phi)}$$

So far, we considered the situation where differential operator for $\phi$ is dropped in [32]. In order to account for weak $\phi$-dependence, we could introduce it by multiplying a slowly varying function, say $F(\phi)$ and write $\Psi(a, \phi) \sim F(\phi)e^{-iS_{cl}}$. Similarly, the wave function can be obtained under the barrier and required to satisfy WKB matching conditions. Furthermore, the regularity condition on the wave function in small scale factor limit and behavior of its derivative with respect to $\phi$ in that limit determine the form of $F(\phi)$. In summary, the Vilenkin boundary conditions yield the following wave functions:

$$\Psi(a, \phi)_V \approx e^{-(1/3V(\phi))(1-[1-a^2V(\phi)]^{3/2})} \qquad [35]$$

$$\Psi(a, \phi)_V \approx e^{-1/3V(\phi)}\, e^{-(i/3V(\phi))[a^2V(\phi)-1]^{3/2}} \qquad [36]$$

Note that [35] is the wave function under the barrier, that is, $a^2V(\phi) < 1$ in this region, whereas [36] is in the classically accessible domain ($a^2V(\phi) > 1$) which is reflected by the oscillatory character. The slowly varying function $F(\phi) \sim e^{-1/3V(\phi)}$ appears as the common factor for the wave functions in the two domains.

The HH no-boundary proposal to derive the wave function of the universe was formulated in the Euclidean path-integral formalism. A considerable amount of attention has been focused in this area. We shall present the HH wave function providing only a sketchy argument. In the Euclidean description, 4-metric is $ds^2 = (N^\perp)^2 d\tau^2 + a^2(\tau)d\Omega_3^2$. The 4-geometry should close in a regular way. If we make the bounding 3-space smaller and smaller, it can be closed with flat space. We can infer about the behavior of the scale factor in the limit $\tau \to 0$ from this consideration. Furthermore, in the semiclassical approximation $\Psi(a, \phi) \sim e^{-S_E}$; we have replaced $(\bar{a}, \bar{\phi})$ by $(a, \phi)$ as remarked earlier. Thus, our aim is to evaluate $S_E$ at the saddle point. This is achieved by writing down the (Euclidean version) field equations for $a$ and $\phi$ and the Hamiltonian constraint, and then solve for $a(\tau), \phi(\tau)$, and $N^\perp(\tau)$. Eventually, we want to eliminate $N^\perp$ and then obtain $S_E$. After all, the path integral is dominated by the classical trajectory, $a(\tau)$, and one does not fix the gauge for $N^\perp$ while solving for $a$. In fact, the lapse gets eliminated by utilizing the Hamiltonian constraint which involve $\tau$-derivatives of both $a$ and $\phi$. We mention, without going into details, that the classical action is not unique. One of the ways to visualize it is to note that the solutions obtained for the lapse from the Hamiltonian constraint have sign ambiguities.

The classical action is

$$S_E^{\pm} = -\frac{1}{3V(\phi)}\left(1 \pm [1 - a^2V(\phi)]^{3/2}\right) \qquad [37]$$

Note that the two solutions correspond to 3-sphere boundary being closed off by sections of 4-sphere. Moreover, the Euclidean action is negative. Hartle and Hawking argue that the negative sign in [37] gives the correct answer since the wave function peaks for that choice. However, there is no unanimity

for HH argument and some authors have put forward a point of view that additional inputs are necessary to arrive at the HH conclusion about choosing the negative sign for $S_E$ in [37]. We refer the reader to the reviews of Hartle and Halliwell for detailed discussions on the choice of contours for path integrals, subtleties involved in getting various solutions for the lapse and their interpretations. We give below the wave function under the barrier (with choice of negative sign in [37]):

$$\Psi_{\mathrm{HH}}(a,\phi) \approx \mathrm{e}^{(1/3v(\phi))(1-[1-a^2V(\phi)]^{3/2})} \qquad [38]$$

$$\Psi_{\mathrm{HH}}(a,\phi) \approx \mathrm{e}^{1/3V(\phi)} \times \cos\left(\frac{1}{3V(\phi)}[a^2V(\phi)-1]^{3/2} - \frac{\pi}{4}\right) \qquad [39]$$

**Remarks** The wave function in [38] is obtained in the classically inaccessible region under the condition $a^2V(\phi) < 1$, and wave function [39] corresponds to the case $a^2V(\phi) > 1$, where the particle motion is permissible classically. Note the factor $\mathrm{e}^{1/3V(\phi)}$ in the wave functions in both the regions and compare that with the Vilenkin's wave function which has the opposite sign. We may conclude where the wave function will peak for each of the two boundary conditions. Whereas Vilenkin's proposal implies that $\Psi_V(a,\phi)$ peaks when $V(\phi)$ takes large values, HH no-boundary condition tells us that it peaks when $V(\phi) \to 0$. Furthermore, we note that $\Psi_V$ is complex and $\Psi_{\mathrm{HH}}$ is real in the oscillatory region. Although the debates on the merits and demerits of each of the boundary proposals are going on for more than two decades, the issue is far from being settled. In the absence of any experimental tests, there is no way to favor one boundary proposal over another. Then, boundary conditions do have predictions about the evolution of the universe after the quantum era and have predictions in that (classical) regime. Therefore, determination of the wave function with specific boundary conditions does have some connections with the laws that govern the evolution of our universe in the present epoch.

It is worthwhile to dwell on the WDW equation from the perspectives of string theories. Indeed, there have been important developments to understand the dynamics of the universe in the string-theoretic framework. It is important to note the key role played by dilaton in string theory: (1) it is one of the massless states of the theory, and (2) the vacuum expectation value (VEV) of this field determines the coupling constants we hope to use in describing fundamental interactions. Therefore, the graviton is always accompanied by the dilaton in any string-theoretic approach to study the universe. The duality symmetries are recognized to provide deep understanding of the string dynamics. Therefore, the investigations of quantum gravity phenomena from the string-theory viewpoint are necessarily influenced by above mentioned facts. Indeed, classical cosmological solutions, derived from string effective action, have several interesting characteristics. We mention is passing that the WDW equation has played an important role to study quantum evolution equations in string cosmology. The choice of operator-ordering prescription in defining the WDW Laplace–Beltrami operator can be resolved by appealing to the duality symmetries. Furthermore, the boundary conditions imposed on the wave function are dictated by string symmetries and therefore, the resulting wave function has very interesting properties. The string theory has addressed some of the most important problems in quantum gravity and it has provided resolutions to several key issues. It is expected that string theory will provide answers to challenging questions in quantum cosmology. In summary, we have conveyed some of the salient aspects of the WDW equation. The canonical quantization technique is adopted to study quantum gravity in this approach. We have illustrated the crucial role of the constraint formalism due to Dirac and argued that some of the nonperturbative aspects of quantum gravity could be retained. In a short article of this nature, it is not possible to provide detailed discussion about the general derivation of the WDW equation and discuss the role of boundary conditions more exhaustively. Instead, we presented some of the key steps in the derivation of the WDW equation adopting the canonical formalism and provided simple examples. The subject is still an active area of research. The interested reader may benefit from the bibliography.

## Introduction

Historically, the first question where the Wulff shapes have appeared is the one of the formation of a droplet or a crystal of one substance inside another. The natural problem here is: what shape such a formation would take? The statement that such a shape should be defined by the minimum of the overall surface energy subject to the volume constraint is physically very natural. In the isotropic case, when the surface tension does not depend on the orientation of the surface, and so is just a positive number, the shape in question should be of course spherical (provided we neglect the gravitational effects). In a more general situation the shape in question is less symmetric. The corresponding variational problem is called the Wulff problem. Wulff (1901) formulated it in his paper, where he also presented a geometric solution to it, called the "Wulff construction."

The Wulff variational problem is formulated as follows. Let $\tau(\boldsymbol{n})$, $\boldsymbol{n} \in S^{d-1}$, be some continuous function on the unit sphere $S^{d-1} \subset \mathbb{R}^d$. We suppose that $\tau > 0$, and that $\tau$ is even: $\tau(\boldsymbol{n}) = \tau(-\boldsymbol{n})$. The value $\tau(\boldsymbol{n})$ plays the role of the surface tension between two phases separated by the hyperplane orthogonal to the vector $\boldsymbol{n}$. For every closed compact (hyper)surface $M^{d-1} \subset \mathbb{R}^d$, we define its surface energy as

$$\mathcal{W}_\tau(M) = \int_M \tau(\boldsymbol{n}_s)\,\mathrm{d}s$$

where $\boldsymbol{n}_s$ is the normal vector to $M$ at $s \in M$. The functional $\mathcal{W}_\tau(M)$ has the meaning of the surface energy of the $M$-shaped droplet made from one of these two phases. It is called the Wulff functional. Let $\mathfrak{W}_\tau$ be the surface which minimizes $\mathcal{W}_\tau(\cdot)$ over all the surfaces enclosing the unit volume. Such a minimizer does exist and is unique up to translation. It is called the Wulff shape.

The following is the geometric construction of $\mathfrak{W}_\tau$. Consider the set

$$K_\tau = \left\{ \boldsymbol{x} \in \mathbb{R}^d:\ \forall \boldsymbol{n} \in S^{d-1} (\boldsymbol{x}, \boldsymbol{n}) \le \tau(\boldsymbol{n}) \right\}$$

If we define the half-spaces

$$L_{\tau,\boldsymbol{n}} = \left\{ \boldsymbol{x} \in \mathbb{R}^d:\ (\boldsymbol{x}, \boldsymbol{n}) \le \tau(\boldsymbol{n}) \right\}$$

then

$$K_\tau = \cap_{\boldsymbol{n}} L_{\tau,\boldsymbol{n}} \qquad [1]$$

In particular, $K_\tau$ is convex. It turns out that

$$\mathfrak{W}_\tau = \lambda_\tau \partial(K_\tau)$$

where the dilatation factor $\lambda_\tau$ is defined by the normalization: $\mathrm{vol}(\lambda_\tau K_\tau) = 1$. The relation [1] is called the Wulff construction. For the future use, we introduce the notation $w_\tau$ for the value of the surface energy of the Wulff shape:

$$w_\tau = \mathcal{W}_\tau(\mathfrak{W}_\tau)$$

The Wulff construction was considered by the rigorous statistical mechanics as just a phenomenological statement, though the notion of the surface tension was among its central notions. The situation changed after the appearance of the book by Dobrushin *et al.* (1992). There it was shown that in the setting of the canonical ensemble formalism, in the regime of the first-order phase transition, the (random) shape occupied by one of the phases has asymptotically (in the thermodynamic limit) a nonrandom shape, given precisely by the Wulff construction! In other words, a typical macroscopic random droplet looks very close to the Wulff shape.

In what follows we will explain the above result. Another important application of the concepts introduced above – the role played by the Wulff

shapes in the theory of metastability – is also described (*see* Metastable States).

## Crystals in the Ising Model

Ising spins $\sigma_x$ take values $\pm 1$, with $x \in \mathbb{Z}^d$. We will wrap $\mathbb{Z}^d$ into a torus $T_N^d$ by taking a factor lattice: $T_N^d = \mathbb{Z}^d / N\mathbb{Z}^d$. Ising-model grand canonical Gibbs state in $T_N^d$ is the probability measure $\mu_N^\beta$:

$$\mu_N^\beta(\sigma) = Z_{N,\beta}^{-1} \exp(-\beta H_N(\sigma))$$

Here $H_N(\sigma) = -\sum_{x,y\,\text{n.n.},\,x,y \in T_N^d} \sigma_x \sigma_y, \beta > 0$ is the inverse temperature, and $Z_{N,\beta}$ is the normalization factor. Ising-model canonical Gibbs state in $T_N^d$ is the probability measure $\mu_N^{\beta,\rho}$, obtained from $\mu_N^\beta$ by taking its conditional distribution:

$$\mu_N^{\beta,\rho}(\sigma) = \mu_N^\beta \left( \sigma \mid \sum_{x \in T_N^d} \sigma_x = \rho N^d \right), \quad |\rho| < 1$$

(Here we make a slight abuse of notation. More precisely, since $\sigma_x = \pm 1$, one has to consider the conditioning $\sum \sigma_x = \rho_N N^d$, where $\rho_N \to \rho$ as $N \to \infty$, while the numbers $(1 - \rho_N)N^d$ are even integers; otherwise the condition is empty.) We will characterize the canonical state $\mu_N^{\beta,\rho}$ by describing the properties of contours, $\{\gamma_i(\sigma)\}$, of configuration $\sigma$. Contours $\gamma_i$ of configuration $\sigma$ are hypersurfaces made of elementary $(d-1)$-dimensional unit cubes of the dual lattice, which separate the nearest-neighbor (n.n.) points $x, y \in T_N^d$ where $\sigma_x \neq \sigma_y$.

Suppose that the temperature $\beta^{-1}$ is low enough, while the density parameter $\rho$ satisfies the constraints:

$$m_d^*(\beta) > \rho > g_d$$

Here $m_d^*(\beta)$ is the spontaneous magnetization of the $d$-dimensional Ising model, while $g_d$ is some geometric factor, the role of which will be explained later. The above constraint forces some amount of the $(-)$-phase into the $(+)$-phase. It turns out that this amount gathers into one big droplet, which has approximately the Wulff shape.

We first formulate the known rigorous results for the case $d = 2$, and then indicate some extensions.

### Two-Dimensional Case

The following holds with $\mu_N^{\beta,\rho}$-probability approaching 1 as $N \to \infty$:

- The set $\{\gamma_i(\sigma)\}$ of contours of $\sigma$ has precisely one "big" contour, $\Gamma(\sigma)$; the diameters of other contours do not exceed $K \ln N$, $K = K(\beta)$.
- The area $|\mathrm{Int}\,\Gamma(\sigma)|$ inside $\Gamma(\sigma)$ satisfies

$$\big| |\mathrm{Int}\,\Gamma(\sigma)| - \nu N^2 \big| \leq K N^{6/5} (\ln N)^{\varkappa}$$

where

$$\nu = \frac{m_2^*(\beta) - |\rho|}{2 m_2^*(\beta)}, \quad \varkappa = \varkappa(\rho)$$

- There is a point $x = x(\sigma)$ – the "center" of $\Gamma(\sigma)$ – such that the shift of $\Gamma(\sigma)$ by $-x(\sigma)$ brings the contour $\Gamma(\sigma)$ very close to the scaled Wulff curve, defined by the Ising-model surface tension $\tau$:

$$r_{\mathrm{H}}\left( \Gamma(\sigma) - x(\sigma), \sqrt{\frac{2\nu}{w_\tau}} N W_\tau \right) \leq K N^{2/3} (\ln N)^{\varkappa} \quad [2]$$

(Here $r_{\mathrm{H}}$ is the Hausdorff distance: for every two sets $A, C \in \mathbb{R}^d$, $r_{\mathrm{H}}(A, C)$ is defined as $\max\{\inf[r : A \subset C + B_r], \inf[r : C \subset A + B_r]\}$, where $B_r$ is the ball of radius $r$.)

The proof of the above result is the content of the book by Dobrushin *et al.* (1992). In the two-dimensional case, it remains true for all temperatures $\beta^{-1}$ below the critical one (Ioffe and Schonmann 1998). The value 2/3 of the exponent is an improvement of the original 3/4 result (Alexander 1992). Probably, it can be further improved down to 1/2. Though Dobrushin *et al.* (1992) treat only the Ising model, their results are valid for a wide range of other models.

The restriction $\rho > g_d$ in the theorem is needed because without it the droplet may prefer to assume the shape of a strip between two meridians rather than to take the Wulff shape.

### Three-Dimensional Case

In the case $d = 3$ or $d \geq 3$, the statement that a typical configuration $\sigma$ has only one big contour $\Gamma(\sigma)$ is still true. But the analog of [2] is not known. It is natural to conjecture that it holds at low temperatures, even in a stronger version, with only a logarithmic term $K(\ln N)^{\varkappa}$ in the RHS. It probably fails at higher subcritical temperatures.

What is known to hold is a weaker version of this theorem, where the distance between random droplet and the Wulff shape is measured not in Hausdorf distance, but in $L^1$ sense. To state the corresponding theorem, we will associate with every configuration $\sigma$ on a lattice torus $T_N^d$ a real-valued function $M_\sigma(t)$ on the unit torus $\mathbb{T}^d = \mathbb{R}^d / \mathbb{Z}^d$, and we then compare this function with the indicator function $\mathbb{I}_{sK_\tau}$, where $sK_\tau \subset \mathbb{T}^d$ is the Wulff body, properly scaled.

The function $M_\sigma(t)$ is defined as follows. We denote by $i_N$ the natural embedding of the discrete torus $T_N^d$ into $\mathbb{T}^d$, the image of $i_N$ being the grid with spacing $1/N$. For $t \in \mathbb{T}^d$ we define $b_N(t) \subset \mathbb{T}^d$ to be

the ball centered at $t$ with radius $\sqrt[d]{1/N}$, and let $B_N(t) \subset \Lambda(N)$ be its preimage under $i_N$. Then

$$M_\sigma(r) = \frac{1}{|B_N(t)|} \sum_{x \in B_N(t)} \sigma(x)$$

We have to expect to see a droplet $sK_\tau$ with

$$s = \sqrt[d]{\frac{d}{w_\tau} \frac{m_d^*(\beta) - \rho}{2m_d^*(\beta)}}$$

Let us introduce for every subset $A \subset \mathbb{T}^d$ the indicator

$$\mathbb{I}_A(t) = \begin{cases} 1, & t \in A \\ -1, & t \in A^c \end{cases}$$

For every function $v$ in $L^1(\mathbb{T}^d)$ we denote by $U(v, \delta)$ its $\delta$-neighborhood in $L^1(\mathbb{T}^d)$.

The result can now be formulated. Suppose the temperature $\beta^{-1}$ is below the critical one. Then the function $M_\sigma(t)$ is close to the characteristic function of the Wulff shape: For every $\delta > 0$

$$\lim_{N \to \infty} \mu_N^{\beta,\rho} \left\{ \frac{1}{m_d^*(\beta)} M_\sigma(\cdot) \in \bigcup_{t \in \mathbb{T}^d} U(\mathbb{I}_{sK_\tau + t}, \delta) \right\} = 1$$

The shifts by all $t$–s of the Wulff shape $sK_\tau$ appear in the statement since the location of the droplet can be arbitrary. Note that if a point $t$ is such that the ball $B_N(t)$ stays away from the boundary of the droplet $\Gamma(\sigma)$ present in the configuration $\sigma$, then the value $M_\sigma(t)$ should be expected to be $\pm m_d^*(\beta)$, depending on whether $t$ is outside or inside the droplet, which explains the factor $1/m_d^*(\beta)$.

For a proof, see Bodineau (1999) and Cerf and Pizstora (1999).

## Yang–Baxter Equations

**J H H Perk and H Au-Yang**, Oklahoma State University, Stillwater, OK, USA

### Introduction

The term Yang–Baxter equations (YBEs) was coined by Faddeev in the late 1970s to denote a principle of integrability, that is, exact solvability, in a wide variety of fields in physics and mathematics. Since then it has become a common name for several classes of local equivalence transformations in statistical mechanics, quantum field theory, differential equations, knot theory, quantum groups, and other disciplines. We shall cover the various versions and their relationships, paying attention also to the early historical development.

#### Electric Networks

The first such transformation came up as early as 1899 when the Brooklyn engineer Kennelly published a short paper, entitled "The equivalence of triangles and three-pointed stars in conducting networks." This work gave the definite answer to such questions as whether it is better to have the three coils in a dynamo – or three resistors in a network – arranged as a star or as a triangle, see Figure 1. Using Kirchhoff's laws, the two situations in Figure 1 can be shown to be equivalent provided

$$Z_1\overline{Z}_1 = Z_2\overline{Z}_2 = Z_3\overline{Z}_3$$

$$= Z_1Z_2 + Z_2Z_3 + Z_3Z_1 \qquad [1]$$

$$= \overline{Z}_1\overline{Z}_2\overline{Z}_3/(\overline{Z}_1 + \overline{Z}_2 + \overline{Z}_3) \qquad [2]$$

Here one has to take either [1] or [2] as second line of the equation, depending on which direction the transformation is to go. The star–triangle transformation thus defined is also known under other names within the electric network theory literature as wye–delta $(\mathrm{Y}-\Delta)$, upsilon–delta $(\Upsilon-\Delta)$, or tau–pi $(\mathrm{T}-\Pi)$ transformation.

#### Spin Models

When Onsager wrote his monumental paper on the Ising model published in 1944, he made a brief remark on an obvious star–triangle transformation relating the model on the honeycomb lattice with the one on the triangular lattice. His details on this were first presented in Wannier's review article of 1945. However, the star–triangle transformation played a much more crucial role in Onsager's reasoning, as it is also intimately connected with his elliptic function uniformizing parametrization.

Furthermore, it implies the commutation of transfer matrices and spin-chain Hamiltonians. Only in his Battelle lecture of 1970 did Onsager explain how he used this remarkable observation in his derivation of the formula for the spontaneous magnetization which he had announced as a conference remark in 1948 and of which the first complete derivation had been published by Yang in 1952 using a completely different method.

Many other applications and generalizations have since appeared. Most generally, we can consider a system whose state variables – also called spins – take values from some suitable discrete or continuous sets. The interactions between spins $a$ and $b$ are given in terms of weight factors $W_{ab}$ and $\overline{W}_{ab}$, which are complex numbers in general, see Figure 2. One quantity of special interest is the partition function – sum of the product of all weight factors over all allowed spin values. The integrability of the model is expressed by the existence of spectral variables – rapidities $p, q, r, \ldots$ – that live on oriented lines, two of which cross between $a$ and $b$ as indicated by the dotted lines in Figure 2. Arrows from $a$ to $b$ are added to keep track of the ordering of $a$ and $b$ in case the weights are chiral (not symmetric).

In Onsager's special choice of the Ising model the spins take values $a, b, c, \ldots = \pm 1$ and the weight factors are the usual real positive Boltzmann weights depending on the product $ab = \pm 1$, uniformizing variable $p - q$, and elliptic modulus $k$. In the integrable chiral Potts model the weights depend on $a - b \bmod N$, with $a, b = 1, \ldots, N$, whereas the rapidities $p$ and $q$ are living in general on a higher-genus curve.

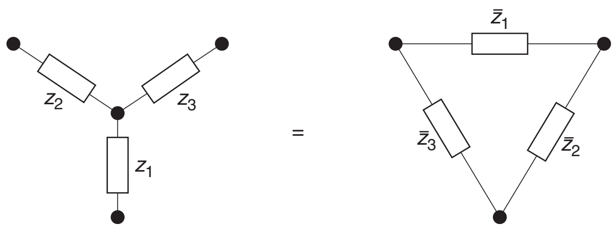

**Figure 1** Star–triangle equation for impedances.

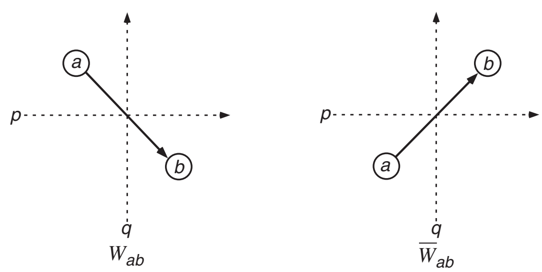

**Figure 2** Spin model weights $W_{ab}(p,q)$ and $\overline{W}_{ab}(p,q)$.

When the weights are asymmetric in the spins, there are two sets of star–triangle equations which can be expressed both pictorially (Figure 3) and algebraically:

$$\sum_d \overline{W}_{cd}(p,q)\overline{W}_{db}(q,r)W_{da}(p,r) = R(p,q,r)W_{ba}(p,q)W_{ca}(q,r)\overline{W}_{cb}(p,r) \quad [3]$$

$$\overline{R}(p,q,r)W_{ab}(p,q)W_{ac}(q,r)\overline{W}_{bc}(p,r) = \sum_d \overline{W}_{dc}(p,q)\overline{W}_{bd}(q,r)W_{ad}(p,r) \quad [4]$$

Note that eqns [3] and [4] differ from each other by the transposition of both spin variables in all six weight factors. In general, there may also appear scalar factors $R(p,q,r)$ and $\overline{R}(p,q,r)$, which can often be eliminated by a suitable renormalization of the weights. If $a$, $b$, and $c$ take values in the same set, we can sum over $a=b=c$, showing that $R=\overline{R}$ in that case.

The Kennelly star–triangle equation [1], [2] can be recovered as a special limit of a spin model where the states are continuous variables.

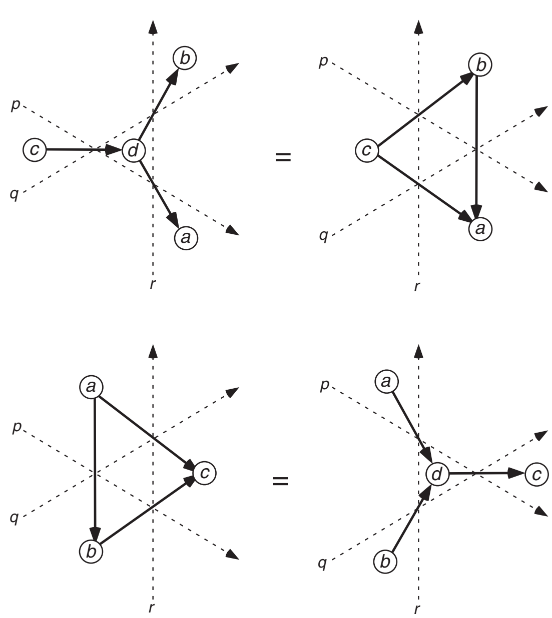

**Figure 3** Star–triangle equation.

### Knot Theory and Braid Group

A seemingly totally different situation occurs in the theory of knots, links, tangles, and braids. In 1926, Reidemeister showed that only three types of moves suffice to show the equivalence between two different configurations, see Figure 4. Moves of type I – removing simple loops – do not apply to braids. Moves of type II, for which one strand crosses twice over another strand, can be reformulated for braids, namely that an overcrossing is the inverse of an undercrossing. The Reidemeister move of type III is a precursor of the more general Yang–Baxter moves and can be represented also by the defining relations of Artin's braid group. Let $\boldsymbol{R}_{i,i+1}$ be the operator representing the situation in which the strand in position $i$ crosses over the one in position $i+1$. Then a braid can be represented by a product of $\boldsymbol{R}_{j,j+1}$'s and their inverses, provided

$$\boldsymbol{R}_{i,i+1}\boldsymbol{R}_{i+1,i+2}\boldsymbol{R}_{i,i+1} = \boldsymbol{R}_{i+1,i+2}\boldsymbol{R}_{i,i+1}\boldsymbol{R}_{i+1,i+2} \quad [5]$$

and

$$[\boldsymbol{R}_{i,i+1}, \boldsymbol{R}_{j,j+1}] = 0, \quad \text{if } |i-j| \geq 2 \quad [6]$$

and similar relations in which $\boldsymbol{R}_{i,i+1}$ and/or $\boldsymbol{R}_{i+1,i+2}$ are replaced by their inverses.

### Factorizable *S*-Matrices and Bethe Ansatz

In the early 1960s, Lieb and Liniger solved the one-dimensional Bose gas with delta-function interaction using the Bethe ansatz. Yang and McGuire then tried to generalize this result to systems with internal degrees of freedom and to fermions. This led to the

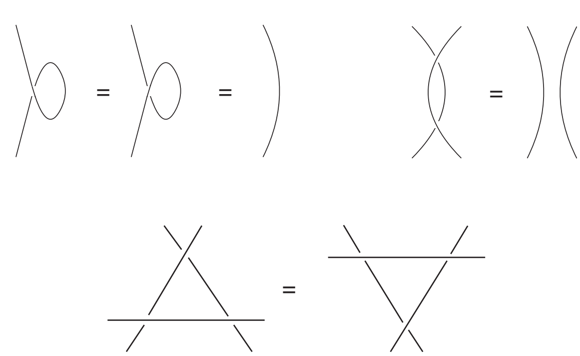

**Figure 4** Reidemeister moves of types I, II, and III.

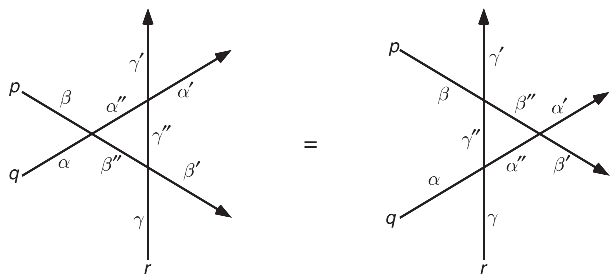

**Figure 5** Vertex model YBE.

discovery of the condition for factorizable *S*-matrices by McGuire in 1964, represented pictorially by Figure 5, where the world lines of the particles are given. Upon collisions the particles can only exchange their rapidities $p, q, r$, so that there is no dispersion. Also indicated are the internal degrees of freedom in Greek letters. In other words, the three-body *S*-matrix can be factorized in terms of two-body contributions and the order of the collisions does not affect the final outcome. McGuire also realized that this condition is all one needs for the consistency of factoring the *n*-body *S*-matrix in terms of two-body *S*-matrices. The consistency condition is obviously related to the Reidemeister move of type III in Figure 4.

Yang succeeded in solving the spin-1/2 fermionic model using a nested Bethe ansatz, utilizing a generalization of Artin's braid relations [5] and [6],

$$\check{R}_{i,i+1}(p-q)\check{R}_{i+1,i+2}(p-r)\check{R}_{i,i+1}(q-r)$$
$$= \check{R}_{i+1,i+2}(q-r)\check{R}_{i,i+1}(p-r)\check{R}_{i+1,i+2}(p-q) \qquad [7]$$

He submitted his findings in two short papers in 1967. The $\check{R}$ operators in eqn [7] – a notation introduced later by the Leningrad school – depend on differences of two momenta or two relativistic rapidities. Sutherland solved the general spin case using repeated nested Bethe ansätze, while Lieb and Wu used Yang's work to solve the one-dimensional Hubbard model.

### Vertex Models

Since Lieb's solution of the ice model by a Bethe ansatz, there have been many developments on vertex models, in which the state variables live on line segments and weight factors $\omega_{\alpha\mu}^{\lambda\beta}$ are assigned to a vertex where four line segments with the four states $\alpha, \mu, \lambda, \beta$ on them meet, see Figure 6.

Baxter solved the eight-vertex model in 1971, using a method based on commuting transfer matrices, starting from a solution of what he then called the generalized star–triangle equation, but what is now commonly called the Yang–Baxter equation (YBE):

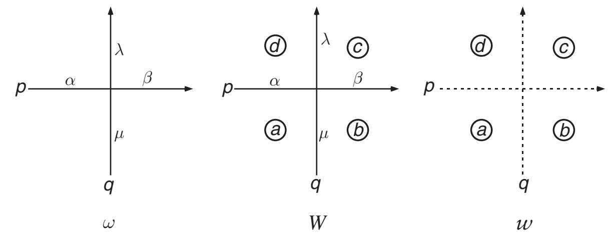

**Figure 6** Vertex model weight $\omega_{\alpha\mu}^{\lambda\beta}(p,q)$, mixed model weight $W_{\alpha\mu}^{\lambda\beta}|_{ab}^{dc}(p,q)$ and IRF model weight $w_{ab}^{dc}(p,q)$.

$$\sum_{\alpha''}\sum_{\beta''}\sum_{\gamma''}\omega_{\beta\alpha}^{\alpha''\beta''}(p,q)\omega_{\alpha''\gamma''}^{\gamma'\alpha'}(q,r)\omega_{\beta''\gamma}^{\gamma''\beta'}(p,r)$$
$$= \sum_{\alpha''}\sum_{\beta''}\sum_{\gamma''}\omega_{\beta''\alpha''}^{\alpha'\beta'}(p,q)\omega_{\alpha\gamma}^{\gamma''\alpha''}(q,r)\omega_{\beta\gamma''}^{\gamma'\beta''}(p,r) \qquad [8]$$

This equation is represented graphically in Figure 5. From it one can also derive a sufficient condition for the commutation of transfer matrices and spin-chain Hamiltonians, generalizing the work of McCoy and Wu, who had earlier initiated the search by showing that the general six-vertex model transfer matrix commutes with a Heisenberg spin-chain Hamiltonian. To be more precise, Baxter found that if $\omega_{\alpha\mu}^{\lambda\beta} = \delta_\alpha^\lambda\delta_\mu^\beta$ for some choice of $p$ and $q$, some spin-chain Hamiltonians could be derived as logarithmic derivatives of the transfer matrix.

### Interaction-Round-a-Face Model

Baxter introduced another language, namely that of the IRF or "interaction-round-a-face" model, which he introduced in connection with his solution of the hard-hexagon model. This formulation is convenient when studying one-point functions using the corner-transfer-matrix method. Now the integrability condition can be represented graphically as in Figure 7 or algebraically as

$$\sum_d w_{cb'}^{a'd}(p,q)w_{dc'}^{a'b}(q,r)w_{b'a}^{dc'}(p,r)$$
$$= \sum_{d'} w_{d'a}^{bc'}(p,q)w_{b'a}^{cd'}(q,r)w_{cd'}^{a'b}(p,r) \qquad [9]$$

The spins live on faces enclosed by rapidity lines and the weights $w_{ab}^{dc}(p,q)$ are assigned as in Figure 6.

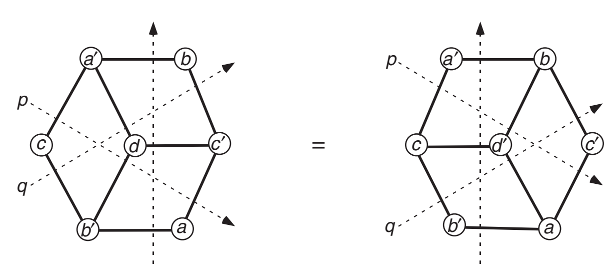

**Figure 7** IRF model YBE.

Baxter discovered a new principle based on eqns [8] and [9], which he called $Z$-invariance, as it expresses an invariance of the partition function $Z$ under moves of rapidity lines. This also implies that typical one-point functions are independent of the values of the rapidities, while two-point functions can only depend on the values of the rapidities of rapidity lines crossing between the two spins considered. Many recent results on correlation functions in integrable models depend on this observation of Baxter.

#### IRF-Vertex Model

In Figure 6, we have also defined mixed IRF-vertex model weights $W^{\lambda\beta}_{\alpha\mu}|^{dc}_{ab}(p,q)$. (We could put further state variables on the vertices, but then the natural thing to do is to introduce new effective weights summing over the states at each vertex.) With the choice made a more general YBE can be represented as in Figure 8, or by

$$\sum_{\alpha''}\sum_{\beta''}\sum_{\gamma''}\sum_{d} W^{\alpha''\beta''}_{\beta\alpha}|^{a'd}_{cb'}(p,q) \times W^{\gamma'\alpha'}_{\alpha''\gamma''}|^{a'b}_{dc'}(q,r)\,W^{\gamma''\beta'}_{\beta''\gamma}|^{dc'}_{b'a}(p,r) = \sum_{\alpha''}\sum_{\beta''}\sum_{\gamma''}\sum_{d'} W^{\alpha'\beta'}_{\beta''\alpha''}|^{bc'}_{d'a}(p,q) \times W^{\gamma''\alpha''}_{\alpha\gamma}|^{cd'}_{b'a}(q,r)\,W^{\gamma'\beta''}_{\beta\gamma''}|^{a'b}_{cd'}(p,r) \qquad [10]$$

#### Quantum Inverse-Scattering Method

The Leningrad school of Faddeev incorporated the methods of Baxter and Yang in their so-called

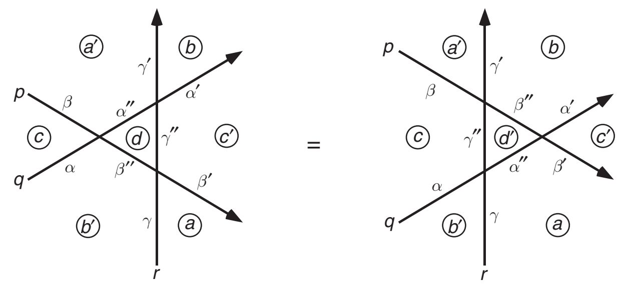

**Figure 8** General YBE.

quantum inverse-scattering method (QISM), coining the term quantum YBEs (QYBEs) for eqns [8]. If special limiting values of $p$ and $q$ can be found, say as $\hbar \to 0$, such that $\omega^{\lambda\beta}_{\alpha\mu} = \delta^{\lambda}_{\mu}\delta^{\beta}_{\alpha} + O(\hbar)$, one can reduce [8] to the classical Yang–Baxter equations (CYBEs) by expanding up to the first nontrivial order in expansion variable $\hbar$. These determine the integrability of certain models of classical mechanics by the inverse-scattering method and the existence of Lax pairs.

## Checkerboard generalizations

Star–triangle equations [3] and [4] imply that there are further generalizations of the YBEs, namely those for which the faces enclosed by the rapidity lines are alternatingly colored black and white in a checkerboard pattern. We can then introduce either vertex model weights $\omega^{\lambda\beta}_{\alpha\mu}(p,q)$ and $\overline{\omega}^{\lambda\beta}_{\alpha\mu}(p,q)$, or IRF-vertex model weights $W^{\lambda\beta}_{\alpha\mu}|^{dc}_{ab}(p,q)$ and $\overline{W}^{\lambda\beta}_{\alpha\mu}|^{dc}_{ab}(p,q)$, or IRF model weights $w^{dc}_{ab}(p,q)$ and $\overline{w}^{dc}_{ab}(p,q)$, see Figure 9.

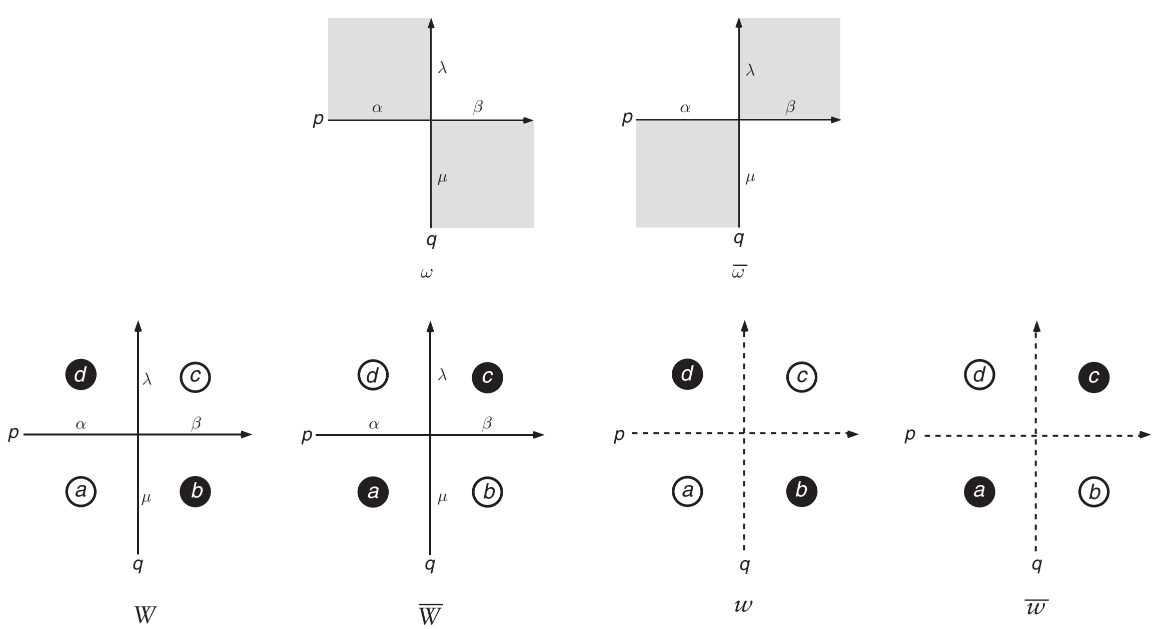

**Figure 9** Checkerboard versions of the weights.

The black faces are those where the spins of the spin model with weights defined in Figure 2 live; the white faces are to be considered empty in Figures 2 and 3 (or, equivalently, they can be assumed to host trivial spins that take on only a single value). Clearly, the IRF-vertex model description contains all the other versions.

### Checkerboard Vertex Model

First we consider the checkerboard vertex model with weights $\omega_{\alpha\mu}^{\lambda\beta}(p,q)$ and $\varpi_{\alpha\mu}^{\lambda\beta}(p,q)$ as assigned in Figure 9. The YBE [8] then generalizes to two sets of equations:

$$\begin{aligned}\sum_{\alpha''}\sum_{\beta''}\sum_{\gamma''}\omega_{\beta\alpha}^{\alpha''\beta''}(p,q)\,\omega_{\alpha''\gamma''}^{\gamma'\alpha'}(q,r)\,\varpi_{\beta''\gamma}^{\gamma''\beta'}(p,r) &= R(p,q,r)\sum_{\alpha''}\sum_{\beta''}\sum_{\gamma''}\varpi_{\beta''\alpha''}^{\alpha'\beta'}(p,q)\\ &\quad\times\varpi_{\alpha\gamma}^{\gamma''\alpha''}(q,r)\,\omega_{\beta\gamma''}^{\gamma'\beta''}(p,r)\end{aligned} \qquad [11]$$

$$\begin{aligned}\overline{R}(p,q,r)\sum_{\alpha''}\sum_{\beta''}\sum_{\gamma''}\varpi_{\beta\alpha}^{\alpha''\beta''}(p,q)\,\varpi_{\alpha''\gamma''}^{\gamma'\alpha'}(q,r)\,\omega_{\beta''\gamma}^{\gamma''\beta'}(p,r) &= \sum_{\alpha''}\sum_{\beta''}\sum_{\gamma''}\omega_{\beta''\alpha''}^{\alpha'\beta'}(p,q)\,\omega_{\alpha\gamma}^{\gamma''\alpha''}(q,r)\,\varpi_{\beta\gamma''}^{\gamma'\beta''}(p,r)\end{aligned} \qquad [12]$$

where scalar factors $R$ and $\overline{R}$ have been added as in [3] and [4]. These equations are represented graphically by Figure 10.

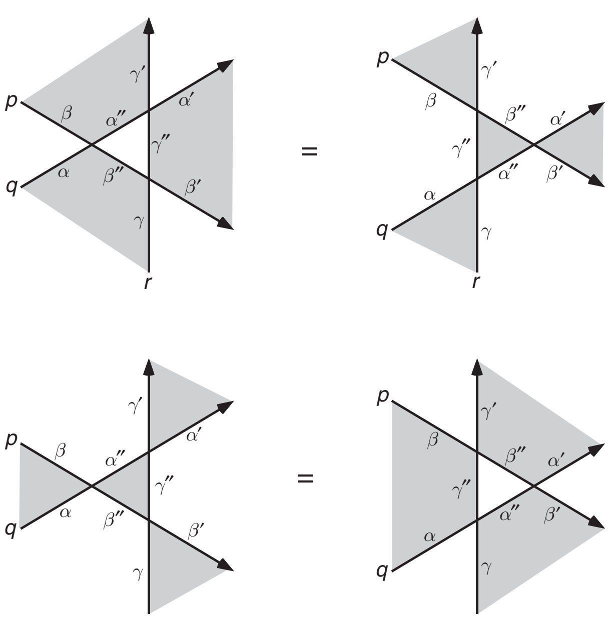

**Figure 10** Checkerboard vertex model YBE.

### Checkerboard IRF Model

The checkerboard IRF version of the YBE [8] becomes

$$\sum_{d} w_{cb'}^{a'd}(p,q)\,w_{dc'}^{a'b}(q,r)\,\overline{w}_{b'a}^{dc'}(p,r) = R(p,q,r)\sum_{d'}\overline{w}_{d'a}^{bc'}(p,q)\,\overline{w}_{b'a}^{cd'}(q,r)\,w_{cd'}^{a'b}(p,r) \qquad [13]$$

$$\overline{R}(p,q,r)\sum_{d}\overline{w}_{cb'}^{a'd}(p,q)\,\overline{w}_{dc'}^{a'b}(q,r)\,w_{b'a}^{dc'}(p,r) = \sum_{d'}w_{d'a}^{bc'}(p,q)\,w_{b'a}^{cd'}(q,r)\,\overline{w}_{cd'}^{a'b}(p,r) \qquad [14]$$

again with scalar factors $R$ and $\overline{R}$ added as in [3] and [4]. These equations can now be represented graphically as in Figure 11. Note that these equations reduce to eqns [3] and [4] if the spins on the white faces are allowed to take only one value, which means that they can be ignored.

### Checkerboard IRF-Vertex Model

Finally, the most general case is represented by the checkerboard IRF-vertex model, with weights defined in Figure 9. For this case the YBEs are given by

$$\begin{aligned}&\sum_{\alpha''}\sum_{\beta''}\sum_{\gamma''}\sum_{d} W_{\beta\alpha}^{\alpha''\beta''}\Big|_{cb'}^{a'd}(p,q)\\ &\quad\times W_{\alpha''\gamma''}^{\gamma'\alpha'}\Big|_{dc'}^{a'b}(q,r)\,\overline{W}_{\beta''\gamma}^{\gamma''\beta'}\Big|_{b'a}^{dc'}(p,r)\\ &= R(p,q,r)\sum_{\alpha''}\sum_{\beta''}\sum_{\gamma''}\sum_{d'}\overline{W}_{\beta''\alpha''}^{\alpha'\beta'}\Big|_{d'a}^{bc'}(p,q)\\ &\quad\times\overline{W}_{\alpha\gamma}^{\gamma''\alpha''}\Big|_{b'a}^{cd'}(q,r)\,W_{\beta\gamma''}^{\gamma'\beta''}\Big|_{cd'}^{a'b}(p,r)\end{aligned} \qquad [15]$$

$$\begin{aligned}&\overline{R}(p,q,r)\sum_{\alpha''}\sum_{\beta''}\sum_{\gamma''}\sum_{d}\overline{W}_{\beta\alpha}^{\alpha''\beta''}\Big|_{cb'}^{a'd}(p,q)\\ &\quad\times\overline{W}_{\alpha''\gamma''}^{\gamma'\alpha'}\Big|_{dc'}^{a'b}(q,r)\,W_{\beta''\gamma}^{\gamma''\beta'}\Big|_{b'a}^{dc'}(p,r)\\ &= \sum_{\alpha''}\sum_{\beta''}\sum_{\gamma''}\sum_{d'}W_{\beta''\alpha''}^{\alpha'\beta'}\Big|_{d'a}^{bc'}(p,q)\\ &\quad\times W_{\alpha\gamma}^{\gamma''\alpha''}\Big|_{b'a}^{cd'}(q,r)\,\overline{W}_{\beta\gamma''}^{\gamma'\beta''}\Big|_{cd'}^{a'b}(p,r)\end{aligned} \qquad [16]$$

with its graphical representation in Figure 12.

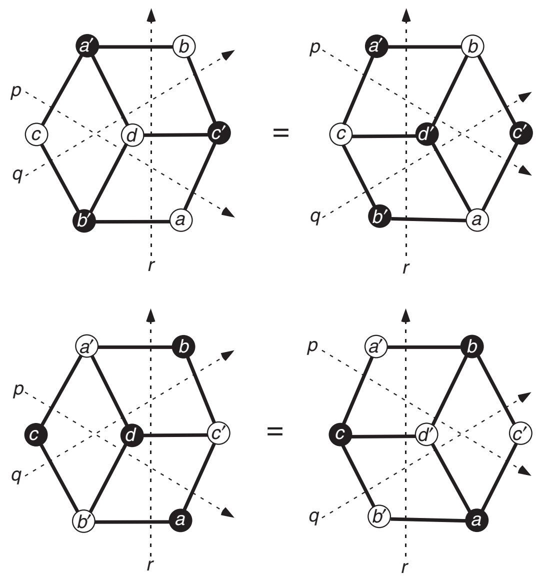

**Figure 11** Checkerboard IRF model YBE.

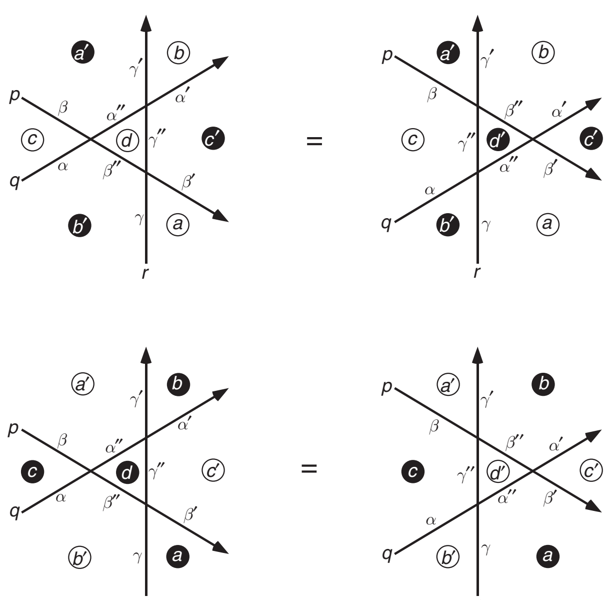

**Figure 12** Checkerboard YBE.

## Formal Equivalence of Languages

### The Square Weight

Combining four weights of a checkerboard model in a square, as is done with four spin model weights in Figure 13, we find a regular vertex model weight with rapidities that are now pairs of the original ones. This gives

$$W_{\alpha\mu}(p_1,q_1)\overline{W}_{\mu\beta}(p_1,q_2)\overline{W}_{\alpha\lambda}(p_2,q_1)W_{\lambda\beta}(p_2,q_2) = \omega_{\alpha\mu}^{\lambda\beta}(p_1,p_2;q_1,q_2) \qquad [17]$$

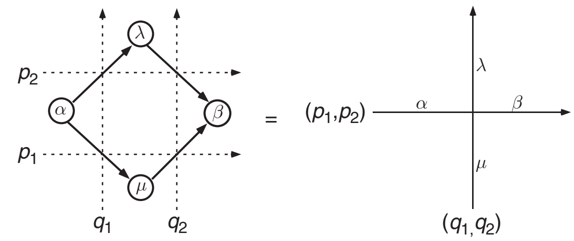

**Figure 13** Square weight as vertex weight.

From any solution of [3] and [4] we can thus construct a solution of YBE [8]. This has been used by Bazhanov and Stroganov to relate the integrable chiral Potts model with a cyclic representation of the six-vertex model.

### Map to Checkerboard Vertex Model

The checkerboard IRF-vertex model formulation contains all other versions mentioned above as special cases. However, collecting the state variables in triples, we can immediately translate it to a vertex model version, writing

$$\omega_{\hat\alpha\hat\mu}^{\hat\lambda\hat\beta}(p,q) = W_{\alpha\mu}^{\lambda\beta}\big|_{ab}^{dc}(p,q), \quad \overline{\omega}_{\hat\alpha\hat\mu}^{\hat\lambda\hat\beta}(p,q) = \overline{W}_{\alpha\mu}^{\lambda\beta}\big|_{ab}^{dc}(p,q)$$
$$\text{if } \begin{cases} \hat\lambda = (d,\lambda,c), & \hat\beta = (b,\beta,c) \\ \hat\alpha = (a,\alpha,d), & \hat\mu = (a,\mu,b) \end{cases} \qquad [18]$$

$$\omega_{\hat\alpha\hat\mu}^{\hat\lambda\hat\beta}(p,q) = \overline{\omega}_{\hat\alpha\hat\mu}^{\hat\lambda\hat\beta}(p,q) = 0 \quad \text{otherwise} \qquad [19]$$

In eqn [19], we have set all vertex model weights zero that are inconsistent with IRF-vertex configurations. Clearly, the translation of IRF models and spin models to vertex models can be done similarly.

### Map to Spin Model

We can, furthermore, translate each vertex model with weights assigned as in Figures 6 or 9 into a spin model with weights as in Figure 2 by defining suitable spins in the black faces, after checkerboard coloring. Each spin is then defined to be the ordered set of states on the line segments of the vertex model, $\underline{a} = (\alpha_1, \alpha_2, \ldots)$, ordering the line segments counterclockwise starting at, say, 12 o'clock. We can then identify $\omega_{\alpha\mu}^{\lambda\beta}(p,q) = W_{\underline{a},\underline{b}}(p,q)$, $\overline{\omega}_{\alpha\mu}^{\lambda\beta}(p,q) = \overline{W}_{\underline{a},\underline{b}}(p,q)$. This is surely not very economical, as many of the weights will be equal, but it helps show that all different versions of the checkerboard YBE are formally equivalent.

Hence, we shall only use the vertex model language in the following. It is fairly straightforward to convert to the other formulations.

#### An sl($m|n$) Example

One fundamental example is a $Q$-state model for which the rapidities have $2Q+1$ components, $\boldsymbol{p}=(p_{-Q},\ldots,p_Q)$, $\boldsymbol{q}=(q_{-Q},\ldots,q_Q)$, etc., and the states on the line segments are arranged in strings of continuing conserved color. The vertex weights, for $\alpha$, $\beta$, $\lambda$, $\mu=1,\ldots,Q$, are given by

$$\omega_{\alpha\mu}^{\lambda\beta}(\boldsymbol{p},\boldsymbol{q})=\omega_{0\alpha\mu}^{\lambda\beta}(p_0,q_0)\frac{p_{+\lambda}q_{-\beta}}{q_{+\alpha}p_{-\mu}} \qquad [20]$$

with ($\rho\neq\sigma$)

$$\begin{aligned}\omega_{0\rho\rho}^{\rho\rho}(p_0,q_0)&=\mathcal{N}\sinh[\eta+\varepsilon_\rho(p_0-q_0)]\\ \omega_{0\sigma\rho}^{\rho\sigma}(p_0,q_0)&=\mathcal{N}G_{\rho\sigma}\sinh(p_0-q_0)\\ \omega_{0\sigma\rho}^{\sigma\rho}(p_0,q_0)&=\mathcal{N}\,\mathrm{e}^{(p_0-q_0)\mathrm{sign}(\rho-\sigma)}\sinh\eta\\ \omega_{0\alpha\mu}^{\lambda\beta}(p_0,q_0)&=0,\quad \text{otherwise}\end{aligned} \qquad [21]$$

where $\mathcal{N}$ is an arbitrary overall normalization factor and $\eta$ is a constant. Furthermore, $\varepsilon_\rho=\pm1$ for $\rho=1,\ldots,Q$, where $m$ of them equal +1 and $n$ of them equal –1. The $G_{\rho\sigma}$'s are constants satisfying $G_{\rho\sigma}=1/G_{\sigma\rho}$, which freedom is allowed because the number of $\rho$-$\sigma$ crossings minus the number of $\sigma$-$\rho$ crossings is fixed by the states on the boundary only, that is, the choice of $\alpha,\alpha',\beta,\beta',\gamma,\gamma'$ in YBE [8] and Figure 5.

The solution [20], [21] has many applications. The case $m=0$, $n=2$ leads to the general six-vertex model; the $m=0, n=n$ case produces the fundamental intertwiner of affine quantum group $U_q\widehat{\mathfrak{sl}}(n)$, whereas the case $m=2, n=1$ corresponds to the supersymmetric one-dimensional $t$–$J$ model.

## Operator Formulations

#### The $R$-Matrix

For a problem with $N$ rapidity lines, carrying rapidities $p_1,\ldots,p_N$, we can introduce a set of matrices $\boldsymbol{R}_{ij}(p_i,p_j)$, for $1\leqslant i<j\leqslant N$, with elements

$$R_{ij}(p_i,p_j)_{\alpha_1\ldots\alpha_N}^{\beta_1\ldots\beta_N}=\omega_{\alpha_i\alpha_j}^{\beta_j\beta_i}(p_i,p_j)\prod_{k\neq i,j}\delta_{\alpha_k}^{\beta_k} \qquad [22]$$

In terms of these, the YBE [8] can be rewritten in matrix form as

$$\begin{aligned}&\boldsymbol{R}_{jk}(p_j,p_k)\boldsymbol{R}_{ik}(p_i,p_k)\boldsymbol{R}_{ij}(p_i,p_j)\\ &\quad=\boldsymbol{R}_{ij}(p_i,p_j)\boldsymbol{R}_{ik}(p_i,p_k)\boldsymbol{R}_{jk}(p_j,p_k)\end{aligned} \qquad [23]$$

where $1\leqslant i<j<k\leqslant N$.

#### The $\check{R}$-Matrix

If we transpose the $\beta$ indices $\beta_i$ and $\beta_j$ in eqn [22], we can define a set of matrices $\check{\boldsymbol{R}}_{i,i+1}(p,q)$ with elements

$$\check{\boldsymbol{R}}_{i,i+1}(p,q)_{\alpha_1\ldots\alpha_N}^{\beta_1\ldots\beta_N}=\omega_{\alpha_i,\alpha_{i+1}}^{\beta_i,\beta_{i+1}}(p,q)\prod_{k\neq i,i+1}\delta_{\alpha_k}^{\beta_k} \qquad [24]$$

Using these, the YBE [8] can be rewritten in matrix form as

$$\begin{aligned}&\check{\boldsymbol{R}}_{i,i+1}(q,r)\check{\boldsymbol{R}}_{i+1,i+2}(p,r)\check{\boldsymbol{R}}_{i,i+1}(p,q)\\ &\quad=\check{\boldsymbol{R}}_{i+1,i+2}(p,q)\check{\boldsymbol{R}}_{i,i+1}(p,r)\check{\boldsymbol{R}}_{i+1,i+2}(q,r)\end{aligned} \qquad [25]$$

and

$$[\check{\boldsymbol{R}}_{i,\,i+1}(p,q),\check{\boldsymbol{R}}_{j,\,j+1}(r,s)]=0,\quad \text{if } |i-j|\geqslant2 \qquad [26]$$

In this formulation, it is clear that many solutions can be found "Baxterizing" Temperley–Lieb and Iwahori–Hecke algebras.

## Classical YBEs

If we expand

$$\boldsymbol{R}_{ij}(p_i,p_j)=\boldsymbol{1}+\hbar\boldsymbol{X}_{ij}(p_i,p_j)+\mathrm{O}(\hbar^2) \qquad [27]$$

in [23], we get in second order in $\hbar$ the classical YBE (CYBE) as the vanishing of a sum of three commutators, that is,

$$\begin{aligned}&[\boldsymbol{X}_{ij}(p_i,p_j),\boldsymbol{X}_{ik}(p_i,p_k)]+[\boldsymbol{X}_{ij}(p_i,p_j),\boldsymbol{X}_{jk}(p_j,p_k)]\\ &\quad+[\boldsymbol{X}_{ik}(p_i,p_k),\boldsymbol{X}_{jk}(p_j,p_k)]=0\end{aligned} \qquad [28]$$

introduced by Belavin and Drinfel'd, where $\boldsymbol{X}_{ij}$ is called the classical $r$-matrix.

## Reflection YBEs

Cherednik and Sklyanin found a condition determining the solvability of systems with boundaries, the reflection YBEs (RYBEs), see Figure 14. Upon

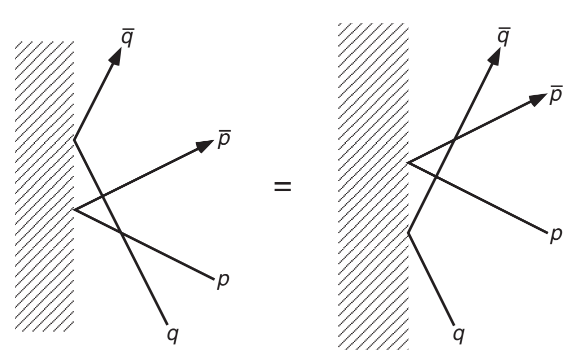

**Figure 14** Reflection YBE.

collisions with a left or right wall the rapidity variable changes from $p$ to $\overline{p}$ and back. In most examples, in which the rapidities are difference variables such that $\boldsymbol{R}(p,q)=\boldsymbol{R}(p-q)$, one also has $\overline{p}=\mu-p$, with $\mu$ some constant. The corresponding left boundary weights are $K_{\alpha}^{\beta}(p,\overline{p})$ satisfying

$$\check{\boldsymbol{K}}_1(q,\overline{q})\check{\boldsymbol{R}}_{12}(\overline{p},q)\check{\boldsymbol{K}}_1(p,\overline{p})\check{\boldsymbol{R}}_{12}(q,p) = \check{\boldsymbol{R}}_{12}(\overline{p},\overline{q})\check{\boldsymbol{K}}_1(p,\overline{p})\check{\boldsymbol{R}}_{12}(\overline{q},p)\check{\boldsymbol{K}}_1(q,\overline{q}) \quad [29]$$

with $\check{\boldsymbol{K}}_1(p,\overline{p})$ defined by a direct product as in [24] appending unit matrices for positions $i\geqslant 2$, and a similar equation must hold for the right boundary. Most work has been done for vertex models, while Pearce and co-workers wrote several papers on the IRF-model version.

## Higher-Dimensional Generalizations

In 1980 Zamolodchikov introduced a three-dimensional generalization of the YBE, the so-called tetrahedron equations (TEs), and he found a special solution. Baxter then succeeded in proving that this solution satisfies all TEs. Baxter and Bazhanov showed in 1992 that this solution can be seen as a special case of the sl($\infty$) chiral Potts model. Several authors found further generalizations more recently.

## Inversion Relations

When $\omega_{\alpha\mu}^{\lambda\beta}(p,\,p) \propto \delta_{\alpha}^{\lambda}\delta_{\mu}^{\beta}$, that is, the weight decouples when the two rapidities are equal, one can derive the local inverse relation depicted in Figure 15, which is a generalization of the Reidemeister move of type II in Figure 4. It is easily shown that $C(q,p)=C(p,q)$.

This local relation implies also a global inversion relation which can be found in many ways. The following heuristic way is the easiest: consider the situation in Figure 16, with $N$ closed $p$-rapidity lines and $M$ closed $q$-rapidity lines. For $M$ and $N$ large, we may expect the partition function of Figure 16 to factor asymptotically in top- and bottom-half contributions. If each line segment carries a state

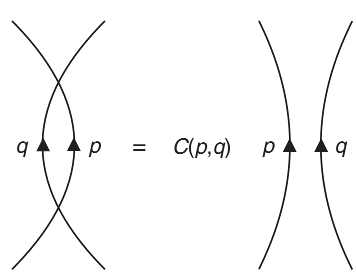

**Figure 15** Local inversion relation.

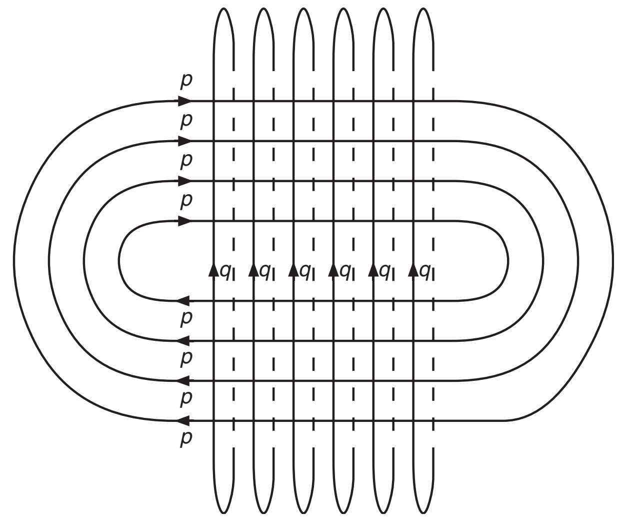

**Figure 16** Heuristic derivation of inversion relation.

variable that can assume $Q$ values, then the total partition function factors by repeated application of the relation in Figure 15 into the contribution of $M+N$ circles. Therefore,

$$Z = Q^{M+N}C(p,q)^{MN} \approx Z_{M,N}(p,q)Z_{N,M}(q,p) \quad [30]$$

Taking the thermodynamic limit,

$$z(p,q) \equiv \lim_{M,N\to\infty} Z_{M,N}(p,q)^{1/MN} \quad [31]$$

one finds

$$z(p,q)z(q,p) = \mathrm{C}(q,p) \quad [32]$$

In many models, eqn [32], supplemented with some suitable symmetry and analyticity conditions, can be used to calculate the free energy per site.
